Dysmenorrhea

Krishna K. Upadhya, Gina S. Sucato

Keywords

dysmenorrhea
endometriosis

Dysmenorrhea, painful uterine cramps that precede and accompany menses, occur in up to 90% of women age 17-24. Although dysmenorrhea is frequently severe enough to interfere with school and other activities, many adolescents undertreat their symptoms, and fewer still seek medical care for relief.

Dysmenorrhea may be primary or secondary. **Primary dysmenorrhea** , characterized by the absence of any specific pelvic pathologic condition, is by far the more commonly occurring form, accounting for approximately 90% of cases. After ovulation, withdrawal of progesterone results in synthesis of prostaglandins by the endometrium, which stimulates local vasoconstriction, uterine ischemia and pain, and smooth muscle contraction, explaining both uterine and GI symptoms. Because of the association with ovulation, primary dysmenorrhea typically presents at least 12 mo after menarche.

Secondary dysmenorrhea results from underlying pathology, such as anatomic abnormality, or infection, such as pelvic inflammatory disease. However, the most common cause of secondary dysmenorrhea in adolescents is **endometriosis** , a condition in which implants of endometrial tissue are found outside the uterus, usually near the fallopian tubes and ovaries. Often, other family members have endometriosis. Although characteristically there is severe pain at menses, adolescents can present with noncyclic pain as well.

Although primary dysmenorrhea is almost always the cause, a careful history and physical examination are required for adolescents who present with pelvic pain. An internal pelvic exam is not required in females who are not sexually experienced and whose presentation is consistent with primary dysmenorrhea. Constipation can vary cyclically in many females, especially those with irritable bowel syndrome, and often significantly contributes to the pain. **Mittelschmerz** , brief severe pain with ovulation, occurs at mid-cycle and can explain what initially appeared to be noncyclic pelvic pain. Table 142.6 lists the differential diagnosis and "red flags" for secondary dysmenorrhea. Ovarian cysts, a frequent concern of families, are usually transient and painless.

Table 142.6

Differential Diagnosis of Dysmenorrhea in Adolescents*

	PRESENTATION	DIAGNOSIS
Primary	Crampy pelvic pain may be accompanied by aching/heaviness in lower back and upper thighs, nausea, emesis, diarrhea, headache, mastalgia, fatigue, and dizziness; symptoms begin at or shortly before onset of menstrual flow and last 1-3 days.	Normal physical exam; internal exam only for sexually active adolescents. Ultrasound can be reserved for those patients with atypical presentations (e.g., onset at menarche) or those whose pain does not respond to NSAIDs and hormonal therapy.
Endometriosis and adenomyosis †	**Increasingly severe dysmenorrhea despite adequate therapy;** pain exacerbated during menses can occur acyclically as well.	Increased risk in patients with obstructive anomalies and possibly bleeding disorders; however, most teenagers with endometriosis have normal anatomy and bleeding indices; diagnosis is made visually during surgery. *Found in up to 69% of adolescents who underwent laparoscopy for persistent pelvic pain.*
Müllerian anomalies	**Pain begins at or shortly after menarche** and occurs with bleeding;	Pelvic ultrasound will demonstrate uterine anomalies (e.g., rudimentary uterine horn); MRI may be required

with partial outflow obstruction	presence of **known renal tract anomaly** (often coexists with müllerian anomaly).	to identify some lesions (e.g., obstructed hemivagina). *Found in 8% of adolescents who underwent laparoscopy for persistent pelvic pain.*
Pelvic inflammatory disease	Abrupt onset of dysmenorrhea more severe than baseline in a sexually active adolescent; presentation can range from mild discomfort to acute abdomen.	Clinical diagnosis made by findings of uterine or adnexal tenderness on bimanual pelvic examination (see Chapter 146); supporting features include dysuria, dyspareunia, **vaginal discharge,** fever, and increased white blood cell count.
Pregnancy complication	Coincident pain and bleeding may be misdiagnosed as dysmenorrhea.	Urine test positive for human chorionic gonadotropin.

[*] **Bold** entries indicate ”red flags” for diagnosis.

[†] Adenomyosis is the presence of endometrial tissue within the uterine myometrium.

Treatment for primary dysmenorrhea is aimed at preventing or decreasing prostaglandin production. The mainstay of treatment is prostaglandin synthetase inhibition with NSAIDs (Table 142.7) beginning at, or preferably the day before, menstruation. High doses of around-the-clock treatment are rarely needed for more than the 1st 2 days. More data are needed to make specific treatment recommendations regarding exercise, but females should be reassured that participation in usual sports and extracurricular activities is not only permissible but a benchmark of adequate treatment.

Table 142.7

Treatment for Dysmenorrhea

	MEDICATION	REGIMEN	COMMENTS
NSAIDs for up to 5 days)	Ibuprofen, 200 mg	2 tablets PO q 4-6 hr	Over-the-counter
	Naproxen sodium, 275 mg	550 mg loading dose, then 275 mg PO q 6 hr	Patients may prefer the equivalent 550 mg PO q 12 hr dosing regimen.
	Celecoxib (cyclooxygenase [COX]-2 inhibitor)[*]	400 mg, then 200 mg PO q 12 hr prn pain	Can be used for patients with von Willebrand disease.
Hormonal contraception	Combined oral contraceptive pills or vaginal ring	Continuous hormone regimens (vs standard 21 hormone days followed by 7 placebo days) may offer better relief but may increase the risk of unscheduled intermenstrual bleeding.	The data favoring rings and pills over the combined hormone patch for this indication are sparse; treatment can be based on patient preference.
	Progestin-only methods	DMPA 150 mg IM or 104 mg SC q 3 mo; levonorgestrel intrauterine device for up to 5 yr; etonogestrel implant for up to 3 yr	DMPA has potential side effects of weight gain and interference with expected bone density increase during adolescence, as well as a higher discontinuation rate than LARC methods.
Gonadotropin-releasing	Depot leuprolide	11.25 mg IM q 3 mo	Consider for patients with presumed endometriosis not responsive to

hormone agonist			hormonal methods; add-back hormones are recommended to prevent bone loss.

[*] This medication may cause serious cardiovascular and gastrointestinal events. Use with caution in patients with impaired renal or liver dysfunction, heart failure, or a history of GI bleeding or ulcer. Full prescribing information can be found at: http://www.accessdata.fda.gov/drugsatfda_docs/label/2011/020998s033 ,021156s003lbl.pdf.

DMPA, Depot medroxyprogesterone acetate; LARC, long-acting reversible contraceptive; NSAIDs, nonsteroidal antiinflammatory drugs.

For those adolescents whose pain does not respond to optimally dosed NSAIDs, or who also require contraception, the currently available forms of hormonal contraception will improve dysmenorrhea. A number of trials have investigated adjuvant treatments including heat, aromatherapy, acupressure, acupuncture, transcutaneous nerve stimulation, herbal remedies, yoga, and dietary supplements; however, the mainstay second-line treatment is hormones. The mechanisms are not fully delineated but are presumed to include elimination of progesterone production from the corpus luteum for those methods that prevent ovulation, and decreased prostaglandin production from the diminished endometrial lining. Up to 3 cycles may be required to appreciate the full benefit. Methods and regimens that eliminate a placebo interval may provide better relief. Females whose pain persists despite more than 3 mo of adequate hormonal therapy require further evaluation and treatment.

142.4

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Krishna K. Upadhya, Gina S. Sucato

Keywords

premenstrual syndrome
PMS
premenstrual dysphoric disorder
PMDD

Premenstrual dysphoric disorder (PMDD) is a depressive disorder that is distinguished from other depressive disorders by its timing. Symptoms of anxiety and depressed mood begin in the luteal phase of the menstrual cycle (i.e., in the 2nd half, after ovulation) and improve within a few days after the onset of menses. PMDD causes significant distress and functional impairment and may be accompanied by physical and behavioral symptoms. PMDD occurs in 2–6% of menstruating females worldwide. Based on a large body of scientific evidence, it has been included in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) as a distinct, treatment-responsive, depressive disorder (Table 142.8). PMDD is distinguished from **premenstrual syndrome (PMS)** , which has similar timing and occurs in up to 30% of adolescents, by the severity and consequences of the affective symptoms. Premenstrual symptoms are precipitated by ovulation; symptoms recur in the luteal phase and should disappear at the end of menstruation. Up to half of women who report PMS do not meet diagnostic criteria for PMDD when symptoms are rated prospectively. Consequently, use of a menstrual calendar to document symptoms prospectively is necessary, because it is important to distinguish PMDD from anxiety, depression, or another mental health disorder, the symptoms of which are exacerbated cyclically but occur throughout the cycle.

Table 142.8

Criteria for Premenstrual Dysphoric Disorder

A. In the majority of menstrual cycles, at least 5 symptoms must be present in the final week before the onset of menses, start to *improve* with a few days after the onset of menses, and become *minimal* or absent in the week post menses.

B. One (or more) of the following symptoms must be present:

1. Marked affective lability (e.g., mood swings; feeling suddenly sad or tearful, or increased sensitivity to rejection).
2. Marked irritability or anger or increased interpersonal conflicts.
3. Marked depressed mood, feelings of hopelessness, or self-deprecating thoughts.
4. Marked anxiety, tension, and/or feelings of being keyed up or on edge.

C. One (or more) of the following symptoms must additionally be present, to reach a total of 5 symptoms when combined with symptoms from criterion B above.

1. Decreased interest in usual activities (e.g., work, school, friends, and hobbies).
2. Subjective difficulty in concentration.
3. Lethargy, easy fatigability, or marked lack of energy.
4. Marked change in appetite; overeating; or specific food cravings.
5. Hypersomnia or insomnia.
6. A sense of being overwhelmed or out of control.
7. Physical symptoms such as breast tenderness or swelling, joint or muscle pain, a sensation of “bloating,” or weight gain.

Note: The symptoms in criteria A-C must have been met for most menstrual cycles that occurred in the preceding year.

D. The symptoms are associated with clinically significant distress or interference with work, school, usual social activities, or relationships with others (e.g., avoidance of social activities; decreased productivity and efficiency at work, school, or home).

E. The disturbance is not merely an exacerbation of the symptoms of another disorder, such as major depressive disorder, panic disorder, persistent depressive disorder (dysthymia), or a personality disorder (although it may co-occur with any of these disorders).

F. Criterion A should be confirmed by prospective daily ratings during at least

2 symptomatic cycles. (*Note:* The diagnosis may be made provisionally prior to this confirmation).

G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition (e.g., hyperthyroidism).

From *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright 2013), American Psychiatric Association, pp 171–172.

Treatment success is gauged by improvement in patient symptoms. In mild cases of PMS, adolescents may have adequate relief following education about the relationship of symptoms to the menstrual cycle and instruction on stress management techniques, including exercise. There is not strong evidence supporting the effectiveness of most combined hormonal contraceptive methods for PMS, particularly in adolescents. However, some experts suggest this treatment option for those patients who also have dysmenorrhea or contraceptive needs.

The treatment option for severe PMS and PMDD with the most supportive evidence is use of selective serotonin reuptake inhibitors (SSRIs), which are first-line therapy for adult women. In contrast to the treatment of depression, SSRIs can be rapidly effective for PMDD and thus can be prescribed either continuously or intermittently, beginning at ovulation (or whenever in the luteal phase symptoms begin) and ending when symptoms resolve. Adolescents can be prescribed the standard doses used for adults, such as fluoxetine, 20 mg PO daily.

CHAPTER 143

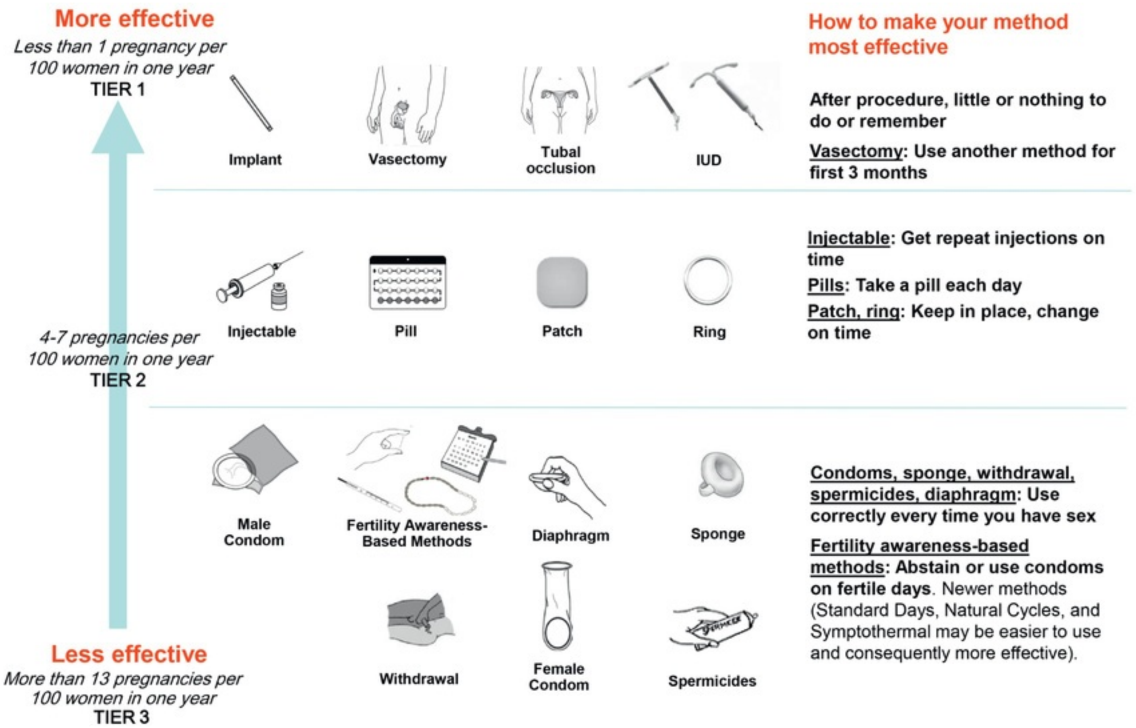
Contraception

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

The untoward consequences of sexual activity, including unintended pregnancy (see Chapter 144) and sexually transmitted infections (STIs; Chapter 146), are experienced by adolescents at unacceptably high rates. Adolescents often do not seek reproductive healthcare until 6-12 mo after initiating sex; many will become pregnant and/or acquire an STI during this interval. Early and appropriate counseling and educational interventions with adolescents, including direct discussion of unwanted pregnancy and STI prevention, can decrease risky sexual behavior; adolescents who plan sexual initiation are 75% more likely to use contraception at sexual debut. Therefore, appropriate counseling and provision of contraception as warranted are a critical component in comprehensive healthcare for adolescents.

Contraceptive Effectiveness

To decrease rates of unintended pregnancy, the American Academy of Pediatrics (AAP) and American College of Obstetricians and Gynecologists (ACOG) recommend adolescents use the most effective forms of reversible contraception. Comparing typical effectiveness of contraceptive methods the chart illustrates a tiered system of contraceptive methods ranging from more effective to less effective methods (Fig. 143.1). These tiers are categorized by **typical-use failure rates** , which reflect the effectiveness of a method for the average person who may not consistently use the method or may not always use the method correctly (Table 143.1). For example, for oral contraceptive pills, the typical-use failure rate is 7%, whereas the *perfect-use* failure rate is <1%. **Tier 1** methods, the most effective, include those with failure rates of <1 pregnancy per 100 women in a year of typical use, and reversible Tier 1 methods include intrauterine devices (IUDs) and implants. **Tier 2** methods have failure rates of 4-7 pregnancies per 100 women in a year of typical use and include injectable contraception, oral contraceptive pills, contraceptive patch, and vaginal ring. **Tier 3** methods have failure rates of >13 pregnancies per 100 women per year of typical use and include the male and female condom, the diaphragm, withdrawal, the sponge, fertility awareness–based methods, and spermicides.



More effective
Less than 1 pregnancy per 100 women in one year
TIER 1
Implant
Vasectomy
Tubal occlusion
IUD
How to make your method most effective
After procedure, little or nothing to do or remember
Vasectomy: Use another method for first 3 months
Injectable
Pill
Patch
Ring
4-7 pregnancies per 100 women in one year
TIER 2
Injectable: Get repeat injections on time
Pills: Take a pill each day
Patch, ring: Keep in place, change on time
Male Condom
Fertility Awareness-Based Methods
Diaphragm
Sponge
Withdrawal
Female Condom
Spermicides
Less effective
More than 13 pregnancies per 100 women in one year
TIER 3
Condoms, sponge, withdrawal, spermicides, diaphragm: Use correctly every time you have sex
Fertility awareness-based methods: Abstain or use condoms on fertile days. Newer methods (Standard Days, Natural Cycles, and Symptothermal may be easier to use and consequently more effective).

FIG. 143.1 Effectiveness of contraceptive methods. (From Trussell J, Aiken ARA, Micks E, Guthrie K. Contraceptive efficacy, safety, and personal considerations. In Hatcher RA, Nelson AL, Trussell J, et al, eds. *Contraceptive technology,* ed 21, New York, 2018, Ayer Company Publishers p. 102.)

Table 143.1

Efficacy of Contraceptives

METHOD	FAILURE RATE*		SOME ADVANTAGES	SOME ADVERSE EFFECTS AND DISADVANTAGES
	Typical Use	Perfect Use		
Implant			Convenience; long-term contraception; no patient compliance required; rapid	Irregular bleeding; removal complications
Nexplanon	0.1%	0.1%		

			return of fertility after removal	
Intrauterine devices (lUDs)			Convenience; long-term contraception; no patient compliance required; rapid return of fertility after removal	Rare uterine perforation; risk of infection with insertion; anemia
ParaGard T380A	0.8%	0.6%	Effective for 10 yr; nonhormonal	Irregular/heavy bleeding and dysmenorrhea
Mirena	0.1%	0.1%	Decreased menstrual bleeding and dysmenorrheal	Irregular bleeding in 1st 3-6 mo, followed by amenorrhea; ovarian cysts
Liletta	0.1%	0.1%	Decreased menstrual bleeding and dysmenorrheal	Irregular bleeding in 1st 3-6 mo; ovarian cysts
Kyleena	0.2%	0.2%	Smaller T-frame and narrower insertion tube	Irregular bleeding in 1st 3-6 mo; ovarian cysts; amenorrhea in 13% of users after 1 yr
Skyla	0.4%	0.3%	Smaller T -frame and narrower insertion tube	Irregular bleeding in 1st 3-6 mo; ovarian cysts; amenorrhea in only 6% of users after 1 yr
Sterilization				
Female	0.5%	0.5%	Long-term contraception; no patient compliance required	Potential for surgical complications; regret among young women; reversal often not possible and expensive
Male	0.15%	0.1%	Long-term contraception; no patient compliance required	Pain at surgical site, regret among young men; reversal often not possible and expensive
Injectable			Convenience; same as progestin-only oral contraceptives	Delayed return to fertility, irregular bleeding and amenorrhea; weight gain; may decrease bone mineral density
Depo-Provera	4%	0.2%		
Combination oral contraceptives	7%	0.3%	Protection against ovarian and endometrial cancer, PID, and dysmenorrhea	Increased rate of thromboembolism, stroke, and myocardial infarction in older smokers; nausea; headache; contraindicated with breastfeeding
Progestin-only oral contraceptives	7%	0.3%	Protection against PID. iron-deficiency anemia, and dysmenorrhea; safe in breastfeeding women and those with cardiovascular risk	Irregular, unpredictable bleeding; must take at same time every day
Transdermal			Convenience of once-weekly application; same benefits as combination oral contraceptives	Dysmenorrhea and breast discomfort may be more frequent than with oral contraceptives; application site reactions; detachment; increased estrogen exposure compared to oral contraceptives
Evra	7%	0.3%		
Vaginal			Excellent cycle control; rapid return to fertility after removal; convenience of once-monthly insertion	Discomfort; vaginal discharge
NuvaRing	7%	0.3%		
Diaphragm with spermicide	17%	16%	Low cost; may reduce risk of cervical cancer	High failure rate; cervical irritation; increased risk of urinary tract infection and toxic shock syndrome; some require fitting by healthcare professional; may be difficult to obtain; available only by prescription
Condom without spermicide				
Female	21%	5%	Protection against STIs; covers external genitalia;	High failure rate; difficult to insert; poor acceptability

			OTC	
Male	13%	2%	Protection against STIs, OTC	High failure rate; allergic reactions; poor acceptability; breakage possible
Withdrawal	20%	4%	No drugs or devices	High failure rate
Sponge	14-27%	9-20%	OTC; low cost; no fitting required; provides 24 hr of protection	High failure rate; contraindicated during menses; increased risk of toxic shock syndrome
Fertility awareness–based methods	15%	-	Low cost; no drugs or devices	High failure rate; may be difficult to learn; requires relatively long periods of abstinence
Standard Days method	12%	5%		
TwoDay method	14%	4%		
Ovulation method	23%	3%		
Symptothermal method	2%	0.4%		
Spermicide alone	21%	16%	OTC	High failure rate; local irritation; must be reapplied with repeat intercourse; increased risk of HIV transmission
No method	85%	85%	-	–

[*] Risk of unintended pregnancy during first year of use; data from Trussel J, et al: In Hatcher RA et al: *Contraceptive technology.* ed 21, New York, 2018, Ayer Company Publishers.

143.1

Contraceptive Use

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

sexual activity
sexual debut

Sexual Activity

According to the Youth Risk Behavior Surveillance System 2015, 41.2% of U.S. high school students had ever had sexual intercourse and approximately one-third reported being currently sexually active.

Although U.S. teens and European teens have similar levels of **sexual activity** and ages of **sexual debut** , U.S. teens are less likely to use contraception and less likely to use the most effective methods. Teen pregnancy rates have been declining worldwide as a result of delayed initiation of sexual activity and increased contraceptive use. Despite declines, the United States still had the highest 2013 teen birthrate in the Western industrialized world, with 26.5 live births per 1,000 females aged 15-19 yr (Fig. 143.2). This is almost 1.5 times higher than the 2013 teen birthrate in the United Kingdom, which has the highest rate in Western Europe, and almost 8 times higher than the teen birthrate in Switzerland, which has the lowest rate in Western Europe. In 2011, of the 574,000 teen pregnancies in the United States, 75% were unintended, indicating an unmet need for reliable, effective contraception that teens will correctly and consistently use.

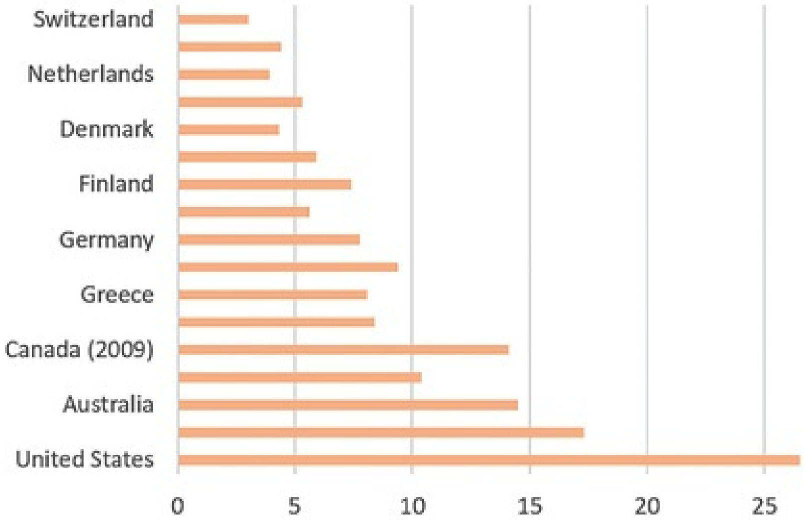

FIG. 143.2 **Teen birthrates in high-income countries, 2013. Live births per 1,000 females age 15-19 yr. (Data from United Nations Statistical Division. Demographic Yearbook 2014, New York, http://unstats.un.org/unsd/demographic/products/dyb/dyb2014.htm , and Martin JA, Hamilton BE, Osterman MJK, et al: Births: final data for 2013, *Natl Vital Stat Rep* 64(1):1–68, 2015.)**

Use of Contraception Among Teens

According to the National Survey of Family Growth, 2011–2013, virtually all sexually experienced teens have used some method of contraception in the past. The most commonly used method by teenage females is the *condom* , followed by withdrawal (both least effective methods) and then the pill (a moderately effective method). IUDs and implants, the most effective reversible methods, are only used by 4.3% of female contraceptive users age 15-19 yr. Use of contraception at **first sex** has greatly increased over the last 50 yr. As of 2010, the condom is the most common method used at first sex, reported by >75% of males and females. Factors associated with contraception use at first sex include increasing age among teens up to age 17 yr; time spent in college; and planning their sexual debut.

More than half of sexually experienced female teens are currently using the most effective reversible contraceptives or moderately effective contraceptive methods. U.S. teens' use of hormonal methods at last intercourse is less frequent compared to teens in other developed countries: 52% of U.S. teens, 56% of Swedish 18-19 yr olds, 67% of French 15-19 yr olds, 72% of British 16-19 yr olds, and 73% of Canadian 15-19 yr olds use hormonal methods. A higher likelihood of female current contraceptive use is associated with older age at sexual initiation, aspirations for higher academic achievement, acceptance of one's own sexual activity, and a positive attitude toward contraception. Despite the importance of dual protection to protect against both unwanted pregnancy and STIs, only 21.3% of sexually active female U.S. teens are using condoms in addition to another, more effective contraceptive method.

143.2

Contraceptive Counseling

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

counseling
effectiveness
typical-use failure rates
confidentiality
teen-friendly

The health screening interview during the adolescent preventive visit offers opportunities to identify and discuss unsafe sexual practices among all adolescents and to identify and reinforce safe sexual behaviors, including abstinence (see Chapter 137). Adolescents with medical conditions, either chronic or acute, are particularly vulnerable to having sexual and reproductive health omitted from their visits, although they have similar sexual health and contraceptive needs as healthy adolescents (see Chapter 734). Their comorbidities or concurrent medication use may make unintended pregnancy an increased health risk and may also reduce contraceptive options. The **U.S. Medical Eligibility Criteria for Contraceptive Use** outlines medical conditions associated with increased risk for adverse health events as a result of pregnancy and also provides recommendations for who can safely use specific contraceptive methods.

The goals of counseling with adolescents are to (1) understand adolescent experiences, preferences, perceptions, and misperceptions about pregnancy and use of contraceptives; (2) help adolescents put unprotected intercourse risk in a personal perspective; (3) educate adolescents about the various methods available using information that is medically accurate, balanced, and provided in a nonjudgmental manner; and (4) help adolescents choose a safe and effective method that can either be provided on site or be easily obtained through prescription or by referral. Counseling should include a review of all contraceptive methods available that the adolescent can use safely (see U.S. Medical Eligibility Criteria), starting with the most effective methods. **Long-acting reversible contraception** (IUDs and implants) is a safe and effective option for many adolescents, including those who have not been pregnant or given birth. The adolescent should be counseled about method effectiveness using typical-use failure rates. It is important to ask about use of **withdrawal** because 60% of female teens have used it for contraception and it has a typical-use failure rate of 20%. **Abstinence** should also be discussed as an option even if teens have engaged in sexual intercourse in the past. Situational abstinence may be the best option if they do not have another method available at a particular time.

Necessary concepts to address while discussing individual methods include how effective the method is, how long the method works, what behaviors are required for correct and consistent use, what side effects may be seen, any noncontraceptive benefits of the method (e.g., reduced menstrual bleeding, protection from STIs), and what signs or symptoms of complications should prompt a return visit. Reviewing common side effects allows teens to anticipate and cope with any changes with reassurance and may avoid method discontinuation. Weighing the possibility of certain side effects with the possibility of an unintended pregnancy may also help with the conversation. It is also important to address any specific misperceptions teens may have for certain contraceptives regarding side effects, effectiveness, or any other concept discussed.

Once an adolescent chooses a method, the provider and adolescent should discuss clear plans on correct and consistent use of the chosen method and strategies for appropriate follow-up (Table 143.1). Providers should help the adolescent consider potential barriers to correct and consistent use (e.g., forgetting to take a pill daily) and develop strategies to deal with each barrier (e.g., use of reminder systems such as daily text messages or phone alarms). The provider should assess whether the teen understood the information discussed and may confirm by asking the teen to repeat back key concepts.

The U.S. Selected Practice Recommendations for Contraceptive Use provides guidance for providers regarding when to start contraception, how to be certain the woman is not pregnant at contraception initiation, and what examinations and tests are recommended before initiating contraception. Generally, women may start a contraceptive method other than an IUD at any time, and an IUD may be placed when a provider is reasonably certain that a woman is not pregnant. Most women do not require any exams or tests before initiating contraception. A pelvic examination is only required for placement of an IUD, unless otherwise indicated. STI screening is appropriate at IUD placement once sexual activity has begun, but most women do not require additional screening if they have been recently screened according to CDC sexually transmitted disease (STD) treatment guidelines. Gonorrhea and chlamydia screening using a self- or provider-collected vaginal swab or urine sample is recommended unless symptoms require a pelvic exam. IUD placement should not be delayed to receive screening results. ACOG guidelines recommend that the female teen should first visit a gynecologist between age 13 and 15 yr, unless necessary at an earlier age. This visit aims to establish rapport, educate the patient and parents or guardian on healthy sexual development, and provide routine preventive services. Cervical cancer screening is not recommended until age 21.

Providers should offer confidential services to adolescents and observe all relevant state laws and legal obligations (e.g., notification or reporting of sexual abuse). Chapter 137 discusses confidentiality and consent issues related to contraceptive management. Providers should also encourage adolescents to involve parents or guardians in their healthcare decisions, while giving parents clear information on their teen's right to confidentiality, privacy, and informed consent. All services should be provided in a youth-friendly manner, meaning that they are accessible, equitable, acceptable, appropriate, comprehensive, effective, and efficient. Resources are available that describe ways to ensure a **teen-friendly** reproductive health visit.

Long-Acting Reversible Contraception

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

LARC
intrauterine devices
implants

Long-acting reversible contraception (**LARC**) includes 4 **levonorgestrel (LNG)** IUDs, the **copper (Cu)** IUD, and the etonogestrel subdermal implant. LARC methods are the only Tier 1 methods that are reversible (see Fig. 143.1). Considered "forgettable" contraception, LARC does not require frequent office or pharmacy visits and does not depend on user compliance for effectiveness. In the Contraceptive CHOICE Project in St. Louis, MO, >9,000 women were given the contraceptive method of their choice at no cost and were followed for 2-3 yr. The failure rates among women who used oral contraceptive pills, transdermal patch, or vaginal ring were >20 times higher than the failure rates for women using a LARC method. Acceptance, continuation, and satisfaction in this project were also higher among adolescents using LARC compared with adolescents using non-LARC methods. *ACOG and AAP support the use of LARC methods for adolescents.* The U.S. Medical Eligibility Criteria supports safe use of both IUDs and implants for adolescents and nulliparous women. Implants are considered category 1 for all ages, and IUDs are considered category 2 for women <20 yr old and for nulliparous women (Table 143.2).

Table 143.2

Categories of Medical Eligibility Criteria for Contraceptive Use

Category 1 : A condition for which there is no restriction for the use of the contraceptive method.

Category 2 : A condition for which the advantages of using the method generally outweigh the theoretical or proven risks.

Category 3 : A condition for which the theoretical or proven risks usually outweigh the advantages of using the method.

Category 4 : A condition that represents an unacceptable health risk if the contraceptive method is used.

Intrauterine Devices

IUDs are small, flexible, plastic objects introduced into the uterine cavity through the cervix. They differ in size, shape, and the presence or absence of pharmacologically active substances. In the United States, 5 IUDs are currently approved by the Food and Drug Administration (FDA): the CuT380A (Paragard) and 4 LNG IUDs (Liletta, Kyleena, Mirena, and Skyla). The effectiveness of the Cu IUD is enhanced by the copper ions released into the uterine cavity, with possible mechanisms including inhibition of sperm transport and prevention of implantation; this IUD is effective for at least 10 yr.

The LNG IUDs also have various actions, from thickening of cervical mucus and inhibiting sperm survival to suppressing the endometrium. LNG IUDs are effective for at least 3 and 5 years. All IUDs have typical-use failure rates of <1% (see Fig. 143.1).

Common misconceptions of IUDs among healthcare providers are that IUDs cause infections, infertility, and generally are not safe for teens or nulliparous women to use; these misconceptions are a barrier to teens accessing these highly effective and acceptable methods. IUDs do not increase risk of infertility and may be inserted safely in teens as well as nulliparous women (category 2; see Table 143.2).

Although early studies suggested an increased risk for upper genital tract infection, theoretically as a result of passing a foreign body through the cervix, newer work has refuted these earlier concerns. Therefore, clinicians are encouraged to consider use of IUDs in adolescents despite relatively high prevalence rates of STIs in this population. Teens should be screened for gonorrhea and chlamydia at or before IUD placement, although placement should not be delayed if results have not returned and there are no signs of current infection (e.g., purulent discharge, erythematous cervix). If STI testing is positive with an IUD in place, the patient may be treated without removing the IUD if she wants to continue the method. Evidence from 2 systematic reviews did not find benefit in routinely administering misoprostol to women undergoing routine IUD placement to decrease pain or improve provider ease of insertion. A paracervical block with lidocaine may reduce patient discomfort during placement and, along with other medications (e.g., NSAIDs, anxiolytics), may be considered on an individual patient basis, but these are not routinely recommended.

Implants

Currently, one contraceptive implant is available in the United States. Originally FDA approved in 2006, the single rod that releases 60 µg/day of **etonogestrel** has been updated to a radiopaque rod with a new inserter. This **progestin-only method** keeps etonogestrel at steady serum levels for at least 3 yr and primarily works to inhibit ovulation. Similar to the levonorgestrel IUD, the progestin acts on the uterus to cause an atrophic endometrium and thicken cervical mucus to block sperm penetration; its typical-use failure rate is also <1% (see Fig. 143.1). Unlike the IUD, no pelvic exam is required for insertion. A trained provider can quickly place or remove the implant in the upper arm under local anesthesia. Common side effects include amenorrhea, irregular bleeding, or infrequent bleeding, and less often, prolonged or frequent bleeding. One potential unique complication of this method relates to localized infection and other side effects after implantation, such as bleeding, hematoma, or scarring, and if inserted too deeply into the muscle, neural damage or migration; however, these events are rare, occurring in <1% of patients. Minor side effects, such as bruising or skin irritation, are more common but most often resolve without treatment.

Other Progestin-Only Methods

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

Depo-Provera
depot medroxyprogesterone acetate
DMPA
progestin-only pills
mini pills

Several progestin-only contraceptive methods are available and include the LNG IUDs and implant (see Chapter 143.3), as well as an injectable and progestin-only pills. These methods do not contain estrogen and may be useful for teens with contraindications to estrogen (Table 143.3) and are considered generally safe for use in teens (category 1 or 2; see Table 143.2). Progestins thicken cervical mucus to block sperm entry into the uterine cavity as well as induce an atrophic endometrium leading to either amenorrhea or less menstrual blood loss; the implant and injectable additionally suppress ovulation. Teens should be provided anticipatory counseling regarding bleeding irregularities that may normally occur in the 1st 3-6 mo of hormonal contraception use.

Table 143.3

Conditions Classified as Category 3 and 4 for Combined Hormonal Contraceptive Use

Category 4

Complicated valvular heart disease
Current breast cancer
Severe decompensated cirrhosis
Deep venous thrombosis/pulmonary embolism (acute; history, not on anticoagulation or on established therapy for at least 3 mo with higher risk recurrence; major surgery with prolonged immobilization)
Complicated diabetes with nephropathy, retinopathy, neuropathy, or other vascular disease or duration of diabetes >20 yr
Migraine with aura
Hypertension (blood pressure >160/100 mm Hg) or hypertension with vascular disease
Ischemic heart disease (history of or current)
Hepatocellular adenoma
Malignant liver tumor
Peripartum cardiomyopathy (diagnosed <6 mo prior or with moderately or severely impaired cardiac function)
Postpartum <21 days
History of cerebrovascular accident
Systemic lupus erythematosus with positive antiphospholipid antibodies
Thrombogenic mutations
Viral hepatitis (acute or flare)

Category 3

Past breast cancer with no evidence of disease for 5 yr
Breastfeeding and <1 mo postpartum
Deep venous thrombosis/pulmonary embolism (history of DVT/PE with lower risk recurrence)
Gallbladder disease (current, medically treated)
History of malabsorptive bariatric surgery
History of cholestasis and past combined oral contraceptive–related
Hypertension (adequately controlled or blood pressure <160/100 mm Hg)
Peripartum cardiomyopathy with mild impairment or >6 mo
Postpartum 21-42 days with other risk factors for venous thromboembolism
Drug interactions (Ritonavir-boosted protease inhibitors; certain anticonvulsants; rifampin or rifabutin)

From Curtis KM, Tepper NK, Jatlaoui TC, et al: U.S. medical eligibility criteria for contraceptive use, 2016, *MMWR Recomm Rep* 65(RR-3):1–104, 2016.

Depo-Provera

An *injectable progestin,* depot **medroxyprogesterone acetate** (**DMPA** , Depo-Provera) is a Tier 2 contraceptive method available as a deep intramuscular (IM) injection (150 mg), or as a subcutaneous (SC) injection (104 mg) with typical-use failure rates of 4% (see Table 143.1). Both preparations must be readministered every 3 mo (13 wk) and act to inhibit ovulation. DMPA is particularly attractive for adolescents who have difficulty with compliance, are intellectually or physically impaired, and are chronically ill or have a condition for which estrogen use is not recommended. Common concerns with DMPA include bleeding changes, bone effects, and weight gain. After 1 yr of use, 50% of DMPA users develop amenorrhea, which may be an added advantage for teens with heavy menstrual bleeding, dysmenorrhea, anemias, or blood dyscrasias, or for those with impairments that make hygiene difficult. Although studies have demonstrated bone mineral density (BMD) loss in adolescents, potentially increasing their risk for osteoporosis later in life, other studies have found that BMD is recovered after discontinuation of this method, and it is thus considered safe for use in this population. Healthcare providers may want to consider a contraceptive containing estrogen in teens who are already at high risk for low BMD, such as those receiving chronic corticosteroid therapy or those with eating disorders (see Chapter 726). Although the FDA issued a black box warning in 2004, AAP and ACOG do not recommend limiting DMPA use to 2 yr for all women and do not recommend routine BMD screening for females using DMPA. Early weight gain may be predictive of progressive gain over time; thus those teens gaining weight in the 1st 3-6 mo should consider another method.

Progestin-Only Pills

Progestin-only oral contraceptive pills (**POPs**) are available for the adolescent in whom the use of estrogen is potentially harmful, such those with active liver disease, replaced cardiac valves, or hypercoagulable states (see Table 143.3). POPs (**mini pills**) are quickly effective after 2 days of initiation in thickening cervical mucus, but are less reliable in inhibiting ovulation. Effects are short-lived, and pill-taking must be punctual, which may be difficult for teens. If a pill is >3 hr late from normal time, an unintended pregnancy may occur. POPs have a typical-use failure rate of 7% (see Table 143.1). Acceptance by adolescents is limited by the necessity of taking the pill at the same time daily and bleeding irregularities, including amenorrhea and breakthrough bleeding.

143.5

Combined Hormonal Contraceptives

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

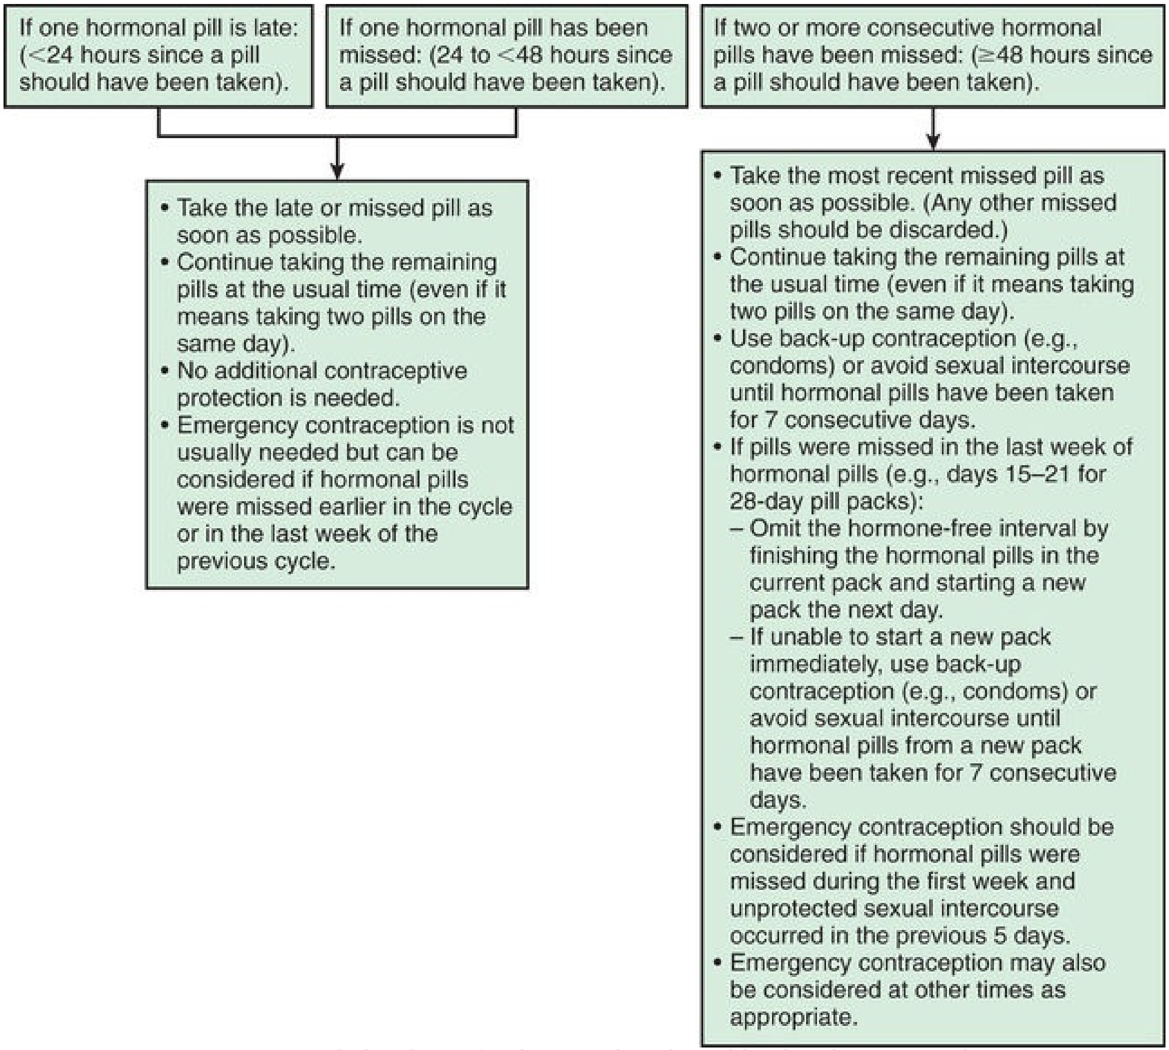
combined hormonal contraceptives
oral contraceptive pills
combined pills
patch
ring

Combined hormonal contraceptives (**CHCs**) are methods that include an estrogenic substance in combination with a progestin; methods available in the United States include several formulations of combined oral contraceptives (**COCs**), a transdermal patch, and a vaginal ring. The major mechanism of action of the **estrogen-progestin** combination is to prevent the surge of luteinizing hormone and thereby inhibit ovulation. Additional effects to the reproductive tract include thickening of the cervical mucus, which prevents sperm penetration, and thinning of the endometrial lining, which may decrease menstrual blood loss. Typical-use failure rates for all CHCs are the same at 7%.

The COCs, patch, and vaginal ring are classified together as CHCs in the U.S. Medical Eligibility Criteria for Contraceptive Use, and recommendations mostly consider estrogen exposure for a given condition or characteristic (see Table 143.3). Venous thromboembolism, hepatic adenomas, myocardial infarction, and stroke are some of the more serious potential complications of exogenous estrogen use. These serious adverse events are exceedingly rare in adolescents. Even though teenage smokers who use oral contraceptives have more than twice the risk of myocardial infarction, the likelihood of its occurrence is very small, and thus clinically insignificant, compared to the risk of dying from other pregnancy-related complications.

Combined Oral Contraceptives

Oral contraceptive pills (OCs) can be either COCs or progestin-only pills and are commonly referred to as “the pill.” The pill is one of the most common contraceptive methods used among women of all ages. To decrease risk of pregnancy and increase continuation, providers are encouraged to provide OCs at the time of patient presentation to start immediately rather than waiting for next menses, as long as the provider is reasonably sure that the patient is not pregnant. Providers are also encouraged to provide up to 13 pill packs at a time, based on evidence that more pill packs given is associated with higher continuation rates. Advanced provision of emergency contraceptive pills is also recommended should patients miss pills and have unprotected sex. The effectiveness of COCs depends on compliance, and unfortunately, adolescents may forget to take a pill each day. Figs. 143.3 and 143.4 list the rules for missed pills or following vomiting or diarrhea.



If one hormonal pill is late: (<24 hours since a pill should have been taken).

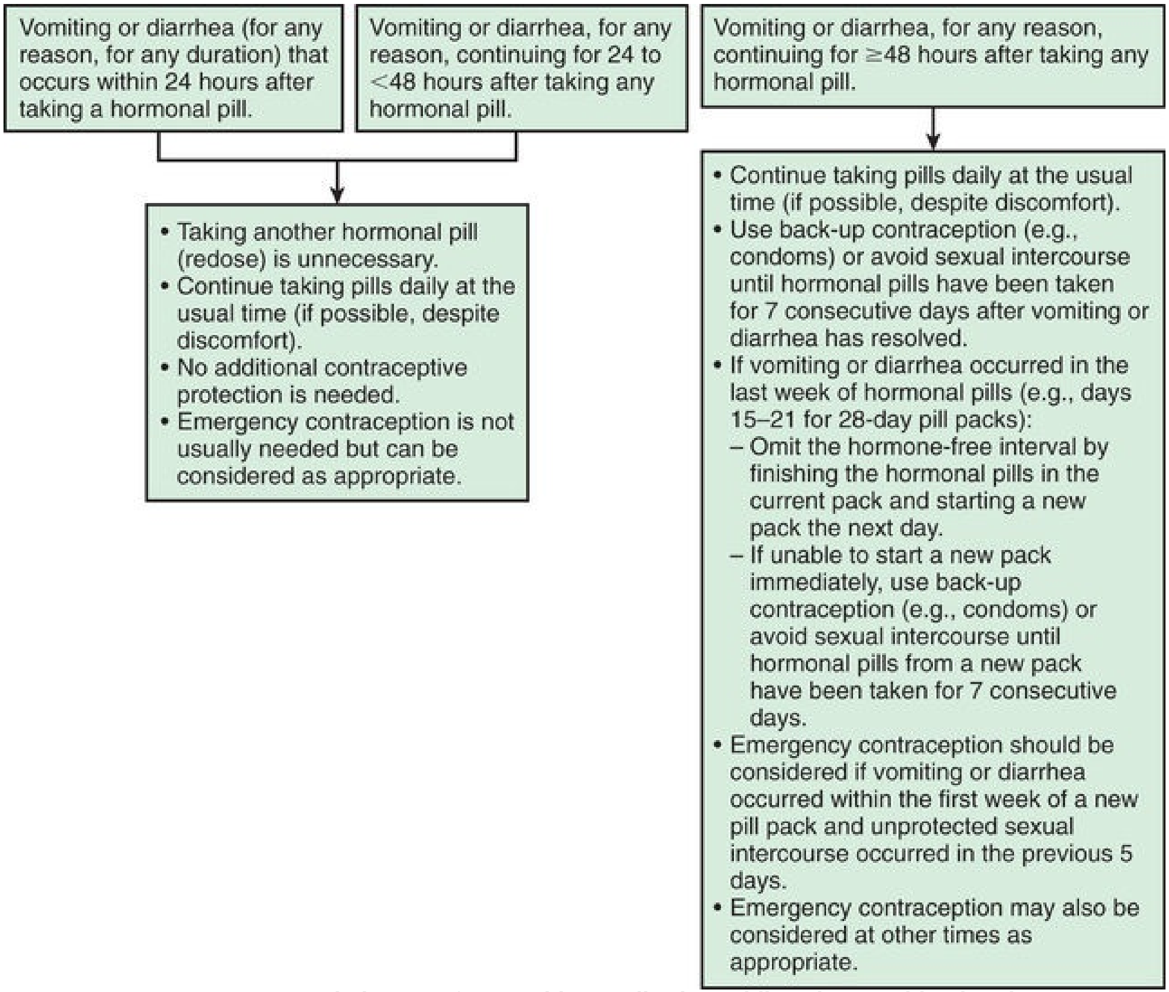
If one hormonal pill has been missed: (24 to <48 hours since a pill should have been taken).

- Take the late or missed pill as soon as possible.
- Continue taking the remaining pills at the usual time (even if it means taking two pills on the same day).
- No additional contraceptive protection is needed.
- Emergency contraception is not usually needed but can be considered if hormonal pills were missed earlier in the cycle or in the last week of the previous cycle.

If two or more consecutive hormonal pills have been missed: (≥48 hours since a pill should have been taken).

- Take the most recent missed pill as soon as possible. (Any other missed pills should be discarded.)
- Continue taking the remaining pills at the usual time (even if it means taking two pills on the same day).
- Use back-up contraception (e.g., condoms) or avoid sexual intercourse until hormonal pills have been taken for 7 consecutive days.
- If pills were missed in the last week of hormonal pills (e.g., days 15–21 for 28-day pill packs):
  - Omit the hormone-free interval by finishing the hormonal pills in the current pack and starting a new pack the next day.
  - If unable to start a new pack immediately, use back-up contraception (e.g., condoms) or avoid sexual intercourse until hormonal pills from a new pack have been taken for 7 consecutive days.
- Emergency contraception should be considered if hormonal pills were missed during the first week and unprotected sexual intercourse occurred in the previous 5 days.
- Emergency contraception may also be considered at other times as appropriate.

FIG. 143.3 **Recommended actions after late or missed combined oral contraceptives. (From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016, *MMWR Recomm Rep* 65(RR-4):1–66, 2016, Fig 2, p 28.)**



Vomiting or diarrhea (for any reason, for any duration) that occurs within 24 hours after taking a hormonal pill.

Vomiting or diarrhea, for any reason, continuing for 24 to <48 hours after taking any hormonal pill.

- Taking another hormonal pill (redose) is unnecessary.
- Continue taking pills daily at the usual time (if possible, despite discomfort).
- No additional contraceptive protection is needed.
- Emergency contraception is not usually needed but can be considered as appropriate.

Vomiting or diarrhea, for any reason, continuing for ≥48 hours after taking any hormonal pill.

- Continue taking pills daily at the usual time (if possible, despite discomfort).
- Use back-up contraception (e.g., condoms) or avoid sexual intercourse until hormonal pills have been taken for 7 consecutive days after vomiting or diarrhea has resolved.
- If vomiting or diarrhea occurred in the last week of hormonal pills (e.g., days 15–21 for 28-day pill packs):
  - Omit the hormone-free interval by finishing the hormonal pills in the current pack and starting a new pack the next day.
  - If unable to start a new pack immediately, use back-up contraception (e.g., condoms) or avoid sexual intercourse until hormonal pills from a new pack have been taken for 7 consecutive days.
- Emergency contraception should be considered if vomiting or diarrhea occurred within the first week of a new pill pack and unprotected sexual intercourse occurred in the previous 5 days.
- Emergency contraception may also be considered at other times as appropriate.

FIG. 143.4 Recommended steps after vomiting or diarrhea while using combined oral contraceptives. (From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016, *MMWR Recomm Rep* 65(RR-4):1–66, 2016, Fig 5, p 30.)

COCs contain 50, 35, 30, 25, or 20 µg of estrogenic substance, typically **ethinyl estradiol** , and as many as 10 progestins have been available in the United States for combined pills. Multiple preparations are available to help select the formulation that satisfies an individual patient, with minimal side effects.

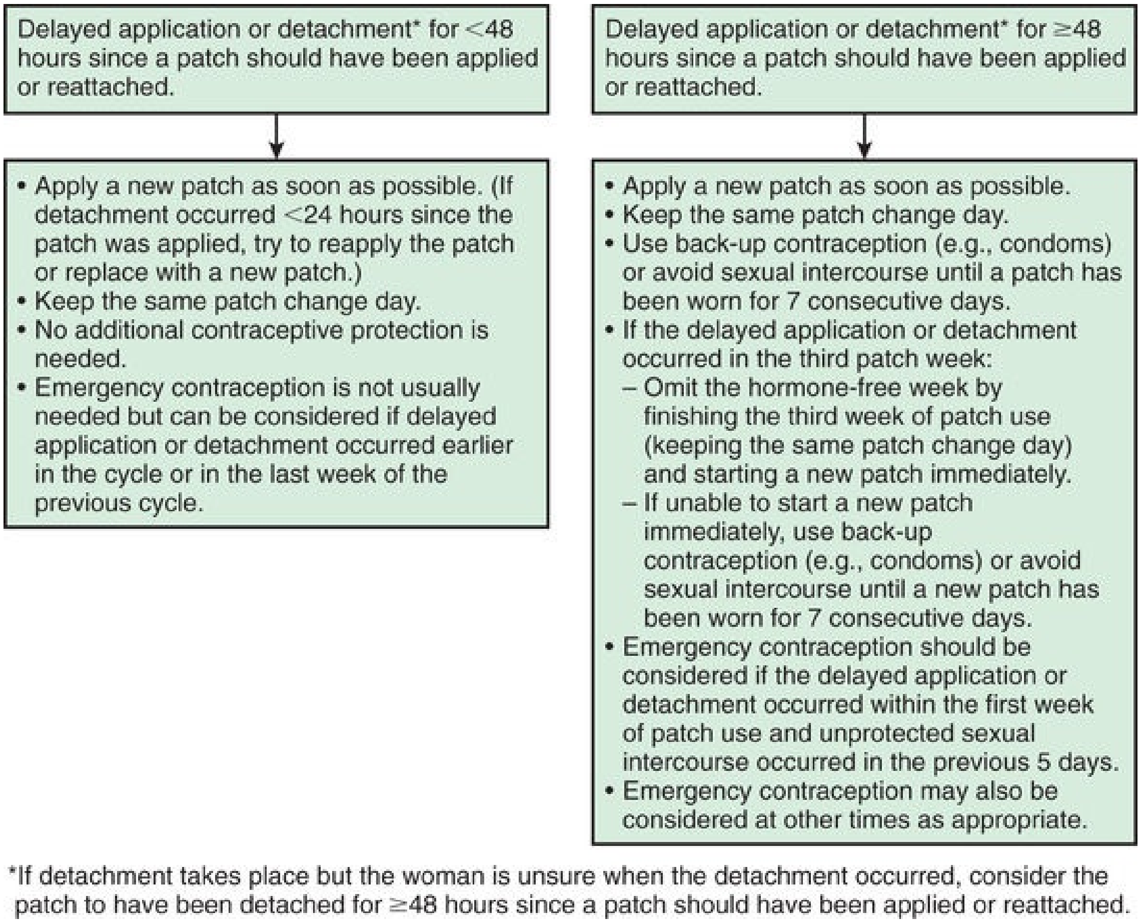
COCs can be packaged as 28-day *monophasic* pills, which contain the same dose of active pills for 21 or 24 days, followed by 7 or 4 days of placebo pills, respectively. Monophasic formulations are also available for extended cycles of 91 days or 1 yr so that withdrawal bleeding does not occur each month, but at the end of each extended cycle. **Extended cycling** of monophasic COCs for adolescents has some anticipated benefits associated with increased ovarian activity suppression and may decrease failure rates. Other advantages include diminished frequency of hormonal withdrawal (premenstrual) effects, including headaches and migraines, mood changes, and heavy monthly bleeding. The most common side effect of extended-cycle OCs is intermenstrual bleeding and/or spotting, with the total days of bleeding over the 1st yr of treatment being similar for extended-cycle users and users following a 28-day cycle regimen. The unscheduled bleeding pattern diminishes over time. *Multiphasic* pill packs contain various levels of estrogen and progestin for 21 active pills and contains 7 placebo pills. Multiphasic formulations are not available for extended-cycle use. Providers can refer to the U.S. Selected Practice Recommendations for Contraceptive Use to counsel patients on how to manage late or missed COCs.

The short-term adverse effects of COCs, such as nausea and weight gain, often interfere with compliance in adolescent patients. These effects are usually transient and may be overshadowed by the beneficial effects of a shortened menses and the relief of dysmenorrhea. The inhibition of ovulation or the suppressant effect of estrogens on prostaglandin production by the endometrium makes COCs effective in preventing dysmenorrhea (see Chapter 142). Acne may be worsened by some and improved by other oral contraceptive preparations (see Chapter 689). The pills with nonandrogenic progestins are particularly effective in reducing acne and hirsutism. **Drospirenone** , a progestin with antimineralocorticoid activity, has been shown to reduce premenstrual symptomatology, but the potential for hyperkalemia as a side effect eliminates patients with renal, liver, or adrenal diseases and patients taking certain medications.

As of 2011, the FDA has concluded that drospirenone-containing OCs may be associated with a higher risk of venous thromboembolism (VTE) than other progestin-containing pills. Although no studies have provided consistent estimates of the comparative risk of VTE between OCs that contain drospirenone and those that do not, or accounted for patient characteristics that may affect VTE risk, there has been a 3-fold increased risk of VTE reported for drospirenone compared with products containing levonorgestrel or other progestins. As a result, the FDA is requiring that labeling be revised for the OCs marketed under the Beyaz, Safyral, Yasmin, and Yaz brands. Despite the risk of VTE with all OCs, the absolute risk remains lower than the risk of developing VTE during pregnancy or the postpartum period.

Transdermal Patch

The transdermal patch (Ortho Evra or Xulane) releases 20 µg ethinyl estradiol and 150 µg norelgestromin daily and is applied to the lower abdomen, buttocks, or upper body, excluding the breasts. It is worn continuously for 1 wk and changed weekly for a total of 3 wk, then no patch is worn for the 4th week, at which time bleeding occurs (see Table 143.1). Limited studies in adolescents suggest higher rates of partial or full detachment compared to adults, with high patient satisfaction and 50–83% continuation rates from 3-18 mo of use (Fig. 143.5). As with other combined hormonal methods, the patch is a Tier 2 contraceptive. Providers can refer to the U.S. Selected Practice Recommendations to counsel patients on how to manage delayed application or detachment of the patch.



Delayed application or detachment* for <48 hours since a patch should have been applied or reattached.

- Apply a new patch as soon as possible. (If detachment occurred <24 hours since the patch was applied, try to reapply the patch or replace with a new patch.)
- Keep the same patch change day.
- No additional contraceptive protection is needed.
- Emergency contraception is not usually needed but can be considered if delayed application or detachment occurred earlier in the cycle or in the last week of the previous cycle.

Delayed application or detachment* for ≥48 hours since a patch should have been applied or reattached.

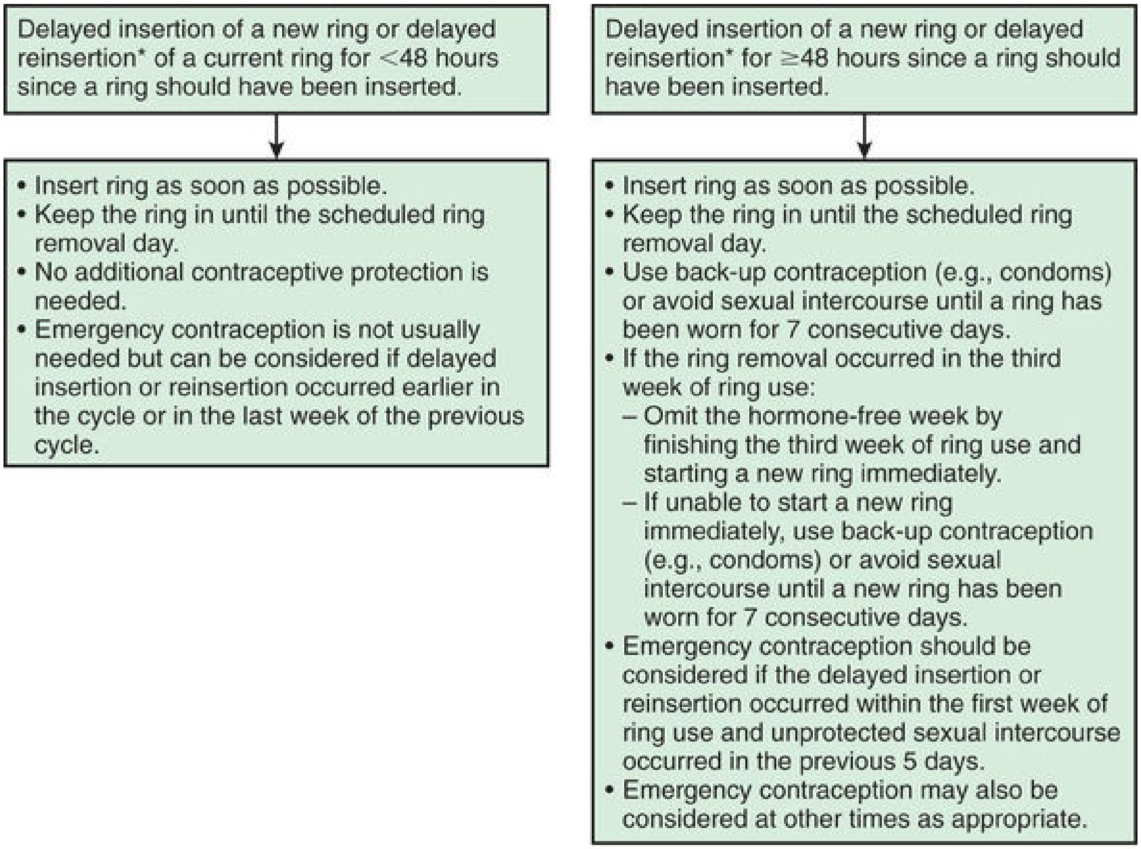
- Apply a new patch as soon as possible.
- Keep the same patch change day.
- Use back-up contraception (e.g., condoms) or avoid sexual intercourse until a patch has been worn for 7 consecutive days.
- If the delayed application or detachment occurred in the third patch week:
  - – Omit the hormone-free week by finishing the third week of patch use (keeping the same patch change day) and starting a new patch immediately.
  - – If unable to start a new patch immediately, use back-up contraception (e.g., condoms) or avoid sexual intercourse until a new patch has been worn for 7 consecutive days.
- Emergency contraception should be considered if the delayed application or detachment occurred within the first week of patch use and unprotected sexual intercourse occurred in the previous 5 days.
- Emergency contraception may also be considered at other times as appropriate.

*If detachment takes place but the woman is unsure when the detachment occurred, consider the patch to have been detached for ≥48 hours since a patch should have been applied or reattached.

FIG. 143.5 Recommended actions after delayed application or detachment with combined hormonal patch. (From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. Selected practice recommendations for contraceptive use, 2016, *MMWR Recomm Rep* 65(RR-4):1–66, 2016, Fig 3, p 28.)

Vaginal Ring

The vaginal contraceptive ring (NuvaRing) is a flexible, transparent, colorless vaginal ring that measures about 2.1 inches in diameter and is inserted into the vagina by the patient. It releases 15 µg ethinyl estradiol and 120 µg etonogestrel per day and remains in place for 3 weeks, during which time these hormones are absorbed. If the ring is accidentally expelled or removed for intercourse, it should be reinserted; however, if it is out of place ≥48 hr, a backup method of contraception should be used (Fig. 143.6). As with other combined hormonal methods, the vaginal ring is a Tier 2 contraceptive. Providers can refer to the U.S. Selected Practice Recommendations to counsel patients on how to manage delayed insertion or reinsertion with the vaginal ring.



Delayed insertion of a new ring or delayed reinsertion* of a current ring for <48 hours since a ring should have been inserted.

- Insert ring as soon as possible.
- Keep the ring in until the scheduled ring removal day.
- No additional contraceptive protection is needed.
- Emergency contraception is not usually needed but can be considered if delayed insertion or reinsertion occurred earlier in the cycle or in the last week of the previous cycle.

Delayed insertion of a new ring or delayed reinsertion* for ≥48 hours since a ring should have been inserted.

- Insert ring as soon as possible.
- Keep the ring in until the scheduled ring removal day.
- Use back-up contraception (e.g., condoms) or avoid sexual intercourse until a ring has been worn for 7 consecutive days.
- If the ring removal occurred in the third week of ring use:
  - Omit the hormone-free week by finishing the third week of ring use and starting a new ring immediately.
  - If unable to start a new ring immediately, use back-up contraception (e.g., condoms) or avoid sexual intercourse until a new ring has been worn for 7 consecutive days.
- Emergency contraception should be considered if the delayed insertion or reinsertion occurred within the first week of ring use and unprotected sexual intercourse occurred in the previous 5 days.
- Emergency contraception may also be considered at other times as appropriate.

*If removal takes place but the woman is unsure of how long the ring has been removed, consider the ring to have been removed for ≥48 hours since a ring should have been inserted or reinserted.

FIG. 143.6 **Recommended actions after delayed insertion or reinsertion with combined vaginal ring. (From Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016, *MMWR Recomm Rep* 65(RR-4):1–66, 2016, Fig 4, p 29.)**

Contraindications

Contraindications to the use of estrogen-containing methods include those conditions for which CHCs pose an unacceptable health risk (category 4) in the U.S. Medical Eligibility Criteria for Contraceptive Use (see Table 143.3): current breast cancer, severe cirrhosis, acute deep venous thrombosis/pulmonary embolism or history of DVT/PE with higher risk for recurrence, major surgery with prolonged immobilization, diabetes with nephropathy, retinopathy or neuropathy, migraines with aura, stage II hypertension, vascular disease, ischemic heart disease, hepatocellular adenoma or malignant liver tumors, multiple risk factors for cardiovascular disease, peripartum cardiomyopathy, postpartum <21 days, complicated solid-organ transplantation, history of cerebrovascular accident, systemic lupus erythematosus with positive antiphospholipid antibodies, thrombogenic mutations, and complicated valvular heart disease. The initial history taken before prescribing CHCs should specifically address these risks. The U.S. Medical Eligibility Criteria provides contraceptive safety guidance with >1,800 recommendations for >120 medical conditions or characteristics.

143.6

Emergency Contraception

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

ulipristal
Plan B
levonorgestrel
LNG
EC
Yuzpe

Unprotected intercourse at mid-cycle carries a pregnancy risk of 20–30%. At other times during the cycle, the risk is 2–4%. The risk may be reduced or eliminated by interventions known collectively as emergency contraception (**EC**) up to 120 hr after unprotected intercourse or contraceptive failure. Table 143.4 lists the indications for use of EC. EC methods include the Cu IUD and emergency contraceptive pills, which include ulipristal acetate, levonorgestrel (LNG), and COCs following the Yuzpe method. Although the mechanism of action of the Cu IUD as EC is unclear, all emergency contraceptive pills work to delay ovulation and are effective only for intercourse that occurs before administration. Initiation of a regular contraceptive method is necessary to prevent pregnancy for any intercourse that occurs for the remainder of the cycle and for future cycles. If pregnancy has already occurred, emergency contraceptive pills will not cause an abortion or have teratogenic effects on the fetus.

Table 143.4

Possible Indications for Emergency Contraception

HIGH RISK SEXUAL ACTIVITY
No contraception during intercourse
Rape
Coitus interruptus
Intoxication (alcohol, drugs)
CONTRACEPTION FAILURES
Condom breaking, spillage, leaks, removal by male (purposeful)
Dislodgement, breaking of diaphragm, female condom, cervical cap
Expulsion of IUD
Spermicide failure to melt before coitus
DELAYED OR MISSED CONTRACEPTION
2 consecutive missed days of combined oral contraceptive
1 missed day of progestin only oral contraceptives
> 2-week late injection of depot medroxyprogesterone
≥ 2 day late start of vaginal ring or patch cycle
OTHER
Exposure to teratogens in absence of contraception

Teens can access EC information through a hotline at 1-888-NOT-2-LATE to obtain EC pills over the counter (OTC). AAP recommends advance provision of EC pills for teens who are or may become sexually active. A follow-up appointment is also recommended to determine the effectiveness of treatment and to diagnose a possible early pregnancy. The visit also provides an opportunity to counsel the adolescent, explore the situation leading up to the unprotected intercourse or contraceptive failure, test for STIs, offer HIV testing, and initiate continuing contraception when appropriate. Pap smear screening is not initiated until age 21.

Copper IUD

The CuT380A (Paragard) is FDA approved for EC and has been shown to be >99% effective if used within 5 days (120 hr) after unprotected sex. The additional benefit of using the Cu IUD for EC is it also provides long-term reversible contraception.

Ulipristal Acetate

This formulation is available for EC and was FDA approved in 2010 for use up to 120 hr after unprotected sex. Ulipristal acetate is available only by prescription regardless of age. A few studies have shown it to be more effective than LNG at and beyond 72 hr. If starting regular contraception after taking ulipristal acetate, it is recommended to start or resume hormonal contraception no sooner than 5 days after taking ulipristal, to avoid a potential interaction and its decreased effectiveness. If starting a method requires an extra visit (e.g., IUDs, implant, Depo-Provera), starting the method at the time of ulipristal may be considered, weighing the risk of decreasing the effectiveness of ulipristal with the risk of not starting a contraceptive method.

Levonorgestrel

In 2013 the FDA approved the emergency contraceptive drug **Plan B** One-Step as an OTC option for all women of childbearing potential. Experience in adolescent women demonstrates more effective use of EC with advance provision, and it is not associated with more frequent unprotected intercourse or less condom or pill use. Nausea and vomiting are uncommon side effects, and in a recent comparison, LNG proved more effective at preventing pregnancy than the Yuzpe method.

The **Yuzpe method** has been replaced by the more effective LNG pills but may be useful for women who already have COCs at home and are in need of EC. For EC, pills consist of COCs totaling 200 µg ethinyl estradiol and 2.0 mg norgestrel or 1.0 mg levonorgestrel. This method is effective in reducing the risk of pregnancy by 75%. The most common side effects are nausea (50%) and vomiting (20%), prompting some clinicians to prescribe or recommend antiemetics along with the COCs.

143.7

Dual Protection

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

condoms
dual protection
female condom

Dual protection refers to contraceptive use that protects against STIs/HIV as well as pregnancy. Although correct and consistent condom use with every act of sexual intercourse provides dual protection, providers should encourage adolescents to use condoms for STI/HIV protection along with a more effective method for pregnancy protection.

Condoms

This method prevents sperm from being deposited in the vagina. No major side effects are associated with the use of a condom. The risk of HIV may have increased the use of condoms among adolescents, with 46.2% of high school students in 1991 reporting using a condom at last sexual intercourse increasing to 56.9% in 2015. The main advantages of condoms are their low price, availability without prescription, little need for advance planning, and, most important for this age-group, their effectiveness in preventing transmission of STIs, including HIV and human papillomavirus (HPV). The typical-use failure rate for male condoms is 13%. For the most effective dual protection, **male latex condoms** are recommended as protection against STIs, and should be used with an effective contraceptive method for adolescents, such as a LARC. According to the National Survey of Family Growth, only 21.3% of females used another contraceptive method along with a condom at last sex during the past 12 mo.

A **female condom** is available OTC in single-size disposable units. It is a 2nd choice over the male latex condom because of the complexity of properly using the device, its high typical-use failure rate of 21%, and the lack of human studies demonstrating its effectiveness against STIs. Most adolescents would require intensive education and hands-on practice to use it effectively.

143.8

Other Barrier Methods

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

cervical cap
sponge
diaphragm

Diaphragm, Cervical Cap, and Sponge

These methods have few side effects but are much less likely to be used by teenagers. Typical use failure rates exceed 14%. The **cervical cap** and **sponge** have lower failure rates in nulliparous women, while the **diaphragm** has similar rates among nulliparous and parous women. Adolescents tend to object to the messiness of the jelly or the insertion of a diaphragm interrupting the spontaneity of sex (to be inserted before sex and left in for several hours afterward), or they may express discomfort about touching their genitals.

143.9

Other Contraceptive Methods

Tara C. Jatlaoui, Yokabed Ermias, Lauren B. Zapata

Keywords

spermicide
withdrawal
fertility awareness–based methods
lactational amenorrhea method

Spermicides

A variety of agents containing the spermicide **nonoxynol-9** are available as foams, jellies, creams, films, or effervescent vaginal suppositories. They must be placed in the vaginal cavity shortly before intercourse and reinserted before each subsequent ejaculation to be effective. Rare side effects include contact vaginitis. Some concern surrounds the vaginal and cervical mucosal damage observed with nonoxynol-9, and the overall impact on HIV transmission is unknown. The finding that nonoxynol-9 is gonococcicidal and spirocheticidal has not been substantiated in randomized clinical trials. Spermicides should be used in combination with other barrier methods because their typical-use failure rate alone is 21%.

Withdrawal

The pregnancy risk for use of withdrawal as a contraceptive method is probably underestimated in adolescents, and high typical-use failure rate of 20% should be specifically addressed with young adolescents; especially since 60% of teens have used withdrawal for contraception.

Fertility Awareness–Based Methods

These include the Standard Days method, basal body temperature method, and Billings method and may also include combinations as well. Since fertility awareness methods are based on regular ovulatory cycles, which are less common in teens, these should be used with caution.

Lactational Amenorrhea Method

The lactational amenorrhea method may be a highly effective, temporary contraceptive method if the following criteria are met: (1) no return of menses,

(2) the infant is <6 mo old, and (3) exclusively breastfeeding.

CHAPTER 144

Adolescent Pregnancy

Cora Collette Breuner

Epidemiology

There has been a trend of decreasing teen births and pregnancies since 1991 (Figs. 144.1 and 144.2). Teen birthrates in the United States are at a historic low secondary to increased use of contraception at first intercourse and use of dual methods of condoms and hormonal contraception among sexually active teenagers. Despite these data, the United States continues to lead other industrialized countries in having high rates of adolescent pregnancy, with >700,000 pregnancies per year. Nonetheless, the National Survey of Family Growth (NSFG) 2006–2010 revealed that less than one third of 15-19 yr old females consistently used contraceptive methods at last intercourse.

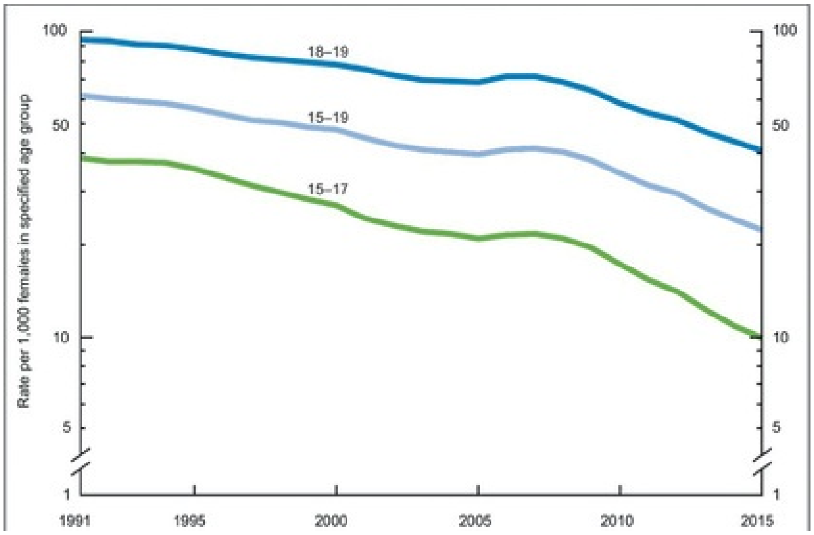

FIG. 144.1 Birthrates for females age 15-19, by age group: United States, 1991–2015. Rates are plotted on a logarithmic scale. For each age group, differences are significant

($p < 0.05$) from 1991–2015, 2007–2015, and 2014–2015. (From Martin JA, Hamilton BE, Osterman MJK, et al: Births: final data for 2015, *Natl Vital Stat Rep* 66(1), 2017, Division of Vital Statistics, National Center for Health Statistics, National Vital Statistics System, Natality. Access data table at http://www.cdc.gov/nchs/data/databriefs/db259_table.pdf#1 .)

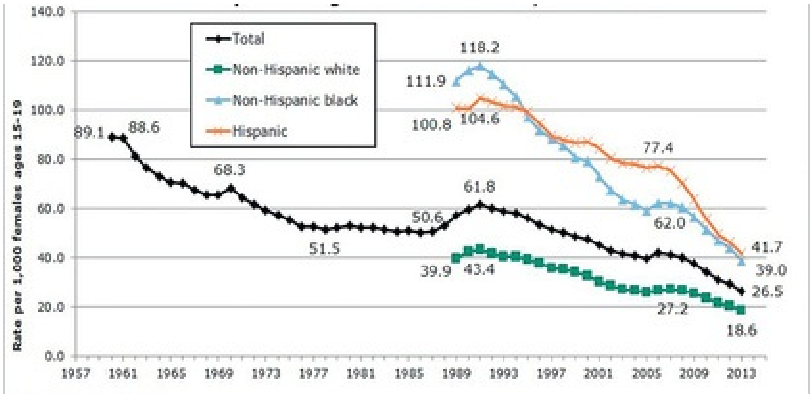

FIG. 144.2 Birthrates (per 1,000) for femals ages 15-19, by race and Hispanic origin: Selected years, 1960–2014. Differences in teen childbearing across the race and Hispanic-origin groups have narrowed from 1991 to 2015. In 1991, there was a difference of 77 births per 1,000 teenagers age 15-19 between the lowest rate (27.3 for Asian Pacific Islander [API] females) and the highest rate (104.6 for Hispanic females), compared with a difference of 28 births between the lowest rate (6.9 for API females) and the highest rate (34.9 for Hispanic females) in 2015. From 2014 to 2015, the birthrate for females age 15-19 declined 10% for API (to 6.9), 9% for non-Hispanic black (31.8), 8% for both non-Hispanic white (16.0) and Hispanic (34.9), and 6% for American Indian or Alaska Native (AIAN) (25.7) females. Since 2007, declines in teen birthrates have ranged from 41% for non-Hispanic white females to 54% for Hispanic females. Since 1991, declines have ranged from 63% for non-Hispanic white females to 75% for API females. Data for 2014 are preliminary. (Data for 1960 from National Center for Health Statistics: Health, United States, 2001 with urban and rural health chartbook, Hyattsville, MD, 2001, Table 3; data for 1970–2011 from Martin JA et al: Births: final data for 2011, *Natl Vital Stat Rep* 62(1), 2013, http://www.cdc.gov/nchs/data/nvsr/nvsr62/nvsr62_01.pdf ; data for 2012 from Martin JA et al: Births: final data for 2012, *Natl Vital Stat Rep* 62(9), 2013, http://www.cdc.gov/nchs/data/nvsr/nvsr62/nvsr62_09.pdf ; data for 2013 from Martin JA et al: Births: preliminary data for 2013, *Natl Vital Stat Rep* 63(2), 2014, http://www.cdc.gov/nchs/data/nvsr/nvsr63/nvsr63_02.pdf .)

The improvement in U.S. female teen birthrates is attributed to 3 factors: more teens are delaying the onset of sexual intercourse, are using some form of contraception when they begin to have sexual intercourse, and are using long-lasting contraceptive agents such as injections, implants, and intrauterine devices (IUDs).

Most pregnancies among U.S. adolescents are **unintended** (unwanted or mistimed); 88% of births to teenagers 15-17 yr old were the result of unintended pregnancies. Birthrate statistics underestimate actual adolescent pregnancy rates because the birthrate numerator includes the number of actual births per 1000 individuals in that age-group, but the pregnancy rate includes actual births, abortions, and best estimates of fetal loss per 1,000 adolescents in that age-group.

The abortion rate among adolescents 15-19 yr old was 14.3 per 1,000 females and accounted for 16.2% of all abortions in 2008. During the decade 1999–2008, the abortion rate decreased by 20.7% among adolescents 15-19 yr old, with a 5.8% decrease noted from 2004–2008.

Etiology

In industrialized countries with policies supporting access to protection against pregnancy and sexually transmitted infections (**STIs**), older adolescents are more likely to use hormonal contraceptives and condoms, resulting in a lowered risk of unplanned pregnancy. Younger teenagers are likely to be less deliberate and logical about their sexual decisions, and their sexual activity is likely to be sporadic or even coercive, contributing to inconsistent contraceptive use and a greater risk of unplanned pregnancy. Better personal hopes for employment and higher educational goals are associated with lowered probability of childbearing in most groups. In nonindustrialized countries, laws permitting marriage of young and mid-teens, poverty, and limited female education are associated with increased adolescent pregnancy rates.

Clinical Manifestations

Adolescents may experience the traditional symptoms of pregnancy: morning sickness (vomiting, nausea that may also occur *any* time of the day), swollen tender breasts, weight gain, and amenorrhea. Often the presentation is less classic; headache, fatigue, abdominal pain, dizziness, and scanty or irregular menses are common presenting complaints.

In the pediatric office, some teens are reluctant to divulge concerns of pregnancy. Denial of sexual activity and menstrual irregularity should not preclude the diagnosis in face of other clinical or historical information. An unanticipated request for a complete checkup or a visit for contraception may uncover a suspected pregnancy. Pregnancy is still the most common diagnosis when adolescents present with secondary amenorrhea.

Diagnosis

Table 144.1 provides classic symptoms, laboratory tests, and physical changes in the diagnosis of pregnancy.

Table 144.1

Diagnosis of Pregnancy Dated from First Day of Last Menstrual Cycle

Classic Symptoms

Missed menses, breast tenderness, nipple sensitivity, nausea, vomiting, fatigue, abdominal and back pain, weight gain, urinary frequency.

Teens may present with unrelated symptoms that enable them to visit the doctor and maintain confidentiality.

Laboratory Diagnosis

Tests for human chorionic gonadotropin in urine or blood may be positive 7-10 days after fertilization, depending on sensitivity.

Irregular menses make ovulation/fertilization difficult to predict.

Home pregnancy tests have a high error rate.

Physical Changes

2-3 wk after implantation: cervical softening and cyanosis.
8 wk: uterus size of orange.
12 wk: uterus size of grapefruit and palpable suprapubically.
20 wk: uterus at umbilicus.
If physical findings are not consistent with dates, ultrasound will confirm.

On physical examination, the findings of an enlarged uterus, cervical cyanosis (**Chadwick sign**), a soft uterus (**Hegar sign**), or a soft cervix (**Goodell sign**) are highly suggestive of an intrauterine pregnancy. A confirmatory pregnancy test is always recommended, either *qualitative* or *quantitative* . Modern **qualitative** urinary detection methods are efficient at detecting pregnancy, whether performed at home or in the office. These tests are based on detection of the beta subunit of human chorionic gonadotropin (**hCG**). Although claims for nonprescription home pregnancy tests may indicate 98% detection on the day of the 1st missed menstrual period, sensitivity and accuracy vary considerably. Office or point-of-care tests have increased standardization and generally have increased sensitivity, with the possibility of detecting a pregnancy within 3-4 days after implantation. However, in any menstrual cycle, ovulation may be delayed, and in any pregnancy, the day of implantation may vary considerably, as may rate of production of hCG. This variability, along with variation of urinary concentration, may affect test sensitivity. *Consequently, each negative test should be repeated in 1-4 wk if there is a heightened suspicion of pregnancy.* The most sensitive pregnancy detection test is a serum **quantitative** βhCG radioimmunoassay, with reliable results within 7 days after fertilization. This more expensive test is used primarily during evaluations for ectopic pregnancy, to detect retained placenta after pregnancy termination, or in the management of a molar pregnancy. It is used when serial measurements are necessary in clinical management.

Although not used for primary diagnosis of pregnancy, pelvic or vaginal **ultrasound** can be helpful in detecting and dating a pregnancy. Pelvic ultrasound will detect a gestational sac at about 5-6 wk (dated from last menstrual period) and vaginal ultrasound at 4.5-5 wk. This tool may also be used to distinguish diagnostically between intrauterine and ectopic pregnancies.

Pregnancy Counseling and Initial Management

Once the diagnosis of pregnancy is made, it is important to begin addressing the psychosocial, as well as the medical, aspects of the pregnancy. The patient's response to the pregnancy should be assessed and her emotional issues addressed. It should not be assumed that the pregnancy was unintended. Discussion of the patient's options should be initiated. These options include (a) releasing the child to an adoptive family, (b) electively terminating the pregnancy, and (c) raising the child herself with the help of family, father of the baby, friends, and/or other social resources. Options should be presented in a supportive, informative, nonjudgmental fashion; for some young women, they may need to be discussed over several visits. Physicians who are uncomfortable in presenting options to their young patients should refer their patients to a provider who can provide this service expeditiously. Pregnancy terminations implemented early in the pregnancy are generally less risky and less expensive than those initiated later.

Other issues that may need discussion are how to inform and involve the patient's parents and the father of the infant; implementing strategies for insuring continuation of the young mother's education; discontinuation of tobacco, alcohol, and illicit drug use; discontinuance and avoidance of any medications that may be considered teratogenic; starting folic acid, calcium, and iron supplements; proper nutrition; and testing for STIs. Especially in younger adolescents, the possibility of **coercive sex** (see Chapter 145) must be considered and appropriate social work/legal referrals made if abuse has occurred, although most pregnancies are not a result of coercive sex. Patients who elect to continue their pregnancy should be referred as soon as possible to an adolescent-friendly obstetric provider.

Risk factors for teen pregnancy include growing up in poverty, having parents with low levels of education, growing up in a single-parent family, fewer opportunities in their community for positive youth involvement, neighborhood physical disorder, foster care (are more than twice as likely to become pregnant than those not in foster care), and having poor performance in school (see later, Psychosocial Outcomes/Risks for Mother and Child).

The Importance of Prevention

Teen pregnancy and childbearing bring substantial social and economic costs through immediate and long-term impacts on teen parents and their children. In 2010, teen pregnancy and childbirth accounted for at least $9.4 billion in costs to U.S. taxpayers for increased healthcare and foster care, increased incarceration rates among children of teen parents, and lost tax revenue because of lower educational attainment and income among teen mothers.

Adolescent Fathers

Those who become fathers as adolescents also have poorer educational achievement than their age-matched peers. They are more likely than other peers to have been involved with illegal activities and with the use of illegal substances. Adult men who father the children of teen mothers are poorer and educationally less advanced than their age-matched peers and tend to be 2-3 yr older than the mother; any combination of age differences may exist. Younger teen mothers are more likely to have a greater age difference between themselves and the father of their child, raising the issue of coercive sex or statutory rape (see Chapter 145).

Male partners have a significant influence on the young woman's decision/desire to become pregnant and to parent her child. Sensitively and appropriately including the male partner in discussions of family planning, contraception, and pregnancy options may be a useful strategy in improving outcomes for all. This can only be successful if the young female patient is willing to have her partner involved in such discussions.

Medical Complications of Mothers and Babies

Although pregnant teens are at higher-than-average risk for some complications of pregnancy, most teenagers have pregnancies that are without major medical complications, delivering healthy infants. The miscarriage/stillbirth risk for adolescents is estimated at 15–20%. In the United States, elective pregnancy termination rates peaked from 1985–1988 at 41–46%, decreasing since then to approximately 30% in 2008. Teen mothers have low rates of age-related chronic disease (diabetes or hypertension) that might affect the outcomes of a pregnancy. They also have lower rates of twin pregnancies than older women. They tolerate childbirth well with few operative interventions. However, compared with 20-39 yr old mothers, teens have higher incidences of low birthweight infants, preterm infants, neonatal deaths, passage of moderate to heavy fetal meconium during parturition, and infant deaths within 1 yr after birth. The highest rates of poor outcomes occur in the youngest and most economically disadvantaged mothers. *Gastroschisis,* although rare, has a much higher incidence in infants of teen mothers, for reasons that are unclear. Teen mothers also have higher rates of anemia, pregnancy-associated hypertension, and eclampsia, with the youngest teens having rates of pregnancy-associated hypertension higher than the rates of women in their 20s and 30s. The youngest teens also have a higher incidence of poor weight gain (<16 lb) during their pregnancy. This correlates with a decrease in the birthweights of their infants. Poor maternal weight gain also has correlated strongly with teens’ late entrance into prenatal care and with inadequate utilization of prenatal care. Sexually active teens have higher rates of STIs than older sexually active women.

Globally, many young women who become pregnant have been exposed to violence or abuse in some form during their lives. There is some evidence that teenage women have the highest rates of **violence** during pregnancy of any group. Violence has been associated with injuries and death as well as preterm births, low birthweight, bleeding, substance abuse, and late entrance into prenatal care. An analysis of the Pregnancy Mortality Surveillance System indicates that in the United States 1991–1999, homicide was the 2nd leading cause of injury-related deaths in pregnant and postpartum women. Women age 19 yr and younger had the highest pregnancy-related homicide rate (see Chapter 139).

Ectopic pregnancy occurs in 1–2% of conceptions and is more common in women with a previous history of an ectopic pregnancy, pelvic inflammatory disease, prior appendicitis, infertility, in utero exposure to diethylstilbestrol, and possibly an IUD. Most ectopic pregnancies are in the fallopian tube (tubal pregnancy). Manifestations include vaginal spotting after a missed menstrual period that may progress to more intense vaginal bleeding (suggestive of spontaneous abortion); vaginal bleeding is absent in 10–20%. Abdominal pain is associated with distention of the fallopian tube; tubal rupture results in more intense pain, hemorrhagic shock, and peritonitis. Some women have nonspecific abdominal complaints and are misdiagnosed with gastroenteritis. Cervical motion and adnexal tenderness (and adnexal mass) may be present. **Transvaginal sonography** (not transabdominal) is the diagnostic test of choice to detect an ectopic pregnancy and reveals an adnexal mass and no uterine pregnancy. Nonetheless, some women will have pregnancy of unknown location by transvaginal sonography; approximately 20% of these will have an ectopic pregnancy. Measurement of sensitive quantitative serum βhCG levels together with transvaginal sonography has value in diagnosing an ectopic pregnancy. If the initial βhCG is above the *discriminatory zone* (level at which one expects an intrauterine pregnancy) but on transvaginal sonography there is no intrauterine pregnancy, there may be an ectopic pregnancy or an abnormal uterine pregnancy. In addition, if the βhCG is below the discriminatory level (usually <3000 mIU/mL) with no definitive diagnosis by sonography, serial βhCG testing should be performed every 48 hr. In a normal uterine pregnancy, βhCG levels should increase approximately 50% every 48 hr; declining levels may suggest a miscarriage or an ectopic pregnancy. Some would perform a dilation and curettage and check for products of conception or follow serial βhCG levels. If there are no products of conception or if βhCG levels plateau or increase, an ectopic pregnancy is present. Treatment of unstable or advanced patients is usually by laparoscopic surgery or by laparotomy. Because of early detection, many patients remain stable *(unruptured)*. Stable patients with an unruptured ectopic pregnancy may be treated with single-dose, or more often multidose, methotrexate to induce abortion. Contraindications to methotrexate in a stable patient include size of the ectopic mass (>3.5 cm) and embryonic cardiac motion.

Prematurity and low birthweight increase the perinatal morbidity and mortality for infants of teen mothers. These infants also have higher-than-average rates of sudden infant death syndrome (see Chapter 402), possibly because of less use of the supine sleep position or cosleeping, and are at higher risk of both intentional and unintentional injury (see Chapter 16). One study showed that risk of homicide is 9-10 times higher if a child born to a teen mother is not the mother's firstborn compared with the risk to a firstborn of a woman age 25 yr or older. The perpetrator is often the father, stepfather, or boyfriend of the mother.

After childbirth, **depressive symptoms** may occur in as many as 50% of teen mothers. Depression seems to be greater with additional social stressors and with decreased social supports. Support from the infant's father and the teen's mother seems to be especially important in preventing depression. Pediatricians who care for parenting teens should be sensitive to the possibility of depression, as well as to inflicted injury to mother or child; appropriate diagnosis, treatment, and referral to mental health or social agencies should be offered and facilitated.

Psychosocial Outcomes/Risks for Mother and Child

Educational Issues

Pregnancy and birth are significant contributors to high school dropout rates among girls. Only about 50% of teen mothers receive a high school diploma by age 22, whereas approximately 90% of women who do not give birth during adolescence graduate from high school. Mothers who have given birth as teens generally remain 2 yr behind their age-matched peers in formal educational attainment at least through their 3rd decade. Maternal lack of education limits the income of many of these young families (see Chapter 1).

The children of teenage mothers are more likely to have lower school achievement and to drop out of high school, have more health problems, and face unemployment as a young adult.

Substance Use

See also Chapter 140 .

Teenagers who abuse drugs, alcohol, and tobacco have higher pregnancy rates than their peers. Most substance-abusing mothers appear to decrease or stop their substance use while pregnant. Use begins to increase again about 6 mo postpartum, complicating the parenting process and the mother's return to school.

Repeat Pregnancy

In the United States, approximately 20% of all births to adolescent mothers (age 15-19) are second order or higher. Prenatal care is begun even later with a 2nd pregnancy, and the 2nd infant is at higher risk of poor outcome than the 1st birth. Mothers at risk of early repeat pregnancy (<2 yr) include those who do not initiate long-acting contraceptives after the index birth, those who do not return to school within 6 mo of the index birth, those with mood disorders, those receiving major childcare assistance from the adolescent's mother, those who are married or living with the infant's father, those having peers who were adolescent parents, and those who are no longer involved with the baby's father and who meet a new boyfriend who wants to have a child. To reduce repeat pregnancy rates in these teens, programs must be tailored for this population, preferably offering comprehensive healthcare for both the young mother and her child (Table 144.2). Healthcare providers should remember to provide positive reinforcement for teen parenting successes (i.e., compliment teen parents when they are doing a good job).

Table 144.2

2012 American Academy of Pediatrics Clinical Guidelines: Care of Adolescent Parents and Their Children

GUIDELINE	**INTERVENTIONS**
Create a medical home for adolescent parents and their children.	Involve both adolescent mothers and coparenting father. Emphasize anticipatory guidance, parenting, and basic childcare skills, especially for teen dads.
Provide comprehensive, multidisciplinary care.	Access community resources such as special Supplemental Nutrition Program for Women, Infants, and Children. Provide medical and developmental services to low-income parents and children. Facilitate coordination of services.
Contraceptive counseling.	Emphasize condom use. Encourage long-acting contraceptive methods.
Encourage breastfeeding.	Support breastfeeding in home, work, and school settings.
Encourage high school completion.	
Assess risk of domestic violence.	
Encourage adolescent parenting.	Work with other involved adults such as grandparents to encourage developmental growth of adolescent as parent as well as optimize infant developmental outcomes.
Adapt counseling to developmental level of adolescent.	Utilize school-, home-, and office-based interventions. Consider use of support groups.
Awareness and monitoring of developmental progression of infant and adolescent parent.	Advocate for high-quality community resources for adolescents, including developmental resources, childcare, and parenting classes. Facilitate access to Head Start and education resources for individuals with disability.

Data from Pinzon JL, Jones VF; Committee on Adolescence and Committee on Early Childhood: Care of adolescent parents and their children, *Pediatrics* 130(6):e1743–e1755, 2012.

Children Born to Teen Mothers

Many children born to teen mothers have behavioral problems that may be seen as early as the preschool period. Many drop out of school early (33%), become adolescent parents (25%), or, if male, are incarcerated (16%). Explanations for these poor outcomes include poverty, parental learning difficulties, negative parenting styles of teen parents, maternal depression, parental immaturity, poor parental modeling, social stress, exposure to surrounding violence, and conflicts with grandparents, especially grandmothers. Continued positive paternal involvement throughout the child's life may be somewhat protective against negative outcomes. Many of these poor outcomes appear to be attributable to the socioeconomic/demographic situation in which the teen pregnancy has occurred, not solely to maternal age. Even when socioeconomic status and demographics are controlled, infants of teen mothers have lower achievement scores, lower high school graduation rates, increased risk of teen births themselves, and, at least in Illinois (where records include age of birth mother), a higher probability of abuse and neglect.

Comprehensive programs focused on supporting adolescent mothers and infants utilizing life skills training, medical care, and psychosocial support demonstrate higher employment rates, higher income, and less welfare dependency in participating adolescents.

Prevention of Teen Pregnancies

Adolescent pregnancy is a multifaceted problem that requires multifactorial solutions. The provision of contraception and education about fertility risk from the primary care physician is important, but insufficient to address the problem fully. Family and community involvement are essential elements for teen pregnancy prevention. Strategies for primary prevention (preventing 1st birth) are different from the strategies needed for secondary prevention (preventing 2nd or more births). Over the last 30 yr, many models of teen pregnancy prevention programs have been implemented and evaluated. Table 144.3 lists the common components of many successful evidence-based programs.

Table 144.3

Common Components of Most Successful Evidence-Based Programs to Prevent Teen Pregnancy

- Information is provided about the benefits of abstinence.
- Information is provided about contraception for those who are already sexually active.
- Information is provided about the signs and symptoms of STIs and how to prevent STIs.
- Interactive sessions on peer pressure are presented.
- Teenagers are taught communication skills.
- Programs are tailored to meet the needs of specific groups of young people (e.g., young men or young women, cultural groups, younger or older teens).

Adapted from Suellentrop K: *What works 2011–2012: curriculum-based programs that help prevent teen pregnancy*, Washington, DC, National Campaign to Prevent Teen and Unplanned Pregnancy. http://www.c-hubonline.org/sites/default/files/resources/main/What_Works_0.pdf .

Abstinence-only sexual education aims to teach adolescents to wait until marriage to initiate sexual activity but, unfortunately, does not mention contraception. Abstinence education is sometimes coupled with “virginity pledges” in which teenagers pledge to remain abstinent until they marry. Other educational programs emphasize HIV and STI prevention and in the process prevent pregnancy, whereas others include both abstinence and contraception in their curricula. Sex education and teaching about contraception do not lead to an increase in sexual activity. Teenagers who participate in programs with **comprehensive** sex education components generally have lower rates of pregnancy than those exposed solely to abstinence-only programs or no sex education at all.

In many U.S. communities, programs that engage youth in community service and that combine sex education and youth development are also successful in deterring pregnancy. Programs vary in their sites of service from schools to social agencies, health clinics, youth organizations, and churches. Programs must be tailored to the cultural background, ethnicity, age-group, and gender of the group being targeted for the prevention services.

Secondary prevention programs are fewer in number. In the United States, some communities have tried to “pay” young mothers not to become pregnant again, but these efforts have not always been fruitful. **Home visiting** by nurses has been successful in some areas, and many communities have developed “Teen Tot” Clinics that provide a “one-stop shopping model” for healthcare for both the teen mother and the baby in the same site at the same time. Both programs have reported some successes.

In the practice setting, the identification of the sexually active adolescent through a confidential clinical interview is a first step in pregnancy prevention. The primary care physician should provide the teenager with factual information in a nonjudgmental manner and then guide the teenager in the decision-making process of choosing a contraceptive (see Chapter 143). The practice setting is an ideal setting to support the teenager who chooses to remain abstinent. When a teenager does become pregnant and requires prenatal care services, healthcare providers should remember that the pregnant teenager is an adolescent who has become pregnant, not a pregnant woman who happens to be an adolescent.

CHAPTER 145

Adolescent Sexual Assault

Allison M. Jackson, Norrell Atkinson

Sexual assault is an act of violence that may or may not involve rape. Rape, also an act of violence, is not an act of sex. Rape is historically defined as coercive sexual intercourse involving physical force or psychological manipulation of a female or a male. Recognizing that sexual intercourse is not a requirement for the definition, the U.S. Department of Justice (DOJ) defines rape as “the penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim.”

Epidemiology

Exact figures on the incidence of rape are unavailable because many rapes are not reported. It is estimated that 1 in 5 women and 1 in 71 men will be raped in their lifetime. Females exceed males as reported rape victims, but male rape may be more underreported than female rape. In 2010 the DOJ National Crime Victimization Survey reported that the annual rates of **sexual victimization** per 1,000 persons were 4.1 for ages 12-17 yr and 3.7 for 18-34 yr. Between 1995 and 2013 the rate of rape and sexual assault was highest for adolescent females between ages 18 and 24 yr. The National Survey of Children's Exposure to Violence (NatSCEV 2014), revealed that 12.9% of 14-17 yr olds experienced any sexual victimization in the past year, 21.7% had experienced any sexual victimization in their lifetime; and 4.2% experienced **sexual assault** in the past year and 10.2% in their lifetime. This survey also demonstrated how other experiences with violence compound the risk for sexual victimization. Youth with a history of maltreatment by a caregiver were 4 times more likely to experience sexual victimization and >4 times more likely to experience sexual victimization if they had any witness to violence. Among older adolescents age 18-24 yr, the rate of rape and sexual assault was 1.2 times higher for those not enrolled in college than those in college. Further, several studies of youth in the juvenile justice system demonstrate a particularly high prevalence of prior sexual victimization of girls in the juvenile justice system.

Rape occurs worldwide and is especially prevalent in war and armed conflicts. The World Health Organization estimates that rape and domestic violence are responsible for 5–16% of healthy years of life lost by females of reproductive age.

Female adolescents and young adults have the highest rates of rape compared to any other age-group. The normal developmental growth tasks of adolescence may contribute to this vulnerability in the following ways: (1) the emergence of independence from parents and the establishment of relationships outside the family may expose adolescents to environments with which they are unfamiliar and situations that they are unprepared to handle; (2) dating and becoming comfortable with one's sexuality may result in activities that are unwanted, but the adolescent is too inexperienced to avoid the unwanted actions; and (3) young adolescents may be naïve and more trusting than they should be (see Chapter 132). Many teens are technologically competent, which gives sexual perpetrators access to unsuspecting vulnerable populations who were previously beyond their reach. Social media, chat rooms, and online dating sites represent a major risk for adolescents, resulting in correspondence with individuals unknown to them or protective family members, while simultaneously providing a false sense of security because of remote electronic communications. A determined perpetrator can obtain specific information to identify the adolescent and arrange for a meeting that is primed for sexual victimization.

Some adolescents are at higher risk of being victims of rape than others (Table 145.1).

Table 145.1

Adolescents at High Risk of Rape Victimization

Male and Female Adolescents

Drug and alcohol users
Runaways

- Those with intellectual disability or developmental delay
- Street youths
- Transgender youth
- Youths with a parental history of sexual abuse
- Sex trafficking

Primarily Females

- Survivors of prior sexual assault
- Newcomers to a town or college

Primarily Males

- Those in institutionalized settings (detention centers, prison)
- Young male homosexuals

Types of Rape

Rape and sexual assault can occur in a variety of circumstances (Tables 145.2 and 145.3). A victim can be sexually assaulted or raped by someone they know or a by stranger, though more often the assailant is someone known to the victim. Understanding those circumstances allows for a more trauma-sensitive approach and may impact the medical management and response to the patient. The circumstances and relationship of the assailant to the victim may impact if, when, and how a patient discloses. The gender of the victim may also affect disclosure; transgendered people and males are uniformly less likely to disclose rape/sexual assault than females. The gender of the assailant may be the same or different than the victim's, and there may be one or more than one perpetrator. In any scenario the sexual assault/rape can be facilitated by threats or coercion, physical force, or drugs.

Table 145.2

Types of Nonstranger Rape

Acquaintance Rape

Most common form of rape for adolescents age 16-24 yr.
Assailant may be a neighbor, classmate, or friend of the family.
Victims are more likely to delay seeking medical care, may never report the crime (males > females), and are less likely to proceed with criminal prosecution even after reporting the incident(s).

Date Rape

Assailant is in an intimate relationship with the victim.
May be associated with intimate partner violence.
Assailant may engage in more sexual activities than other men his age and often has a history of aggressive behavior toward women.

Sexual Abuse

All sexual contact or exposure between an adult and a minor, or when there is a significant age or developmental difference between the youth.
The assailant may be a relative, close family friend, or someone of authority.

Statutory Rape

Sexual activity between an adult and an adolescent under the age of legal consent, as defined by individual state law.
Based on the premise that below a certain age or beyond a specific age difference with the assailant, an individual is not legally capable of giving consent to engage in sexual intercourse.
The intent of such laws is to protect youth from being victimized, but they may inadvertently lead a teenager to withhold pertinent sexual information from a clinician for fear that her sexual partner will be reported to the law.

Male Rape

Same-sex rape of males.

More prevalent in institutional settings.

Males are less likely than females to report rape and less likely to seek professional help.

Gang Rape

See Table 145.3 .

Table 145.3

Types of Stranger Rape

Sex Trafficking and Commercial Sexual Exploitation of Children (CSEC)

The average age of recruitment into CSEC is between 12 and 13 yr.

The assailant(s) can be the pimp (acquaintance) or the john/“date” (stranger).

Victims often have a history of child maltreatment.

Fear of the pimp results in reluctance to disclose.

Drug-Facilitated Rape

Alcohol is the most common drug associated with sexual victimization.

Gang Rape

When a group of males rapes a solitary female victim.

May be part of a ritualistic activity or rite of passage for some male groups (e.g., gang, college fraternity), or may be displaced rage on the part of the assailants.

Victims may fear retaliation or confrontation with assailants.

Victims may desire or require relocation.

Acquaintance rape , the most common form of rape, is committed by a person known to the victim outside of the family. If the known assailant is a family member, caregiver, or someone in a position of authority, it would be considered **sexual abuse** . The victim–assailant relationship may cause conflicting loyalties in families, and the teen's report may be received with disbelief and/or skepticism by the family. Adolescent acquaintance rape differs from adult acquaintance rape because weapons are less often used, and victims are less likely to sustain physical injuries.

Date rape is sexual violence perpetrated by a person in an intimate relationship with the victim. These victims may be new to a specific environment (college freshman, newcomer to a town or high school) and lack strong social support. Victims may have difficulty establishing boundaries or limits with their partner and in some cases may be intoxicated when the incident takes place. The assailant may interpret passivity as assent and deny the charge of coercion or force, and he may also be intoxicated at the time of the assault.

Drug-facilitated rape may involve illicit and/or legal substances. The opportunity for acquaintance and date rape may be greater with individuals under the influence of alcohol. Even more predatory is the furtive administration of pharmaceuticals to potential victims. In these scenarios, date rape drugs such as γ-hydroxybutyric acid (GHB), flunitrazepam (Rohypnol), and ketamine hydrochloride are the leading agents used for these illegal purposes, but may also include alcohol, benzodiazepines, stimulants, barbiturates, opiates, and other drugs (see Chapter 140). Their pharmacologic properties make these drugs effective for this use because they have simple modes of administration, are easily concealed (colorless, odorless, tasteless), have rapid onset of action with resulting induction of anterograde amnesia, and have rapid elimination because of a short half-life. Detection of these drugs requires a high index of suspicion and medical evaluation within 8-12 hr, prompting specific testing because routine toxicology screening is insufficient.

Acquaintance and date rape victims often experience long-term issues of trust, self-blame, and guilt, resulting in lost confidence in judgment concerning future relationships. Survivors are nearly always ashamed of the incident and are less likely to report the rape. They are also typically reluctant to talk about the rape to family, friends, or a counselor and may never heal from the psychological scars that ensue. For those adolescents who are LGBTQ, the shame and reluctance to disclose the rape may be even greater.

The **commercial sexual exploitation of children (CSEC)** , also known as **sex trafficking** , is a more complex form of sexual victimization and is considered a form of child abuse (see Chapter 15). Sex trafficking is federally defined as the recruiting, harboring, transporting, providing, obtaining, patronizing, or soliciting of an individual through the means of force, fraud, or coercion for commercial sex. While a pimp often personally recruits victims, he may use others to recruit. These youth may experience physical and sexual assault by the pimp as well as the "johns." Many of these youth have a history of child maltreatment, increasing their vulnerability to this form of abuse. Fear of the consequences of disclosure and the survival skills acquired often yield a very guarded presentation in the healthcare setting.

Male rape generally refers to same-sex rape of males. Specific subgroups of young men are at high risk of being victims of rape (see Table 145.1). Male rape that occurs outside of institutional settings typically involves coercion of the male teen by someone considered an authority figure, either male or female. Male rape victims often experience conflicted sexual identity about whether they are homosexual. Issues of loss of control and powerlessness are particularly bothersome for male rape victims, and these young men usually have symptoms of anxiety, depression, sleep disturbance, and suicidal ideation.

Stranger rape occurs less frequently within the adolescent population and is similar to adult rape. There can be a variety of scenarios for stranger rape (see Table 145.3). Nevertheless, such rapes frequently occur with abduction, use of weapons, and increased risk of physical injuries. These rapes are more likely to be reported and prosecuted.

Clinical Manifestations

The adolescent's acute presentation following a rape may vary considerably, from histrionics to near-mute withdrawal. Even if they do not appear afraid, most victims are extremely fearful and very anxious about the incident, the rape report, examination, and the entire process, including potential repercussions. Because adolescents are between the developmental lines of childhood and adulthood, their responses to rape may have elements of both child and adult behaviors. Many teens, particularly young adolescents, may experience some level of cognitive disorganization.

Adolescents may be reluctant to report rape for a variety of reasons, including self-blame, fear, embarrassment, or in the circumstances of drug-facilitated rape, uncertainty of event details. Adolescent victims, unlike child victims who elicit sympathy and support, often face intense scrutiny regarding their credibility and inappropriately misplaced societal blame for the assault. This view is baseless and should not be used during an evaluation of any teenage victim, including acquaintance rape.

When adolescents do not report a rape, they may present at a future date with concerns for pregnancy, symptoms of or concerns for a sexually transmitted infection (STI), and symptoms of posttraumatic stress disorder (see Chapter 38), such as sleep disturbances, nightmares, mood swings, and flashbacks. Other teens may present with psychosomatic complaints or difficulties with schoolwork; all adolescents should be screened for possible sexual victimization at most health examination visits.

Interview and Physical Examination

The purpose of the adolescent medical evaluation following a sexual assault is to provide medical care for the teen and to collect and document evidence of the assault when applicable. Although many teens delay seeking medical care, others present to a medical facility within 72 hr (or up to 96 hr depending on the protocol used) of the rape, at which time forensic evidence collection should be offered to the patient. Experienced clinicians with training and knowledge of forensic evidence collection and medical-legal procedures should complete the rape evaluation or supervise the evaluation when possible.

The clinician's responsibilities are to provide support, obtain the history in a nonjudgmental manner, conduct a complete examination without retraumatizing the victim, and collect forensic evidence. The clinician must complete laboratory testing, administer prophylaxis treatment for STIs and emergency contraception, arrange for counseling services, and file a report to appropriate authorities in accordance with the law. It is not the clinician's responsibility to decide whether a rape has occurred; the legal system will make that determination.

Ideally, a clinician trained in forensic interviewing should obtain the history. In all cases, the history should be obtained by asking *only* open-ended questions to obtain information about (1) what happened; (2) where it happened; (3) when it happened; and (4) who did it. After obtaining a concise history, including details of the type of physical contact that occurred between the victim and the assailant, the clinician should conduct a thorough and complete physical examination and document all injuries. Clinicians should provide sensitive, nonjudgmental support during the entire evaluation, as the adolescent victim has experienced a major trauma and is susceptible to retraumatization during this process. Each component of the evaluation should be explained in detail to the victim, allowing the adolescent as much control as possible, including refusal to complete any part or all of the forensic evidence collection process. It is often useful to permit a trusted supportive person, such as a family member, friend or rape crisis advocate, to be present during the evaluation if that is the adolescent's wish.

The examining clinician should be familiar with the **forensic evidence collection** kit prior to initiating the examination. In the United States, each state's forensic evidence kit is different, but most include some or all of the following components: forensic evidence of semen deposits detected by a fluorescent lamp with a wavelength near 490 nm (many Woods lamps are inadequate); swabs of bite mark impressions to collect genetic markers (DNA, ABO group); swabs of any penetrated orifice or body surface where saliva may be present; and documentation of acute cutaneous injuries using body diagram charts and photographs with visible standard measurements. Areas of restraint should be carefully inspected for injuries; these areas include extremities, neck, and the inner aspect of the oral mucosa, where a dentition impression may be seen.

The genital examination of a female rape victim should be undertaken with the patient in the lithotomy position. The prone knee-chest position may be used as an exam-clarifying technique, specifically to evaluate the posterior rim of the hymen. The genital exam of a male rape victim should be undertaken with the patient in supine position. The clinician's exam should include careful inspection of the entire pelvic, genital, and perianal areas. The clinician should document any acute injuries such as edema, erythema, petechiae, bruising, hemorrhage, or tearing. Aqueous solution of toluidine blue (1%), which adheres to nucleated cells, may be used during the acute examination to improve visualization of microtrauma in the perianal area. Any disruption to the superficial epidermis will allow for dye uptake and thus cannot differentiate between disruption of the skin from trauma, irritation, or infection. Additionally, a colposcope may be used to provide magnification and photo documentation of injuries.

Laboratory Data

When adolescents present for medical care within 72-96 hr of a sexual assault, a forensic evidence collection kit should be offered to the patient. Regardless of an adolescent's decision to have evidence collection completed, medical care, including physical examination, laboratory testing (Table 145.4), and prophylactic therapies, should be offered to the patient. Follow-up evaluations should be scheduled to repeat these laboratory studies.

Table 145.4

Laboratory Evaluation of Sexual Assault

Within 8-12 hr (if Indicated by History)

Urine and blood for date rape drugs (GHB, Rohypnol, ketamine)

Within 24 hr (if Indicated by History)

Blood for comprehensive toxicology screen (for other classes of drugs)

Within 72 hr (or Up to 96 hr Depending on the Protocol Used)

Forensic evidence kit
Pregnancy test
Hepatitis B screen (hepatitis B surface antigen, surface antibody, and core antibody)
Syphilis (rapid plasma reagin [RPR], Venereal Disease Research Laboratories [VDRL])
HIV infection
Bacterial vaginosis (BV) and candidiasis: point-of-care testing and/or wet mouth with measurement of vaginal pH and KOH application for whiff test
Trichomonas vaginalis : nucleic acid amplification tests (NAATs) by urine or vaginal specimen or point-of-care testing (DNA probes) from vaginal specimen
Chlamydia and *Neisseria gonorrhoeae* : nucleic acid amplification testing (NAATs) at sites of penetration or possible penetration:

1. *N. gonorrhoeae:* oropharynx, rectum, urine*
2. *Chlamydia* : urine,* rectum

---

* Dirty urine sample may be used as alternate for genital swab.

From Centers for Disease Control and Prevention: Sexually transmitted diseases:

treatment guidelines 2015, *MMWR Recomm Rep* 64(RR-3):1–140, 2015, and Updated guidelines for antiretroviral postexposure prophylaxis after sexual, injection drug use, or other nonoccupational exposure to HIV—United States, 2016.

Treatment

Treatment includes **prophylactic antimicrobials** for STIs (see Chapter 146) and emergency contraception (see Chapter 143). The Centers for Disease Control and Prevention (CDC) reports that trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydial infection are the most frequently diagnosed infections among women who have been sexually assaulted. Antimicrobial prophylaxis is recommended for adolescent rape victims because of the risk of acquiring an STI and the risk of pelvic inflammatory disease (Table 145.5). A two- or three-drug antiretroviral regimen for HIV **postexposure prophylaxis (PEP)** must be considered and an infectious disease specialist consulted if higher transmission risk factors are identified (e.g., knowing that the perpetrator is HIV-positive, significant mucosal injury of the victim) to prescribe a triple-antiretroviral regimen (Fig. 145.1). Similar considerations should be made for possible exposure to the hepatitis B virus in vaccinated/unvaccinated individuals. Clinicians should review the importance for patient's compliance with medical and psychological treatment and follow-up care.

Table 145.5

Postexposure Prophylaxis (PEP) for Acute Sexual Assault Victims

Routine

Recommended Regimen for STI Prophylaxis

> Ceftriaxone 250 mg intramuscularly
> *plus*
> Azithromycin 1g orally in a single dose
> *plus*
> Metronidazole 2 g orally in a single dose *or*
> Tinidazole 2 g orally in a single dose

Pregnancy Prophylaxis*

Levonorgestrel (Plan B) 1.5 mg orally in a single dose
OR
Ulipristal acetate (Ella) 30 mg is effective for up to 120 hr.

Human Papillomavirus (HPV)

Assess HPV vaccine history; to unimmunized, administer initial vaccine at initial exam, with 2 follow-up doses at 1-2 mo and at 6 mo if >15 yr old *or* a single follow-up dose at 6-12 mo if ≤15 yr old

As Indicated

All persons offered PEP should be prescribed a 28-day course of a two- or three-drug antiretroviral regimen.

Human Immunodeficiency Virus (HIV) †

Preferred regimen:

Tenofovir 300 mg and fixed-dose combination emtricitabine, 200 mg (Truvada) once daily
plus
Raltegravir 400 mg twice daily *or*
Dolutegravir 50 mg daily ‡

Alternative regimens available (The National Clinicians Consultation Center is a resource for providers prescribing PEP, reachable at 1-888-448-4911.)

Hepatitis B virus (HBV)

Specific indications for vaccine, immunoglobulin and/or booster dependent upon assailant's status

---

[*] Provided for patients with negative urine pregnancy screen. In addition, antiemetic (Compazine, Zofran) can be prescribed for patients receiving emergency contraception.

[†] HIV PEP is provided for patients with penetration and when the assailant is known to be HIV-positive or at high risk because of a history of incarceration, intravenous drug use, or multiple sexual partners. If provided, laboratory studies must be drawn before administration of medication (HIV, CBC, LFTs, BUN/Cr, amylase, lipase), and follow-up must be arranged.

[‡] Dolutegravir has been associated with neural tube defects if the exposure occurs within the first trimester of pregnancy. Therefore it should be avoided in pregnant patients or those at risk for becoming pregnant. U.S. Department of Health and Human Services, U.S. Food & Drug Administration. Data from Centers for Disease Control and Prevention: Sexually transmitted diseases: treatment guidelines 2015, *MMWR Recomm Rep* 64(RR-3):1–140, 2015, and Updated guidelines for antiretroviral postexposure prophylaxis after sexual, injection drug use, or other nonoccupational exposure to HIV—United States, 2016.

Substantial exposure risk
Negligible exposure risk
≤72 hours since exposure
>72 hours since exposure
Source patient known to be HIV-positive
Source patient of unknown HIV status
nPEP recommended
Case-by-case determination
nPEP not recommended

Substantial Risk for HIV Acquisition

Exposure of
vagina, rectum, eye, mouth,
or other mucous membrane,
nonintact skin, or percutaneous contact

With
blood, semen, vaginal secretions, rectal
secretions, breast milk, or any body fluid
that is visibly contaminated with blood

When
the source is known to be HIV-positive

Negligible Risk for HIV Acquisition

Exposure of
vagina, rectum, eye, mouth,
or other mucous membrane,
intact or nonintact skin, or
percutaneous contact

With
urine, nasal secretions, saliva, sweat,
or tears if not visibly contaminated
with blood

Regardless
of the known or suspected HIV status
of the source

FIG. 145.1 Algorithm for evaluation and treatment of possible human immunodeficiency virus (HIV) infection. nPEP, Nonoccupational postexposure prophylaxis. (From Seńa AC, Hsu KK, Kellogg N, et al: Sexual assault and sexually transmitted infections in adults, adolescents, and children, *Clin Infect Dis* 61(Suppl 8):S859, 2015.)

At the time of presentation, the clinician should address the need for follow-up care, including psychological counseling. Adolescent victims are at increased risk of posttraumatic stress disorder, depression, self-abusive behaviors, suicidal ideation, delinquency, substance abuse, eating disorders, and sexual revictimization. It is important for the adolescent victim and parents to understand the value of timely counseling services to decrease these potential long-term sequelae. Counseling services should be arranged during the initial evaluation, with follow-up arranged with the primary care physician to improve compliance. Counseling services for family members of the victim may improve their ability to provide appropriate support to the adolescent victim. Caution parents not to use the assault as a validation of their parental guidance, as it will only serve to place blame inappropriately on the adolescent victim.

Prevention

Primary prevention may be accomplished through education of preadolescents and adolescents on the issues of rape, healthy relationships, internet dangers, and drug- and alcohol-facilitated rape. Prevention messages should be targeted to both males and females at high schools and colleges. Particular emphasis on prevention efforts during college orientation is highly recommended. High-risk situations that may increase the likelihood of a sexual assault (use of drugs or alcohol) should be discouraged. **Secondary prevention** includes informing adolescents of the benefits of timely medical evaluations when rape has occurred. Individual clinicians should ask adolescents about past experiences of forced and unwanted sexual behaviors and offer help in dealing with those experiences. The importance of prevention cannot be overstated because adolescents are disproportionately affected by rape, and they are particularly vulnerable to long-term consequences.

CHAPTER 146

Sexually Transmitted Infections

Gale R. Burstein

Age-specific rates of many sexually transmitted infections (**STIs**) are highest among sexually experienced adolescents and young adults, after controlling for sexual activity. Although some STI pathogens present as STI syndromes with a specific constellation of symptoms, most are asymptomatic and only detected by a laboratory test. The approach to prevention and control of these infections lies in education, screening, and early diagnosis and treatment.

Etiology

Any adolescent who has had oral, vaginal, or anal sexual intercourse is at risk for acquiring an STI. Not all adolescents are at equal risk; physical, behavioral, and social factors contribute to the adolescent's higher risk (Table 146.1). Adolescents who initiate sex at a younger age, youth residing in detention facilities, youth attending sexually transmitted disease (STD) clinics, young men having sex with men, and youth who are injection drug users are at higher risk for STIs. Risky behaviors, such as sex with multiple concurrent partners or multiple sequential partners of limited duration, failure to use barrier protection consistently and correctly, and increased biologic susceptibility to infection, also contribute to risk. Although all 50 states and the District of Columbia explicitly allow minors to consent for their own sexual health services, many adolescents encounter multiple obstacles to accessing this care. Adolescents who are victims of sexual assault may not consider themselves “sexually active,” given the context of the encounter, and need reassurance, protection, and appropriate intervention when these circumstances are uncovered (see Chapter 145).

Table 146.1

Circumstances Contributing to Adolescents' Susceptibility to Sexually Transmitted Infections

Physical

Younger age at puberty
Cervical ectopy
Smaller introitus leading to traumatic sex
Asymptomatic nature of sexually transmitted infection
Uncircumcised penis

Behavior Limited by Cognitive Stage of Development

Early adolescence: have not developed ability to think abstractly
Middle adolescence: develop belief of uniqueness and invulnerability

Social Factors

Poverty
Limited access to “adolescent-friendly” healthcare services
Adolescent health-seeking behaviors (forgoing care because of confidentiality concerns or denial of health problem)
Sexual abuse, trafficking, and violence
Homelessness
Drug use
Young adolescent females with older male partners
Young men having sex with men

From Shafii T, Burstein G: An overview of sexually transmitted infections among adolescents, *Adolesc Med Clin* 15:207, 2004.

Epidemiology

STI prevalence varies by age, gender, and race/ethnicity. In the United States, although adolescents and young adults ages 15-24 yr represent 25% of the sexually experienced population, this age-group accounts for almost 50% of all incident STIs each year. Adolescents and young adults <25 yr of age have the highest reported prevalence of **gonorrhea** (see Chapter 219) and **chlamydia** (see Chapter 253); among females and males, rates are highest in the 15-24 yr old age-groups (Fig. 146.1). In 2015, females age 20-24 yr had the highest reported chlamydia rate (3,730 per 100,000 population), followed by females 15-19 yr of age (2,994/100,000). The reported 2015 chlamydia rate for 15-19 yr old females was almost 4 times higher than for 15-19 yr old males. Chlamydia is common among all races and ethnic groups; Blacks, Native American/Alaska Native, and Hispanic females are disproportionately affected. In 2015, non-Hispanic black females 20-24 yr of age had the highest chlamydia rate of any group (6,783), followed by black females 15-19 yr of age (6,340). Data from the 2007–2012 National Health and Nutrition Examination Survey (NHANES) estimated the prevalence of chlamydia among the U.S. population was highest among African Americans (Fig. 146.2).

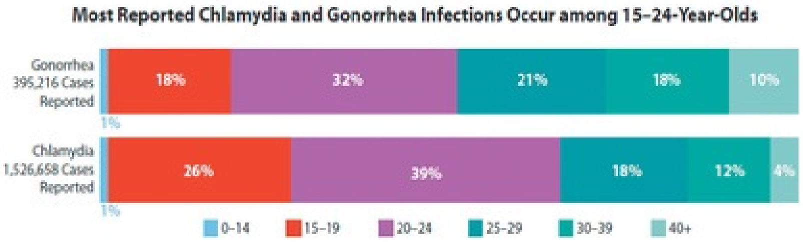

FIG. 146.1 Proportion of reported gonorrhea and chlamydia cases by age, United States, 2015. (Adapted from Centers for Disease Control and Prevention: Reported STDs in the United States. https://www.cdc.gov/nchhstp/newsroom/docs/factsheets/STD-Trends-508.pdf .)

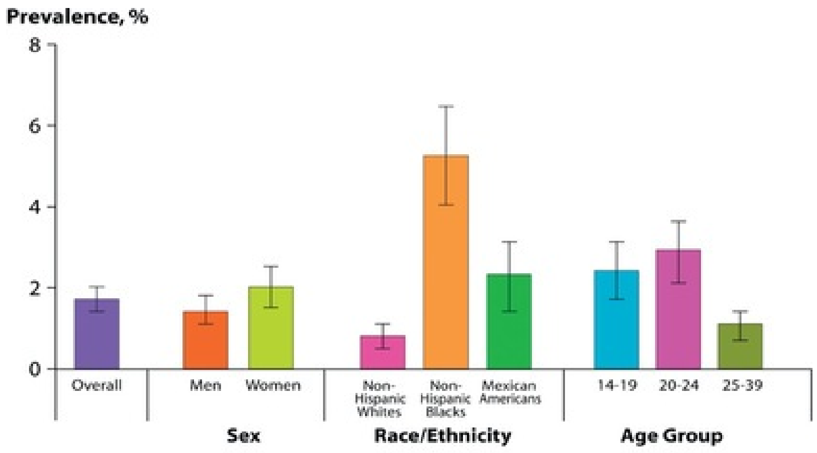

NOTE: Error bars indicate 95% confidence intervals.

FIG. 146.2 Chlamydia prevalence among persons age 14-39 yr by sex, race/ethnicity, and age-group, National Health and Nutrition Examination Survey, 2007–2012. (From Centers for Disease Control and Prevention: Sexually transmitted disease surveillance, 2015. https://www.cdc.gov/std/stats15/slides/chlamydia.pptx .)

Reported rates of other bacterial STIs are also high among adolescents and young adults. In 2015, 20-24 yr old females had the highest (547/100,000) and 20-24 yr old males had the second highest **gonorrhea rates** (539/100,000) compared to any other age/sex group (see Chapter 219). Gonorrhea rates among 15-24 yr old males and females increased between 2014 and 2015. **Syphilis rates** are increasing at an alarming rate, especially among males, accounting for >90% of all primary and secondary syphilis cases. Of those male cases, **men who have sex with men (MSM)** account for 82% of male cases when the gender of the sex partner is known. Males age 20-24 yr have the 2nd highest rate of primary and secondary syphilis among males of any age-group (36/100,000); whereas rates among males 15-19 yr old (8/100,000) are much lower. Female primary and secondary syphilis rates are much lower than male rates (5/100,000 among 20-24 yr olds; 3/100,000 among 15-19 yr olds) (see Chapter 245). **Pelvic inflammatory disease (PID)** rates are highest among females age 15-24 compared with older women.

Adolescents also carry a large burden of viral STIs. U.S. youth are at persistent risk for **HIV infection** (see Chapter 302). In 2015, youth age 13-24 yr accounted for 22% (8,807) of all new HIV diagnoses in the United States, with most (81%) occurring among gay and bisexual males. Of those new infections, 55% (4,881) were among blacks, 22% (1,957) among Hispanic/Latinos, and 17% (1,506) among whites. Only 10% of high school students have been tested for HIV. Among male students who had sexual contact with other males, only 21% have ever been tested for HIV.

Human papillomavirus (HPV) is the most frequently acquired STI in the United States. According to NHANES, prevalence of HPV vaccine types 6, 11, 16, and 18 (**4vHPV**) declined between the prevacccine (2003–2006) and vaccine (2009–2012) eras: from 11.5% to 4.3% among females age 14-19 yr and from 18.5% to 12.1% among females age 20-24 (see Chapter 293).

Herpes simplex virus type 2 **(HSV-2)** is the most prevalent viral STI (see Chapter 279). NHANES data show that among 14-19 yr olds, HSV-2 seroprevalence has remained low (<2%, in 1999–2010 surveys). In addition, according to NHANES, HSV-1 seroprevalence among 14-19 yr olds has significantly decreased, from 39% in 1999–2004 to 30% in 2005–2010, indicating less orolabial infection in this age-group. Studies have also found that genital HSV-1 infections are increasing among young adults. Youth who lack HSV-1 antibodies at sexual debut are more susceptible to acquiring a genital HSV-1 infection and developing symptomatic disease from primary genital HSV-2 infection. Increasing oral sex among adolescents and young adults also has been suggested as a contributing factor in the rise in genital HSV-1 infections.

Pathogenesis

During puberty, increasing levels of estrogen cause the vaginal epithelium to thicken and cornify and the cellular glycogen content to rise, the latter causing the vaginal pH to fall. These changes increase the resistance of the vaginal epithelium to penetration by certain organisms (including *Neisseria gonorrhoeae*) and increase the susceptibility to others (*Candida albicans* and *Trichomonas* ; see Chapter 310). The transformation of the vaginal cells leaves columnar cells on the ectocervix, forming a border of the 2 cell types on the ectocervix, known as the squamocolumnar junction. The appearance is referred to as **ectopy** (Fig. 146.3). With maturation, this tissue involutes. Prior to involution, it represents a unique vulnerability to infection for adolescent females. The association of early sexual debut and younger gynecologic age with increased risk of STIs supports this explanation of the pathogenesis of infection in young adolescents.

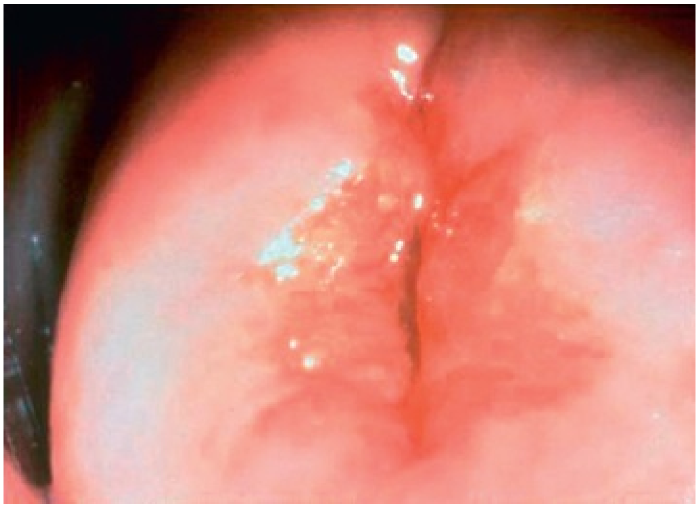

FIG. 146.3 Cervical ectopy. (From Seattle STD/HIV Prevention Training Center, University of Washington, Claire E. Stevens.)

Screening

Early detection and treatment are primary **STI control** strategies. Some of the most common STIs in adolescents, including HPV, HSV, chlamydia, and gonorrhea, are usually asymptomatic and if undetected can be spread inadvertently by the infected host. **Screening** initiatives for chlamydial infections have demonstrated reductions in PID cases by up to 40%. Although federal and professional medical organizations recommend annual chlamydia screening for sexually active females <25 yr old, according to the National Center for Quality Assurance, in 2015 among sexually active 16-20 yr old females, approximately 42% of commercial health maintenance organization (HMO) members and 52% Medicaid HMO members were tested for chlamydia during the previous year. The lack of a dialog about STIs or the provision of STI services at annual preventive service visits to sexually experienced adolescents are missed opportunities for screening and education. Comprehensive, confidential, reproductive health services, including STI screening, should be offered to all sexually experienced adolescents (Table 146.2).

Table 146.2

Routine Laboratory Screening Recommendations for Sexually Transmitted Infections in Sexually Active Adolescents and

Young Adults

Chlamydia Trachomatis and *Neisseria Gonorrhoeae*

- Routine screening for *C. trachomatis* and *N. gonorrhoeae* of all sexually active females aged <25 yr is recommended annually.
- Routinely screen sexually active adolescent and young adult MSM at sites of contact for chlamydia (urethra, rectum) and gonorrhea (urethra, rectum, pharynx) at least annually regardless of condom use. More frequent screening (i.e., at 3-6 mo intervals) is indicated for MSM who have multiple or anonymous partners or who have sex with illicit drug use.
- Consider screening for *C. trachomatis* of sexually active adolescent and young adult males annually who have a history of multiple partners in clinical settings with high prevalence rates, such as jails or juvenile corrections facilities, national job training programs, STD clinics, high school clinics, or adolescent clinics.

Human Immunodeficiency Virus (HIV)

- HIV screening should be discussed and offered to all adolescents at least once by age 16-18 yr and throughout young adulthood in healthcare settings. HIV risk should be assessed annually for >13 yr and offered if HIV risk factors identified.
- Routinely screen sexually active adolescent and young adult MSM at least annually regardless of condom use. More frequent screening (i.e., at 3-6 mo intervals) is indicated for MSM who have multiple or anonymous partners or who have sex with illicit drug use.

Syphilis

- Syphilis screening should be offered to sexually active adolescents reporting risk factors, including MSM.
- Routinely screen sexually active adolescent and young adult MSM at least annually regardless of condom use. More frequent screening (i.e., at 3-6 mo intervals) is indicated for MSM who have multiple or anonymous partners

or who have sex with illicit drug use.

- Providers should consult with their local health department regarding local syphilis prevalence and associated risk factors that are associated with syphilis acquisition.

Hepatitis C Virus (HCV)

- Screening adolescents for HCV who report risk factors, i.e., injection drug use, receipt of an unregulated tattoo, received blood products or organ donation before 1992, received clotting factor concentrates before 1987, long-term hemodialysis.
- Given the high HCV prevalence among young injection drug users, screening should be strongly considered.

MSM, Men who have sex with men; STD, sexually transmitted disease.

From Centers for Disease Control and Prevention. https://www.cdc.gov/std/tg2015/screening-recommendations.htm .

Common Infections and Clinical Manifestations

STI syndromes are generally characterized by the location of the manifestation (vaginitis) or the type of lesion (genital ulcer). Certain constellations of presenting symptoms suggest the inclusion of a possible STI in the differential diagnosis.

Urethritis

Urethritis is an STI syndrome characterized by inflammation of the urethra, usually caused by an infectious etiology. Urethritis may present with urethral discharge, dysuria, urethral irritation, or meatal pruritus. Urgency, frequency of urination, erythema of the urethral meatus, and urethral pain or burning are less common clinical presentations. Approximately 30–50% of males are asymptomatic but may have signs of discharge on diagnosis. On examination, the classic finding is mucoid or purulent discharge from the urethral meatus (Fig. 146.4). If no discharge is evident on exam, providers may attempt to express discharge by applying gentle pressure to the urethra from the base distally to the meatus 3-4 times. *Chlamydia trachomatis* and *N. gonorrhoeae* are the most commonly identified pathogens. *Mycoplasma genitalium* has been associated with urethritis, but data supporting *Ureaplasma urealyticum* have been inconsistent. *Trichomonas vaginalis* can cause nongonococcal urethritis (NGU), but the prevalence varies. HSV-1, HSV-2, and Epstein-Barr virus (EBV) are also potential urethritis pathogens in some cases. Sensitive diagnostic *C. trachomatis* and *N. gonorrhoeae* tests are available for the evaluation of urethritis. However, other pathogens can be considered when NGU is not responsive to treatment, although commercial diagnostic tests are not available for males. Noninfectious causes of urethritis include urethral trauma or foreign body. Unlike in females, urinary tract infections (UTIs) are rare in males who have no genitourinary medical history. In the typical sexually active adolescent male, dysuria and urethral discharge suggest the presence of an STI unless proven otherwise.

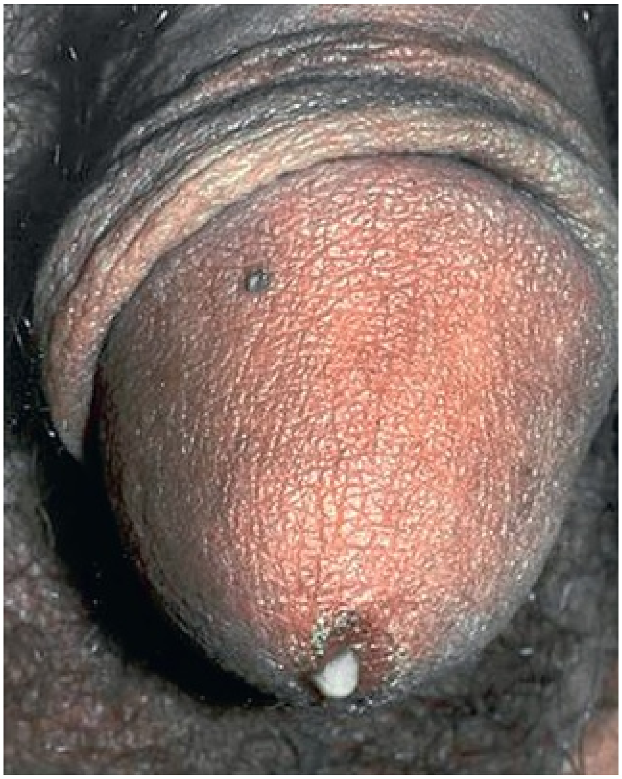

FIG. 146.4 **Gonococcal urethral discharge. (From Seattle STD/HIV Prevention Training Center, University of Washington, Connie Celum and Walter Stamm.)**

Epididymitis

The inflammation of the epididymis in adolescent males is most often associated with an STI, most frequently *C. trachomatis* or *N. gonorrhoeae* . The presentation of unilateral scrotal swelling and tenderness, often accompanied by a hydrocele and palpable swelling of the epididymis, associated with the history of urethral discharge, constitute the presumptive diagnosis of epididymitis. Males who practice insertive anal intercourse are also vulnerable to *Escherichia coli* infection. **Testicular torsion** , a surgical emergency usually presenting with sudden onset of severe testicular pain, should be considered in the differential diagnosis (see Chapter 560). The evaluation for epididymitis should include obtaining evidence of urethral inflammation by physical exam, Gram stain of urethral secretions, urine leukocyte esterase test, or urine microscopy. A *C. trachomatis* and *N. gonorrhoeae* **nucleic acid amplification test (NAAT)** should be performed.

Vaginitis

Vaginitis is a superficial infection of the vaginal mucosa frequently presenting as a vaginal discharge, with or without vulvar involvement (see Chapter 564). **Bacterial vaginosis** , **vulvovaginal candidiasis** , and **trichomoniasis** are the predominant infections associated with vaginal discharge. Bacterial vaginosis is replacement of the normal hydrogen peroxide (H_2O_2)–producing *Lactobacillus* species vaginal flora by an overgrowth of anaerobic microorganisms, as well as *Gardnerella vaginalis, Ureaplasma* , and *Mycoplasma* . Although bacterial vaginosis is not categorized as an STI, sexual activity is associated with increased frequency of vaginosis. Vulvovaginal candidiasis, usually caused by *C. albicans* , can trigger vulvar pruritus, pain, swelling, and redness and dysuria. Findings on vaginal examination include vulvar edema, fissures, excoriations, or thick curdy vaginal discharge. Trichomoniasis is caused by the protozoan *T. vaginalis* . Infected females may present with symptoms characterized by a diffuse, malodorous, yellow-green vaginal discharge with vulvar irritation or may be diagnosed by screening an asymptomatic patient. Cervicitis can sometimes cause a vaginal discharge. Laboratory confirmation is recommended because clinical presentations may vary and patients may be infected with >1 pathogen.

Cervicitis

The inflammatory process in cervicitis involves the deeper structures in the mucous membrane of the cervix uteri. Vaginal discharge can be a manifestation, but cervicitis frequently is asymptomatic, Patients also present with complaints of irregular or postcoital bleeding. Two major diagnostic signs characterize cervicitis: (1) a purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen (e.g., swab sign; Fig. 146.5), called **mucopurulent cervicitis** or cervicitis, and (2) sustained endocervical bleeding easily induced by gentle passage of a cotton swab through the cervical os, signifying friability. Cervical changes associated with cervicitis must be distinguished from cervical ectopy in the younger adolescent to avoid the overdiagnosis of inflammation (Fig. 146.6 ; see Fig. 146.3). The pathogens identified most frequently with cervicitis are *C. trachomatis* and *N. gonorrhoeae*, although no pathogen is identified in most cases. HSV is a less common pathogen associated with ulcerative and necrotic lesions on the cervix.

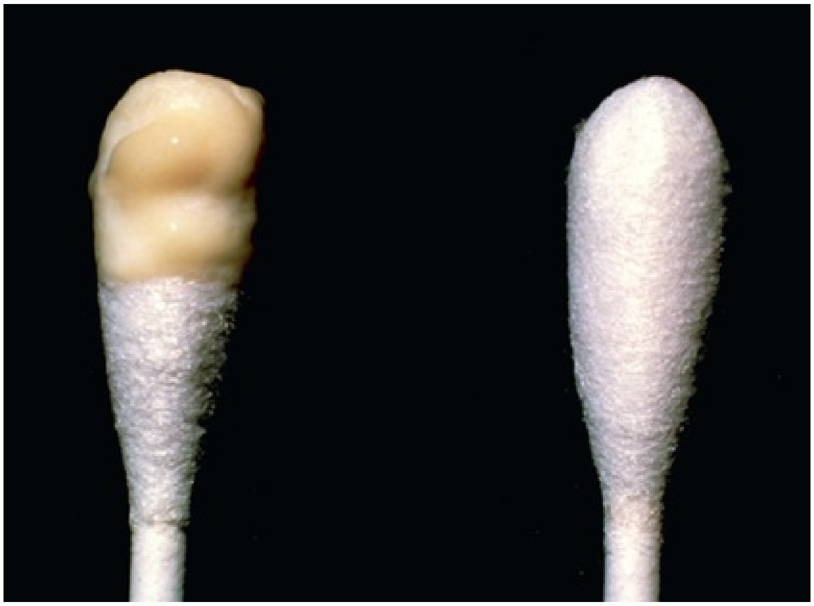

FIG. 146.5 **Mucopurulent cervical discharge positive swab test. (From Seattle STD/HIV Prevention Training Center, University of Washington, Claire E. Stevens and Ronald E. Roddy. http://www2a.cdc.gov/stdtraining/ready-to-use/pid.htm .)**

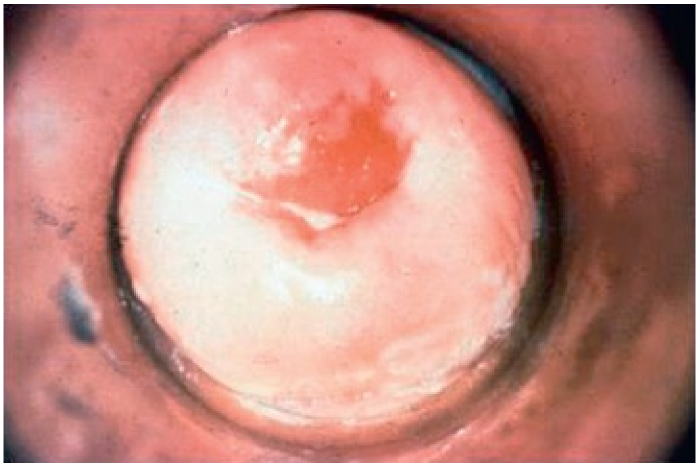

FIG. 146.6 Inflamed cervix caused by gonococcal cervicitis. (From Centers for Disease Control and Prevention: STD clinical slides. http://www.cdc.gov/std/training/clinicalslides/slides-dl.htm .)

Pelvic Inflammatory Disease

PID encompasses a spectrum of inflammatory disorders of the female upper genital tract, including **endometritis** , **salpingitis** , **tuboovarian abscess** , and **pelvic peritonitis** , usually in combination rather than as separate entities. *N. gonorrhoeae* and *C. trachomatis* predominate as the involved pathogenic organisms in younger adolescents (see Chapters 219 and 253), although PID should be approached as multiorganism etiology, including pathogens such as anaerobes, *G. vaginalis* , *Haemophilus influenzae* , enteric gram-negative rods, and *Streptococcus agalactiae.* In addition, cytomegalovirus, *Mycoplasma hominis* , *Ureaplasma urealyticum* , and *M. genitalium* may be associated with PID. PID (tuboovarian abscess) has rarely been reported in virgins and is usually caused by *E. coli* and associated in some patients with obesity and possible pooling of urine in the vagina.

PID is difficult to diagnose because of the wide variation in the symptoms and signs. Many females with PID have subtle or mild symptoms, resulting in many unrecognized cases. Healthcare providers should consider the possibility of PID in young, sexually active females presenting with vaginal discharge or abdominal pain.

The clinical diagnosis of PID is based on the presence of at least 1 of the minimal criteria, either cervical motion tenderness, uterine tenderness, or adnexal tenderness, to increase the diagnostic sensitivity and reduce the likelihood of missed or delayed diagnosis. Providers should also consider that adolescents are the population in whom PID is typically diagnosed and thus should have a low threshold for initiating empirical treatment. In addition, the majority of females with PID have either mucopurulent cervical discharge or evidence of white blood cells (WBCs) on a microscopic evaluation of a vaginal fluid–saline preparation. If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be investigated. Specific, but not always practical, criteria for PID include evidence of endometritis on biopsy, transvaginal sonography or MRI evidence of thickened, fluid-filled tubes, or Doppler evidence of tubal hyperemia or laparoscopic evidence of PID.

Genital Ulcer Syndromes

An **ulcerative lesion** in a mucosal area exposed to sexual contact is the unifying characteristic of infections associated with these syndromes. These lesions are most frequently seen on the penis and vulva but also occur on oral and rectal mucosa, depending on the adolescent's sexual practices. HSV and *Treponema pallidum* (syphilis) are the most common organisms associated with genital ulcer syndromes.

Genital herpes , the most common ulcerative STI among adolescents, is a chronic, lifelong viral infection. Two sexually transmitted HSV types have been identified, HSV-1 and HSV-2. The majority of cases of recurrent genital herpes are caused by HSV-2. However, among young women and MSM, an increasing proportion of anogenital herpes has been HSV-1. Most HSV-2–infected persons are unaware of their diagnosis because they experience mild or unrecognized infections but continue to shed virus intermittently in the genital tract. Therefore, most genital herpes infections are transmitted by asymptomatic persons who are unaware of their infection.

Although the initial herpetic lesion is a vesicle, by the time the patient presents clinically, the vesicle most often has ruptured spontaneously, leaving a shallow, painful ulcer (Fig. 146.7*A*), although recurrences are generally less intense and painful (Fig. 146.7*B*). Up to 50% of first genital herpes episodes are caused by HSV-1, but recurrences and subclinical shedding are much more frequent for genital HSV-2 infection.

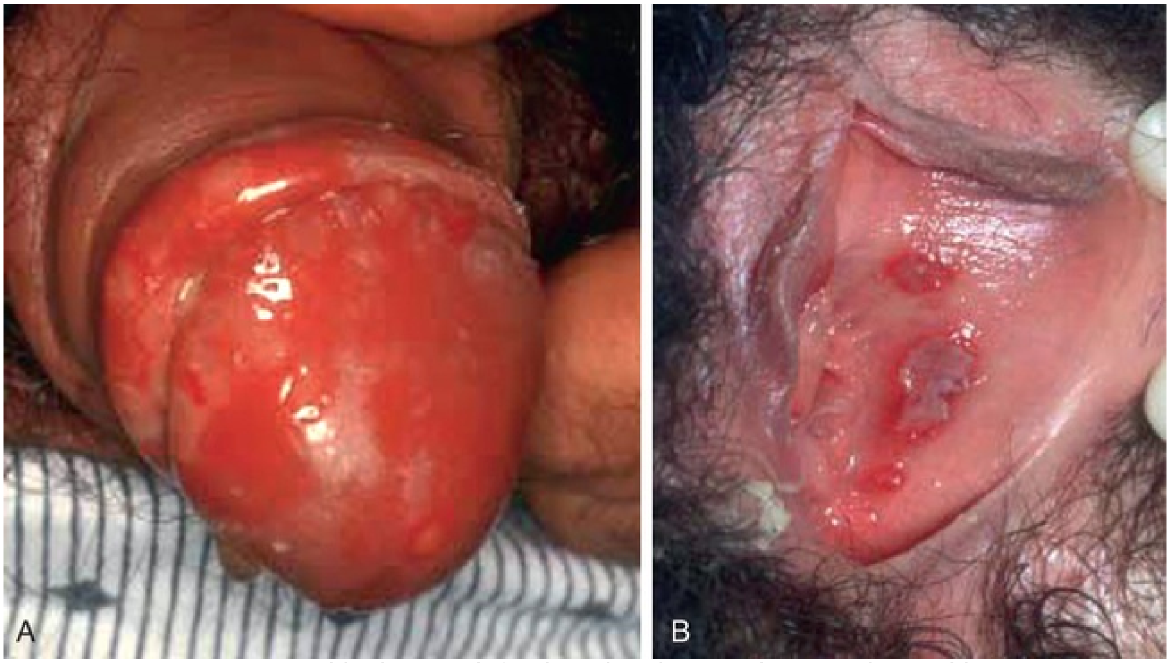

FIG. 146.7 **A,** Initial herpes infection showing multiple erosions with polycyclic outlines surrounded by an erythematous halo and associated with intense pain. **B,** Erosions surrounded by an erythematous halo. Clinical signs and symptoms of recurrences are usually less intense than those of initial infection. (From Martín JM, Villalón G, Jordá E: Update on treatment of genital herpes, *Actas Dermosifiliogr* 100:22–32, 2009, Figs 1 and 2.)

Syphilis is a less common cause of genital ulcers in adolescents than in adults. **Lymphogranuloma venereum** caused by *C. trachomatis* serovars L1-L3 is uncommon, although outbreaks do occur in MSM. In these circumstances, proctitis or proctocolitis is the usual manifestation. HIV is often present in affected men. Unusual infectious causes of genital, anal, or perianal ulcers in the United States and other industrialized countries include chancroid and donovanosis.

Table 146.3 presents the clinical characteristics differentiating the lesions of the most common infections associated with genital ulcers, along with the required laboratory diagnosis to identify the causative agent accurately. The differential diagnosis includes Behçet disease (see Chapter 186), Crohn disease (Chapter 362), aphthous ulceration, and **acute genital ulcers** caused by cytomegalovirus (Chapter 282) or Epstein-Barr virus (Chapter 281). Acute genital ulcers often follow a flu or mononucleosis-like illness in an immunocompetent female and is unrelated to sexual activity. The lesions are 0.5-2.5 cm in size, bilateral, symmetric, multiple, painful, and necrotic, and are associated with inguinal lymphadenopathy. This primary infection is also associated with fever and malaise. The diagnosis may require Epstein-Barr virus titers, or polymerase chain reaction (PCR) testing. Treatment is supportive care including pain management.

Table 146.3

Signs, Symptoms, and Presumptive and Definitive Diagnoses of Genital Ulcers

SIGNS/SYMPTOMS	HERPES SIMPLEX VIRUS	SYPHILIS (PRIMARY)	CHANCROID
Ulcers	Vesicles rupture to form shallow ulcers	Ulcer with well-demarcated indurated borders and a clean base (chancre)	Unindurated and undermined borders and a purulent base
Painful	Painful	Painless*	Painful
Number of lesions	Usually multiple	Usually single	Multiple
Inguinal lymphadenopathy	First-time infections may cause constitutional symptoms and lymphadenopathy.	Usually mild and minimally tender	Unilateral or bilateral painful adenopathy in >50% Inguinal bubo formation and rupture may occur.
Clinical suspicion	Typical lesions; positive HSV-2 type-specific serology test	Early syphilis: typical chancre plus reactive nontreponemal test (RPR, VDRL) and no history of syphilis, or 4-fold increase in quantitative nontreponemal test in person with history of syphilis; positive treponemal EIA with reactive nontreponemal test (RPR, VDRL) and no prior history of syphilis treatment	Exclusion of other causes of ulcers in the presence of (a) typical ulcers and lymphadenopathy, (b) typical Gram stain, and (c) history of contact with high-risk individual (prostitute) or living in an endemic area
Definitive diagnosis	Detection of HSV by culture or PCR from ulcer scraping or aspiration of vesicle fluid	Identification of *Treponema pallidum* from a chancre or lymph node aspirate on dark-field microscopy	Detection of *Haemophilus ducreyi* by culture

* Primary syphilitic ulcers may be painful if they become co-infected with bacteria or 1 of the other organisms responsible for genital ulcers.

DFA, Direct fluorescent antibody; EIA, enzyme immunoassay; HSV, herpes simplex virus; PCR, polymerase chain reaction; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratories.

Data from Centers for Disease Control and Prevention: Sexually transmitted diseases: treatment guidelines, *MMWR* 64(RR-3), 2015. https://www.cdc.gov/std/tg2015/default.htm .

Genital Lesions and Ectoparasites

Lesions that present as outgrowths on the surface of the epithelium and other limited epidermal lesions are included under this categorization of syndromes. HPV can cause genital warts and genital-cervical abnormalities that can lead to cancer (see Chapter 293). **Genital HPV** types are classified according to their association with cervical cancer. Infections with low-risk types, such as **HPV types 6 and 11** , can cause benign or low-grade changes in cells of the cervix, genital warts, and recurrent respiratory papillomatosis. High-risk HPV types can cause cervical, anal, vulvar, vaginal, and head and neck cancers. **High-risk HPV types 16 and 18** are detected in approximately 70% of **cervical cancers** . Persistent infection increases the risk of cervical cancer. **Molluscum contagiosum** and **condyloma latum** associated with secondary syphilis complete the classification of genital lesion syndromes.

As a result of the close physical contact during sexual contact, common ectoparasitic infestations of the pubic area occur as **pediculosis pubis** or the papular lesions of **scabies** (see Chapter 688).

HIV Disease and Hepatitis B

HIV and hepatitis B virus (HBV) present as asymptomatic, unexpected occurrences in most infected adolescents. High vaccination coverage rates among infants and adolescents have resulted in substantial declines in acute HBV incidence among U.S.-born adolescents. Risk factors identified in the history or routine screening during prenatal care are much more likely to result in suspicion of infection, leading to the appropriate laboratory screening, than are clinical manifestations in this age-group (see Chapters 302 and 385).

Diagnosis

Most often, adolescents infected with viral and bacterial STI pathogens do not report symptoms suggestive of infection. With the use of very sensitive, noninvasive chlamydia and gonorrhea NAAT, providers are finding that most genital infections in females as well as many males are asymptomatic. A thorough sexual history is key to identifying adolescents who should be screened for STIs and for identifying those who require a laboratory diagnostic evaluation for an STI syndrome.

When eliciting a sexual health history, discussions should be appropriate for the patient's developmental level. In addition to questions regarding vaginal or urethral discharge, genital lesions, and lower abdominal pain among females, one should ask about prior treatment of any STI symptoms, including self-treatment using nonprescription medications. **Dyspareunia** is a consistent symptom in adolescents with **PID** . Providers must ask about oral or anal sexual activity to determine sites for specimen collection.

Urethritis should be objectively documented by evidence of inflammation or infectious etiology. Patient complaint without objective clinical or laboratory evidence does not fulfill diagnostic criteria. Inflammation can be documented by (a) observing urethral mucopurulent discharge, (b) ≥2 WBCs per high-power field on microscopic examination of Gram stain urethral secretions, (c) urine microscopic findings of ≥10 WBCs per high-power field of first-void urine specimen, or (d) a positive urine leukocyte esterase test of a first-void specimen. Laboratory evaluation is essential to identify the involved pathogens to determine treatment, partner notification, and disease control. *C. trachomatis* and *N. gonorrhoeae* NAATs of a urine specimen are recommended. The presence of gram-negative intracellular diplococci on microscopy obtained from a male urethral specimen confirms the diagnosis of gonococcal urethritis.

An essential component of the diagnostic evaluation of vaginal, cervical, or urethral discharge is a chlamydia and gonorrhea NAAT. NAATs are the most sensitive chlamydia and gonorrhea tests available and are licensed for use with urine, urethral, vaginal, and cervical specimens. Many of the chlamydia NAATs are approved by the U.S. Food and Drug Administration (FDA) to test patient-collected vaginal swabs in the clinical setting and liquid cytology specimens. Female vaginal swab specimens and male first-void urine are considered the optimal specimen types. Female urine remains an acceptable chlamydia and gonorrhea NAAT specimen, but may have slightly reduced performance when compared with cervical or vaginal swab specimens. Urine is the recommended specimen for male urethral infection. Gonorrhea and chlamydia NAATs perform well on rectal and oropharyngeal specimens and can be performed by clinical laboratories that have completed the appropriate verification studies to obtain Clinical Laboratory Improvement Amendments (CLIA) approval, which includes most clinical laboratories.

Evaluation of adolescent females with **vaginitis** includes laboratory data. Traditionally, the cause of vaginal symptoms was determined by pH and microscopic examination of the discharge. However, CLIA-waived point-of-care vaginitis tests are available. Using pH paper, an elevated pH (i.e., >4.5) is common with bacterial vaginosis or trichomoniasis. Because pH testing is not highly specific, discharge should be further examined. For microscopic exam, a slide can be made with the discharge diluted in 1-2 drops of 0.9% normal saline solution and another slide with discharge diluted in 10% potassium hydroxide (KOH) solution. Examining the saline specimen slide under a microscope may reveal motile or dead *T. vaginalis* or clue cells (epithelial cells with borders obscured by small bacteria), which are characteristic of **bacterial vaginosis** . WBCs without evidence of trichomonads or yeast are usually suggestive of cervicitis. The yeast or pseudohyphae of ***Candida*** species are more easily identified in the KOH specimen (Fig. 146.8). The sensitivity of microscopy is approximately 50% and requires immediate evaluation of the slide for optimal results. Therefore, lack of findings does not eliminate the possibility of infection. More sensitive point-of-care vaginitis tests include the OSOM Trichomonas Rapid Test (Sekisui Diagnostics, Lexington, MA), an immunochromatographic capillary flow dipstick technology with reported 83% sensitivity. The OSOM BVBLUE Test (Sekisui) detects elevated vaginal fluid sialidase activity, an enzyme produced by bacterial pathogens associated with bacterial vaginosis, including *Gardnerella* , *Bacteroides* , *Prevotella*, and *Mobiluncus* , and has a reported 90% sensitivity. Both tests are CLIA waived, with results available in 10 min.

FIG. 146.8 Common normal and abnormal microscopic findings during examination of vaginal fluid. KOH, Potassium hydroxide solution; PMN, polymorphonuclear leukocyte; RBCs, red blood cells. (From *Adolescent medicine: state of the art reviews,* vol 14, no 2, Philadelphia, 2003, Hanley & Belfus, pp 350–351.)

Clinical laboratory–based vaginitis tests are also available. The Affirm VPIII (Becton Dickenson, San Jose, CA) is a moderate-complexity nucleic acid probe test that evaluates for *T. vaginalis* , *G. vaginalis* , and *C. albicans* and has a sensitivity of 63% and specificity >99.9%, with results available in 45 min. Some gonorrhea and chlamydia NAATs also offer an assay for *T. vaginalis* testing of female specimens tested for *N. gonorrhoeae* and *C. trachomatis* , considered the gold standard for *Trichomonas* testing.

Objective signs of vulvar inflammation in the absence of vaginal pathogens, along with a minimal amount of discharge, suggest the possibility of mechanical, chemical, allergic, or other noninfectious irritation of the vulva (Table 146.4).

Table 146.4

Pathologic Vaginal Discharge

INFECTIVE DISCHARGE	OTHER REASONS FOR DISCHARGE

COMMON CAUSES	**COMMON CAUSES**
Organisms	Retained tampon or condom
Candida albicans	Chemical irritation
Trichomonas vaginalis	Allergic responses
Chlamydia trachomatis	Ectropion
Neisseria gonorrhoeae	Endocervical polyp
Mycoplasma genitalium	Intrauterine device
Conditions	Atrophic changes
Bacterial vaginosis	**LESS COMMON CAUSES**
Acute pelvic inflammatory disease	Physical trauma
Postoperative pelvic infection	Vault granulation tissue
Postabortal sepsis	Vesicovaginal fistula
Puerperal sepsis	Rectovaginal fistula
LESS COMMON CAUSES	Neoplasia
Ureaplasma urealyticum	Cervicitis
Syphilis	
Escherichia coli

The **definitive diagnosis of PID** is difficult based on clinical findings alone. Clinical diagnosis is imprecise, and no single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. Clinical criteria have a positive predictive value of only 65–90% compared with laparoscopy. Although healthcare providers should maintain a low threshold for the diagnosis of PID, additional criteria to enhance specificity of diagnosis, such as transvaginal ultrasonography, can be considered (Table 146.5).

Table 146.5

Evaluation for Pelvic Inflammatory Disease (PID)

2015 CDC Diagnostic Criteria

Minimal Criteria

- Cervical motion tenderness

or

- Uterine tenderness

or

- Adnexal tenderness

Additional Criteria to Enhance Specificity of the Minimal Criteria

- Oral temperature >38.3°C (101°F)
- Abnormal cervical or vaginal mucopurulent discharge*
- Presence of abundant numbers of WBCs on saline microscopy of vaginal secretions*
- Elevated ESR or C-reactive protein
- Laboratory documentation of cervical *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection

Most Specific Criteria to Enhance the Specificity of the Minimal Criteria

- Transvaginal sonography or MRI techniques showing thickened, fluid-filled tubes, with or without free pelvic fluid or tuboovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia)
- Endometrial biopsy with histopathologic evidence of endometritis
- Laparoscopic abnormalities consistent with PID

Differential Diagnosis (Partial List)

- Gastrointestinal: appendicitis, constipation, diverticulitis, gastroenteritis, inflammatory bowel disease, irritable bowel syndrome
- Gynecologic: ovarian cyst (intact, ruptured, or torsed), endometriosis, dysmenorrhea, ectopic pregnancy, mittelschmerz, ruptured follicle, septic or threatened abortion, tuboovarian abscess
- Urinary tract: cystitis, pyelonephritis, urethritis, nephrolithiasis

ESR, Erythrocyte sedimentation rate; WBCs, white blood cells.

---

* If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be investigated.

Adapted from Centers for Disease Control and Prevention (CDC). https://www.cdc.gov/std/tg2015/screening-recommendations.htm .

Cell culture and polymerase chain reaction (PCR) are the preferred **HSV tests** . Viral culture sensitivity is low, and intermittent viral shedding causes false-negative results. NAATs, including PCR assays for HSV DNA, are more sensitive and increasingly available for diagnosing genital HSV. The Tzanck test is insensitive and nonspecific and should not be considered reliable.

Accurate type-specific **HSV serologic assays** are based on the HSV-specific glycoproteins G2 (HSV-2) and G1 (HSV-1). Both laboratory-based point-of-care tests are available. Because almost all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection. The presence of HSV-1 antibody alone is more difficult to interpret because of the frequency of oral HSV infection acquired during childhood. Type-specific HSV serologic assays might be useful in the following scenarios: (1) recurrent genital symptoms or atypical symptoms with negative HSV cultures; (2) a clinical diagnosis of genital herpes without laboratory confirmation; and (3) a patient with a partner with genital herpes, especially if considering suppressive antiviral therapy to prevent transmission.

For **syphilis testing** , nontreponemal tests, such as the rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL), and treponemal testing, such as fluorescent treponemal antibody absorbed tests, the *T. pallidum* passive particle agglutination (TP-PA) assay, and various enzyme and chemiluminescence immunoassays (EIA/CIA), are recommended. However, many clinical laboratories have adopted a *reverse sequence* of screening in which a treponemal EIA/CIA is performed first, followed by testing of reactive sera with a nontreponemal test (e.g., RPR). A positive treponemal EIA or CIA test can identify both *previously treated and untreated or incompletely treated syphilis* . False-positive results can occur, particularly among populations with low syphilis prevalence. Persons with a positive treponemal screening test should have a standard nontreponemal test with titer (RPR or VDRL) to guide patient management decisions. If EIA/CIA and RPR/VDRL results are discordant, the laboratory should perform a different treponemal test to confirm the results of the initial test. Patients with discordant serologic results by EIA/CIA and RPR/VDRL testing whose sera are reactive by TP-PA testing are considered to have past or present syphilis; if sera is TP-PA nonreactive, syphilis is unlikely (Fig. 146.9).

FIG. 146.9 Centers for Disease Control and Prevention (CDC) recommended algorithm for reverse-sequence syphilis screening: treponemal test screening followed by nontreponemal test confirmation. (From Association of Public Health Laboratories: Suggested reporting language for syphilis serology testing, 2015.)

Rapid HIV testing with results available in 10-20 min can be useful when the likelihood of adolescents returning for their results is low. Point-of-care CLIA-waived tests for whole blood fingerstick and oral fluid specimen testing are available. Clinical studies have demonstrated that the rapid HIV test performance is comparable to those of EIAs. Because some reactive test results may be false positive, every reactive rapid test must be confirmed.

Treatment

See Part XVI for chapters on the treatment of specific microorganisms and Tables 146.6 to 146.8 . Treatment regimens using nonprescription products for candidal vaginitis and pediculosis reduce financial and access barriers to rapid treatment for adolescents, but potential risks for inappropriate self-treatment and complications from untreated more serious infections must be considered before using this approach. Minimizing noncompliance with treatment, notifying and treating the sexual partners, addressing prevention and contraceptive issues, offering available vaccines to prevent STIs, and making every effort to preserve fertility are additional physician responsibilities.

Table 146.6

Management Guidelines for Uncomplicated Bacterial STIs in Adolescents and Adults

PATHOGEN	RECOMMENDED REGIMENS	ALTERNATIVE REGIMENS AND SPECIAL CONSIDERATIONS
Chlamydia trachomatis	Azithromycin 1 g orally once *or* Doxycycline 100 mg orally twice daily for 7 days	**For pregnancy:** Azithromycin 1 g orally once **Alternative regimens:** Erythromycin base 500 mg orally 4 times daily for 7 days *or* Erythromycin ethylsuccinate 800 mg orally 4 times daily for 7 days *or* Levofloxacin 500 mg orally once daily for 7 days *or* Ofloxacin 300 mg orally twice daily for 7 days
Neisseria gonorrhoeae (cervix, urethra, and rectum)	Ceftriaxone 250 mg IM in a single dose *plus* Azithromycin 1 g orally once	Single-dose injectable cephalosporin regimens (other than ceftriaxone 250 mg IM) that are safe and effective against uncomplicated urogenital and anorectal gonococcal infections include ceftizoxime 500 mg IM, cefoxitin 2 g IM with probenecid 1 g orally, and cefotaxime 500 mg IM *plus* Azithromycin 1 g orally once *Alternative if unable to offer IM:* Cefixime 400 mg orally in a single dose *plus* Azithromycin 1 g orally in a single dose **If patient is allergic to azithromycin:** Doxycycline 100 mg orally twice daily for 7 days may be substituted for azithromycin as the 2nd antimicrobial. **Severe cephalosporin allergy:** Gemifloxacin 320 mg orally *plus* azithromycin 2 g orally in a single dose *or* Gentamicin 240 mg IM *plus* oral azithromycin 2 g orally in a single dose
N. gonorrhoeae (pharynx)	Ceftriaxone 250 mg IM in a single dose *plus* Azithromycin 1 g orally once	**No recommended alternative therapy** Possibly gemifloxacin *plus* azithromycin as above for cervix, urethra, rectum Patients treated with an alternative regimen should return 14 days after treatment for a test of cure using either culture or NAAT.
Treponema pallidum (primary and	Benzathine penicillin G 2.4 million units IM in a	**Penicillin allergy:** Doxycycline 100 mg orally twice daily for 14 days, *or* tetracycline 500 mg orally 4 times daily for

secondary syphilis or early latent syphilis, i.e., infection <12 mo)	single dose	14 days. Limited data suggest ceftriaxone 1-2 g daily either IM or IV for 10-14 days. *or* Azithromycin 2 g orally in a single dose has been effective. but treatment failures have been documented.
T. pallidum (late latent syphilis or syphilis of unknown duration)	Benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1 wk intervals	**Penicillin allergy:** Doxycycline 100 mg orally twice daily for 28 days, *or* tetracycline 500 mg orally 4 times daily for 28 days, with close serologic and clinical follow-up
Haemophilus ducreyi (chancroid: genital ulcers, lymphadenopathy)	Azithromycin 1 g orally in a single dose *or* Ceftriaxone 250 mg IM in a single dose *or* Ciprofloxacin 500 mg orally twice daily for 3 days *or* Erythromycin base 500 mg orally 3 times daily for 7 days	
C. trachomatis serovars L1, L2, or L3 (lymphogranuloma venereum)	Doxycycline 100 mg orally twice daily for 21 days	**Alternative:** Erythromycin base 500 mg orally 4 times daily for 21 days *or* Azithromycin 1 g orally once weekly for 3 wk

IM, Intramuscularly; IV, intravenously; NAAT, nucleic acid amplification test.

Table 146.7

Management Guidelines for Uncomplicated Miscellaneous Sexually Transmitted Infections in Adolescents and Adults

PATHOGEN	RECOMMENDED REGIMENS	ALTERNATIVE REGIMENS AND SPECIAL CONSIDERATIONS
Trichomonas vaginalis	Metronidazole 2 g orally in a single dose *or* Tinidazole 2 g orally in a single dose	Metronidazole 500 mg orally twice daily for 7 days
Phthirus pubis (pubic lice)	Permethrin 1% cream rinse applied to affected areas and washed off after 10 min *or* Pyrethrins with piperonyl butoxide applied to affected areas and washed off after 10 min	Malathion 0.5% lotion applied for 8-12 hr and washed off *or* Ivermectin 250 µg/kg orally, repeat in 2 wk

	Launder clothing and bedding	
Sarcoptes scabiei (scabies)	Permethrin 5% cream applied to all areas from the neck down, washed off after 8-14 hr or Ivermectin 200 µg/kg orally, repeated in 2 wk Launder clothing and bedding	Lindane (1%) 1 oz of lotion or 30 g of cream in thin layer to all areas of body from neck down; wash off in 8 hr

Adapted from Centers for Disease Control and Prevention: Sexually transmitted diseases: treatment guidelines, *MMWR* 64(RR-3), 2015. https://www.cdc.gov/std/tg2015/default.htm .

Table 146.8

Management Guidelines for Uncomplicated Genital Warts and Genital Herpes in Adolescents and Adults

PATHOGEN	RECOMMENDED REGIMENS	ALTERNATIVE REGIMENS AND SPECIAL CONSIDERATIONS
HUMAN PAPILLOMAVIRUS (HPV)		
External anogenital warts (penis, groin, scrotum, vulva, perineum, external anus, and perianus)	**Patient applied:** Imiquimod 3.75% cream self-applied to warts at bedtime nightly for up to 16 wk; wash off after 6-10 hr *or* Imiquimod 3 5% cream self-applied to warts at bedtime 3 times weekly for up to 16 wk; wash off after 6-10 hr *or* Podofilox 0.5% solution or gel self-applied to warts twice daily for 3 consecutive days each wk followed by 4 days of no therapy. May be repeated for up to 4 cycles. *or* Sinecatechins 15% ointment self-applied 3 times daily for up to 16 wk. Do not wash off after use, and avoid genital, anal, and oral sexual contact while ointment is on skin. **Provider-administered:** Cryotherapy with liquid nitrogen or cryoprobe. Repeat applications every 1-2 wk. *or* Surgical removal either by electrocautery, tangential	**Provider administered:** Podophyllin resin 10–25% in a compound tincture of benzoin applied to each wart and then allowed to air-dry; thoroughly wash after off 1-4 hr; can be repeated weekly. Systemic toxicity has been reported when podophyllin resin was applied to large areas of friable tissue and was not washed off within 4 hr. Many persons with external anal warts also have intraanal warts and might benefit from inspection of anal canal by digital examination, standard anoscopy, or high-resolution anoscopy.

	excision with scissors or scalpel, or by carbon dioxide (CO_2) laser *or* Trichloroacetic acid (TCA) or bichloracetic acid (BCA) 80–90%; small amount applied only to warts and allowed to dry, when white “frosting” develops; can be repeated weekly.	
Cervical warts	Cryotherapy with liquid nitrogen *or* Surgical removal *or* TCA or BCA 80–90% solution Management should include consultation with a specialist.	
Vaginal warts	Cryotherapy with liquid nitrogen; avoid cryoprobe use. *or* Surgical removal *or* TCA or BCA 80–90%; small amount applied only to warts and allowed to dry, when white “frosting” develops; can be repeated weekly.	
Urethral meatal warts	Cryotherapy with liquid nitrogen *or* Surgical removal	
Intraanal Warts	Cryotherapy with liquid nitrogen *or* Surgical removal *or* TCA or BCA 80-90% applied to warts. A small amount should be applied only to warts and allowed to dry, at which time a white “frosting” develops. Can be repeated weekly	Management of intraanal warts should include consultation with a specialist.
HERPES SIMPLEX VIRUS (HSV; GENITAL HERPES)		
First clinical episode	**Treat for 7-10 days with 1 of the following:** Acyclovir 400 mg orally 3 times daily Acyclovir 200 mg orally 5 times daily	Consider extending treatment if healing is incomplete after 10 days of therapy

	Valacyclovir 1 g orally twice daily Famciclovir 250 mg orally 3 times daily	
Episodic therapy for recurrences	**Treat with 1 of the following:** Acyclovir 400 mg orally 3 times daily for 5 days Acyclovir 800 mg orally twice daily for 5 days Acyclovir 800 mg orally 3 times daily for 2 days Valacyclovir 500 mg orally twice daily for 3 days Valacyclovir 1,000 mg orally once daily for 5 days Famciclovir 125 mg orally twice daily for 5 days Famciclovir 1,000 mg orally twice daily for 1 day Famciclovir 500 mg orally once, then 250 mg twice daily for 2 days	Effective episodic treatment of recurrences requires initiation of therapy within 1 day of lesion onset or during the prodrome that precedes some outbreaks. The patient should be provided with a supply or a prescription for the medication with instructions to initiate treatment immediately when symptoms begin.
Suppressive therapy to reduce frequency of recurrences	**Treat with 1 of the following:** Acyclovir 400 mg orally twice daily Valacyclovir 500 mg orally once daily[*] or 1 g orally once daily Famciclovir 250 mg orally twice daily	All patients should be counseled regarding suppressive therapy availability, regardless of number of outbreaks per year. Since the frequency of recurrent outbreaks diminishes over time in many patients, providers should periodically discuss the need to continue therapy.

[*] Valacyclovir 500 mg once daily might be less effective than other valacyclovir or acyclovir dosing regimens in patients who have very frequent recurrences (i.e., ≥10 episodes per year).

Adapted from Centers for Disease Control and Prevention: Sexually transmitted diseases: treatment guidelines, *MMWR* 64(RR-3), 2015. https://www.cdc.gov/std/tg2015/default.htm .

Chlamydia- and gonorrhea-infected males and females should be retested approximately 3 mo after treatment, regardless of whether they believe that their sex partners were treated, or whenever persons next present for medical care in the 12 mo following initial treatment. Once an infection is diagnosed, partner evaluation, testing, and treatment are recommended for sexual contacts within 60 days of symptoms or diagnosis, or the most recent partner if sexual contact was >60 days, even if the partner is asymptomatic. Abstinence is recommended for at least 7 days after both patient and partner are treated. A test for pregnancy should be performed for all females with suspected PID because the test outcome will affect management. Repeat testing 3 mo after treatment is also recommended for *Trichomonas* infection.

Diagnosis and therapy are often carried out within the context of a **confidential** relationship between the physician and the patient. Therefore, the need to report certain STIs to health department authorities should be clarified at the outset. Health departments are Health Insurance Portability and Affordability Act (HIPAA) exempt and will not violate confidentiality. The health department's role is to ensure that treatment and case finding have been accomplished and that sexual partners have been notified of their STI exposure. **Expedited partner therapy (EPT)** , the clinical practice of treating sex partners of patients diagnosed with chlamydia or gonorrhea, by providing prescriptions or medications to the patient to take to the partner without the healthcare provider first examining the partner, is a strategy to reduce further transmission of infection. In randomized trials, EPT has reduced the rates of persistent or recurrent gonorrhea and chlamydia infection. Serious adverse reactions are rare with recommended chlamydia and gonorrhea treatment regimens, such as doxycycline, azithromycin, and cefixime. Transient gastrointestinal side effects are more common but rarely result in severe morbidity. Most states expressly permit EPT or may allow its practice. Resources for information regarding EPT and state laws are available at the Centers for Disease Control and Prevention website (http://www.cdc.gov/std/ept/).

Prevention

Healthcare providers should integrate **sexuality education** into clinical practice with children from early childhood through adolescence. Providers should counsel adolescents regarding sexual behaviors associated with risk of STI acquisition and should educate using evidence-based prevention strategies, which include a discussion of abstinence and other risk reduction strategies, such as consistent and correct condom use. The U.S. Preventive Services Task Force recommends **high-intensity behavioral counseling** to prevent STIs for all sexually active adolescents. The HPV vaccine (Gardasil 9) is recommended for 11 and 12 yr old males and females as routine immunization. Catch-up vaccination is recommended for females age 13-26 and for males age 13-21 who have not yet received or completed the vaccine series; males age 22 through 26 may be vaccinated.

CHAPTER 147

Chronic Overlapping Pain Conditions

Thomas C. Chelimsky, Gisela G. Chelimsky

This chapter was made possible with the support of an Advancing Healthier Wisconsin 5520298 grant.

In chronic overlapping pain conditions (**COPCs**), several painful symptoms affecting different body systems coexist without clear underlying pathophysiology. Other terms for COPCs include **medically unexplained symptoms** , **functional somatic syndromes** (FSS), and **central sensitivity syndromes** . These disorders are probably highly prevalent; for example, 2 COPCs, irritable bowel syndrome (IBS) and migraine, *each* affect 10–20% of the population. Pediatric COPC studies usually focus on populations with 1 painful condition (headaches) and their psychiatric comorbidities, rather than somatic comorbidities. The overlap of these disorders with psychiatric conditions has led both the public and the medical specialists to dichotomize these disorders artificially into “physical,” by implication, “real” disorders; and “psychological,” by implication, “not real” disorders. This classification ignores the unity of brain and body and hinders progress in understanding these disorders. COPC connotes a nonassumptive neutral position, appropriately attributing no assumed pathophysiology to the disorder, in contrast to other terms, such as “medically unexplained syndrome,” subtly suggesting a psychological process, more strongly implied in the term “functional.”

Prevalence

The prevalence of COPCs is unknown, ranging from 20% to >50% depending on which symptom is being assessed and how much overlap exists across disorders. A large study from 28 countries (about 400,000 participants) found a prevalence of headache of 54%, stomachache 50%, and backache 37%, occurring at least once a month for at least 6 mo. Females had a higher prevalence of having all 3 complaints when compared to males; the prevalence increased with age. These three pain syndromes, headache, stomach-ache and backache, frequently coexist.

IBS and chronic abdominal pain affect 6–20% of children and adolescents. Idiopathic musculoskeletal pain affects about 16% of schoolchildren age 5-16 yr and is often associated with sleep disturbances, headache, abdominal pain, daytime tiredness, and feeling sad (see Chapter 193). Migraines present >6 mo occur in about 8% of the population (children and adolescents <20 yr) (see Chapter 613.1). **Fibromyalgia** is present in 1.2–6% (see Chapter 193.3). The prevalence of chronic disabling fatigue increases during adolescence from about 1.9% at age 13 to 3% at 18 yr (see Chapter 147.1). As with most COPCs, fibromyalgia has many comorbid disorders, such as sleep disturbance, fatigue, headache, sore throat, joint pain, and abdominal pain. The American College of Rheumatology definition of fibromyalgia incorporates some of these comorbid conditions.

Symptom/Disorder Overlap

Diagnostic criteria of many of these disorders overlap with one another, making differentiation between two disorders more of a semantic issue rather than a clinical differentiation. **Chronic fatigue syndrome (CFS)** , clinically the most concerning symptom, shares many of the diagnostic criteria with fibromyalgia. Patients with a single pain condition, such as fibromyalgia, CFS, IBS, multiple chemical sensitivity (MCS), headaches, or temporomandibular joint disorder (TMJD), will typically have another disorder. This overlap of symptoms may reflect a shared pathophysiology, possibly a central nervous system (CNS) dysfunction, as was implied in the prior term “central sensitization syndrome”. A CNS pathophysiology would also explain the “invisibility” of these disorders to usual screening tools that most often target an end organ.

COPCs also harbor many symptoms that are not strictly “pain,” although they may be equally or more disabling. Adolescents seen in a tertiary referral center with a **functional gastrointestinal disorder (FGID)** also manifest dizziness, chronic nausea, chronic fatigue and sleep disturbance, as well as migraines. Up to 50% of adolescents complain of weekly fatigue, and 15%, daily fatigue.

Migraine headaches are frequently associated with anxiety and depression. **Anxiety** also predicts the persistence of migraine headaches. Sleep disturbance and migraine also interact closely. Poor sleep can trigger a migraine or a migraine cluster; migraine headache itself disturbs sleep. Juvenile fibromyalgia is associated with sleep disturbances such as prolonged sleep latency, frequent awakening, less total sleep time, and periodic limb movements. Adult patients with IBS also have sleep disturbances, correlating with anxiety, depression, and stress.

The comorbidities of **hypermobility Ehlers-Danlos** (**hEDS**) and **postural orthostatic tachycardia syndrome (POTS)** have been significant. Patients with hEDS may complain of widespread and sometimes debilitating pain with or after activity, severe fatigue, handwriting difficulties, "cracking" of joints, joint swelling, joint dislocation, subluxation, or back pain. The chronic pain reduces exercise tolerance, with poorer quality of life and an ever-worsening cycle because exercise is a key piece of management. Patients with FGID may also have hEDS, fibromyalgia, chronic pains, and higher somatizations scores than those with organic gastrointestinal (GI) disorders.

Diagnosis of **pediatric POTS** requires an increase in heart rate >40 beats/min in the 1st 10 min of upright tilt test associated with orthostatic symptoms. POTS is also associated with multiple comorbidities, including sleep disruption, chronic pain, Raynaud-like symptoms, GI abnormalities, and less frequently headaches, syncope, and urinary complaints. Patients with both POTS and hEDS usually have more migraines and syncope than those with POTS alone. The prevalence of comorbid disorders in children with COPC is identical whether they have POTS or hEDS.

Psychiatric Comorbidities

Many of these disorders have significant psychiatric comorbidities. Juvenile fibromyalgia is associated with anxiety disorders and major mood disorders. Children with medically unexplained symptoms generally have more anxiety and depression than children with other chronic disorders. Other associations include disruptive behaviors, symptom internalization, fearfulness, greater dependency, hyperactivity, and concern about sickness.

Predisposing Factors

Female gender and older age (adolescence) increase the risk of COPCs. Certain conditions (e.g., headache) are more common in males or have similar prevalence across genders during childhood, but the prevalence in females increases after puberty. Trauma or posttraumatic stress disorder increases psychological comorbidities in juvenile fibromyalgia. Some studies suggest that anxiety predisposes to chronic pain. A population-based study following children from 18 mo to 14 yr of age suggested that maternal psychological distress in early childhood and depressive and pain complaints in preadolescence increase the risk of recurrent abdominal pain at age 14. Postinfectious IBS is an identifiable risk factor for new-onset anxiety, depression, and sleep disruption in adults. Children with recurrent abdominal pain often have parents with abdominal pain. It is unclear if this association is caused by a common environmental/genetic factor or a learned behavior of the child imitating the parent.

Natural History

The natural history of COPC is not well known. Chronic disabling fatigue in the general adolescent population persists 2-3 yr in about 25% of patients, but only 8% of youth affected at age 13 still had the complaints at ages 16 and 18. A meta-analysis suggests that the prognosis of CFS in children is usually good, with a small minority having persistent disabling symptoms. The patient's belief in an underlying physical disorder and the presence of psychiatric comorbidities predicts a poorer outcome.

In a study of children with FGID, the outcome depended on specific variables. Those who perceived their abdominal pain as more threatening, with high levels of pain catastrophization and little capacity to cope with pain because of reduced activity levels, had a poorer outcome. This “high pain dysfunctional profile” subgroup was predominantly female (70%) with a mean age of 12.2 yr. Two thirds of this subgroup still complained of FGID at follow-up, vs about one third of those in the other groups. These groups included a “high pain adaptive profile” group with similar pain levels but better adaptive skills and less catastrophization, predominantly slightly younger (11.8 yr) females, and a “low pain adaptive profile” group, slightly younger (11.1 yr), with equal males and females but less abdominal pain, better coping mechanisms, and less impairment of daily activities. In the high pain dysfunctional profile group, 41% had both FGID and nonabdominal chronic pain at follow-up, vs 11% in the high pain adaptive and 17% in the low pain adaptive group. Another study following children age 4-16.6 yr with IBS demonstrated resolution of symptoms in 58%, usually without medication. The differences between these studies may result from the age of the groups, with better outcome in the younger patients, as well as the number of comorbidities and psychological profile.

Proposed Pathophysiology

There may be dysfunction in the hypothalamic-hypophyseal-adrenal axis, circadian patterns, autonomic responses, some aspects of CNS processing, the inflammatory immune response, and the musculoskeletal system. Vagal tone measured by heart rate variability is decreased in some children with FGID symptoms and in children with COPCs. Alterations in the autonomic nervous system may affect the immune system, as well as circadian patterns. The stress response may increase muscle tone, which in turn leads to body aches and tension headaches. In fibromyalgia the cortisol response is altered, with lower cortisol levels on awakening and throughout the day. **Orthostatic intolerance** from autonomic abnormalities may also contribute to poor concentration from brain hypoperfusion and blood pooling in the lower extremities.

The pathophysiology has been better studied in myalgic encephalomyelitis (ME)/CFS (Chapter 147.1). ME/CFS has been associated with joint hypermobility, orthostatic intolerance, decreased range of motion, and reduced activity. These patients demonstrate excessive glial activation resulting in neuroexcitation, neuroinflammation, and possibly neurodegeneration. These features may contribute to the cognitive issues and fatigue present in this disorder.

Neuroinflammation and other changes in processing may lead to abnormal descending inhibitory pain pathways, resulting in distal pain and “central sensitization.” The malfunction of descending antinociceptive pathways allows pain to spread in the body, associated with increased activity of the nociceptive facilitator pathways. These facilitator pathways are further activated by psychological factors, such as catastrophization, depression, lack of acceptance, and hypervigilance. Other signals such as pressure, sound, heat, and cold are also aberrantly processed, with activation of areas of the brain that are typically activated only by acute pain stimuli, such as the insula, prefrontal cortex, and anterior cingulate cortex, as well as some regions usually not involved in pain processing.

Treatment

As general rules, *chronic pain should never be treated with opioids* , and *cognitive-behavioral therapy (CBT) and a gradually progressive exercise program constitute the cornerstones of treatment*. The complex comorbid nature of COPCs typically requires a multidisciplinary approach. Since neither CBT nor exercise will have any effect in the absence of full patient engagement and understanding, the team must include the family and the patient, a pain psychologist with experience in CBT, a physical therapist, and the primary care physician. Depending on comorbid conditions, rheumatology, neurology, or gastroenterology may have important roles for symptom management and possible alternative diagnosis. Depending on the initial symptomatology, the differential diagnosis should include inflammatory bowel disease, celiac disease, juvenile idiopathic arthritis, systemic lupus erythematosus, dermatomyositis, autoinflammatory disorders, Fabry disease, porphyrias, hereditary sensory-autonomic neuropathies, and Ehlers-Danlos syndrome.

When a thorough evaluation for a structural cause of symptoms is unrevealing, an important next step is patient and family **education** . This should include the common presentation, the expectation that “markers” for these types of disorders would typically be absent, and the presence of solid management tools with high probability of improvement. Families and patients need to receive encouragement to stop seeking a “magic diagnosis and cure” and to begin the path to full recovery. Without this step, critical patient engagement in the treatment will not occur. In our practice, we sometimes call *functional* disorders a problem of “software,” in contrast to *structural* issues that would involve “hardware.” We explain that successful management must change the software, not just mask symptoms. Approaches that accomplish such a goal include CBT, and a rehabilitative program that may require physical therapy, vigorous exercise program with interval training, meditation, and/or yoga. Patients are often deconditioned and may need to start with a very low level of physical activity. In addition, their exercise tolerance may be significantly hampered by an orthostatic intolerance syndrome (e.g., POTS). For these reasons, we frequently recommend starting with a *water aerobics* program, which provides several benefits: (1) very low gravitational force, so the patient can be set up for success, working only on conditioning and not simultaneously fighting an orthostatic challenge; (2) builds both limb and core strength; and (3) gentle on joints for those with arthralgias or a hypermobility syndrome. When water is unavailable, we recommend starting with a recumbent exercise program such as a recumbent stationary bike. In both circumstances, we then slowly introduce upright aerobic activities on land over 2-3 mo. Strength exercises are also useful. A Cochrane Review in adults with painful disorders showed exercise to have minimal side effects, to improve functionality, reduce pain, and improve quality of life. Patients with fibromyalgia who undergo a 3 mo multidisciplinary program with twice-weekly physical therapy and CBT benefited in function and physical activity level, and most importantly continued to exercise regularly at 1 yr follow-up. Pharmacologic interventions have less impact than nonmedical treatments.

When children are missing school or are homebound, it is important to work closely with the school to encourage reentry to school. This may require modifying the school schedule initially, starting with fewer hours at school, and providing extra time for homework on days that the children are not feeling well.

Although medications such as tricyclic antidepressants are often added to the treatment, the improvement with these medications for chronic pain is minimal, and the side effects need to be considered. Nonetheless, **amitriptyline** is often used because it helps in treating headaches and abdominal pain and improves sleep quality, a critical element to manage any chronic pain condition.

147.1

Chronic Fatigue Syndrome

Mark R. Magnusson

Keywords

myalgic encephalomyelitis
ME/CFS
systemic exertion intolerance disease
SEID

postexertion malaise
infectious mononucleosis

postural orthostatic tachycardia syndrome
fibromyalgia
cognitive impairment
cognitive-behavioral therapy
orthostatic intolerance

Chronic fatigue syndrome (**CFS**), also known as **myalgic encephalomyelitis (ME)** , is a complex, diverse, and debilitating illness characterized by chronic or intermittent fatigue accompanied by select symptoms and occurring in children, adolescents, and adults. The combination of fatigue and other symptoms interferes significantly with daily activities and has no identified medical explanation (Fig. 147.1). The fatigue does not require exertion by the patient, nor does rest relieve it. Some consider **postexertion malaise,** or worsening of the fatigue with additional symptoms after mental or physical exertion and lasting >24 hr, to be characteristic of CFS. A definitive causal agent or process has not been identified, although the differential diagnosis includes infectious, inflammatory, metabolic, genetic, and autoimmune diseases. Our understanding of this condition is largely from studies of adults and adolescents, with limited descriptions of chronic fatiguing illnesses in younger children.

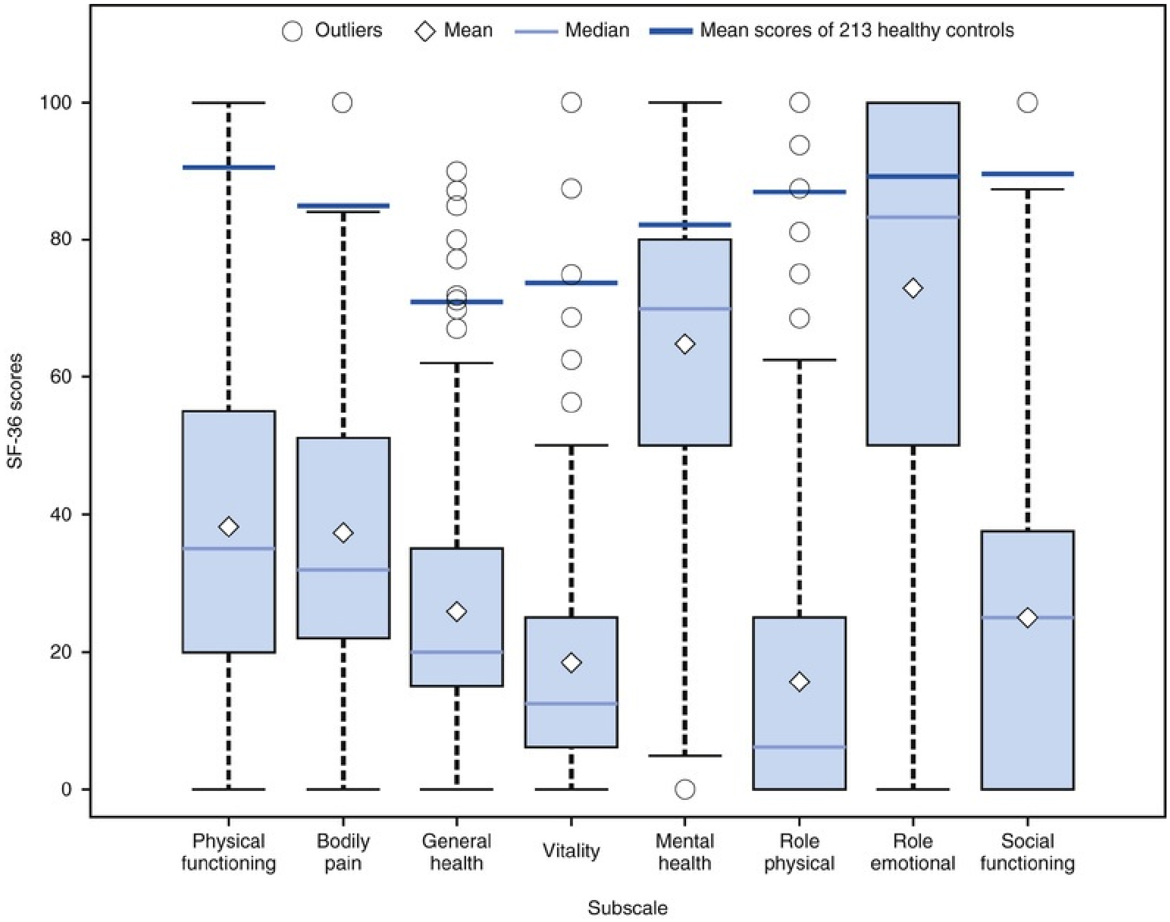

FIG. 147.1 Functional status* of 471 patients enrolled in CDC Multisite Clinical Assessment[†] of ME/CFS[§] —United States, September 2015. *Measured by box plots of scores in the 8 subscales of Short-Form Health Survey (SF-36) scores (25th and 75th percentile at *bottom* and *top* of box). SF-36 scores range from 0-100, with higher scores indicating better functioning. [†] https://www.cdc.gov/cfs/programs/clinical-assessment/index.html . [§] ME/CFS (myalgic encephalomyelitis/chronic fatigue syndrome) patients show significant impairment, particularly in vitality and physical functioning subscale scores, but with preservation of mental health and emotional role functioning. (From Unger ER, Lin JMS, Brimmer DJ, et al: CDC Grand Rounds: Chronic fatigue syndrome—advancing research and clinical education, *MMWR* 65(50-51):1434–1438, 2016.)

The illness was formally defined in 1988 as *chronic fatigue syndrome* because persistent unexplained fatigue was considered the principal and invariable physical symptom. A variety of other names have been used to describe the illness, including chronic mononucleosis, chronic Epstein-Barr virus (EBV) infection, postinfection syndrome, and immune dysfunction syndrome. Several case definitions have been developed and are in use in both clinical care and research (Table 147.1).

Table 147.1

Overview of Current Case Definitions for Systemic Exertion Intolerance Disease (SEID) and Past Definitions of Chronic Fatigue Syndrome or Myalgic Encephalomyelitis

SYMPTOM	SEID	CFS	ME
Fatigue and impairment of daily function	≥ 6 mo	≥ 6 mo	≥ 6 mo
Sudden onset	Yes	Yes	
Muscle weakness			Yes
Muscle pain		Yes	
Postexertional symptoms	Yes	Yes	Yes
Sleep disturbance	Yes		Yes
Memory or cognitive disturbances	Yes		Yes
Autonomic symptoms			Yes
Sore throat		Yes	
Lymph node involvement		Yes	
Cardiovascular symptoms	Yes		
Headaches		Yes	
Arthralgias		Yes	Yes

CFS, Chronic fatigue syndrome; ME, myalgic encephalomyelitis.

Data from Institute of Medicine: Beyond Myalgic Encephalomyelitis/Chronic Fatigue Syndrome Redefining an Illness. Washington, DC, National Academies Press 2015; Jason L, Evans M, Porter N, et al: The development of a revised Canadian myalgic encephalomyelitis chronic fatigue syndrome case definition. Am J Biochem Biotechnol 6:120 135, 2010; Reeves WC, Wagner D, Nisenbaum R, et al: Chronic fatigue syndrome—a clinically empirical approach to its definition and study. BMC Med 3:19, 2005.

The Institute of Medicine (IOM) 2015 recommendations apply to all ages and include a special focus on pediatrics. The IOM suggested new diagnostic criteria and a new name, **systemic exertion intolerance disease (SEID)** , to emphasize the postexertion malaise criterion and better understand the illness (Table 147.2). The most recent expert consensus report (June 2017) from the International Writing Group for Pediatric ME/CFS provides a primer for diagnosis and management.

Table 147.2

Criteria for Diagnosis of Myalgic Encephalomyelitis/Chronic Fatigue Syndrome (ME/CFS)

Patient has each of the following 3 symptoms at least half the time, to at least a moderately severe degree:

- A substantial reduction or impairment in the ability to engage in preillness levels of occupational, educational, social, or personal activities that persists for >6 mo and is accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest.
- Postexertional malaise*
- Unrefreshing sleep*

Plus at least 1 of the 2 following manifestations (chronic, severe):

- Cognitive impairment*
- Orthostatic intolerance

---

[*] Frequency and severity of symptoms should be assessed. The diagnosis of ME/CFS should be questioned if patients do not have these symptoms at least half of the time with moderate, substantial, or severe intensity.

From Institute of Medicine: *Beyond myalgic encephalomyelitis/chronic fatigue syndrome: redefining an illness*, Washington, DC, 2015, National Academies Press.

Epidemiology

Based on worldwide studies, 0.2–2.3% of adolescents or children have CFS. Most epidemiology studies use the 1994 definition. CFS is more prevalent in adolescents than in younger children. The variation in CFS prevalence estimates may result from variations in case definition, study methodology and application, study population composition (specialty vs general practice or general population), and data collection (parent, self-reporting vs clinician evaluation). Gender distribution in children differs from that in adults, with a more equal distribution in children <15 yr old, while remaining 2-3–fold higher in females 15-18 yr old. Few studies have reported the incidence of CFS among children <10 yr old, leading to uncertainty in this group. In adolescents in The Netherlands, the pediatrician-diagnosed incidence of CFS/ME was 0.01%, and in the United Kingdom, 0.5%.

Pathogenesis

Although etiology and pathophysiology of CFS are unknown, some patients and clinicians correlate the onset with a recent episode of a viral illness such as infectious mononucleosis (10–12%) (EBV; see Chapter 281). A pathophysiologic relationship of CFS to infection is suggested because the symptoms and biologic markers elicited by the nonspecific innate host responses to infections in general are present in CFS. CFS-like illness after infectious mononucleosis is not predicted by viremia or altered host response to EBV infection but is associated with the severity of the primary infection. A wide variety of other candidate viral infections have been associated with postinfectious fatigue syndromes, particularly in adolescents and adults. There are ongoing efforts to determine if infections with these or other agents may produce the illness.

Similarities between CFS symptoms and those experienced by patients with autoimmune and other inflammatory disorders suggests primary perturbation of immune function in the pathogenesis of CFS. Hypo- and hypergammaglobulinemia, immunoglobulin subclass deficiencies, elevated levels of circulating immune complexes, altered helper/suppressor lymphocyte ratios, natural killer cell dysfunction, elevated cytokines, and monocyte dysfunction have been reported in adult patients with CFS. These findings have not been consistent among studies. CFS patients as a group differ from healthy controls, but most laboratory values of the immune parameters are not outside the normal range.

Autonomic nervous system (ANS) changes are suggested by the **orthostatic intolerance** (OI) experienced by some patients with CFS. OI syndromes with circulatory dysfunction include **neutrally mediated hypotension** and **postural orthostatic tachycardia syndrome** (POTS) (see Chapter 147) have been observed in some patients with CFS and could contribute to the syndrome. The pathophysiology of these manifestations among adolescents with CFS is unclear, but in postinfectious states could be associated with unreplenished fluid and electrolyte losses associated with acute infection or immune-mediated injury (autoantibodies directed against ANS).

Because the widespread musculoskeletal pain in CFS is similar to **fibromyalgia** (see Chapter 193.3), and because some consider these to be overlapping syndromes, fibromyalgia and CFS may share similarities in pathogenesis. Other hypotheses under investigation for the biologic basis of CFS involve alterations in energy metabolism (e.g., mitochondrion, particularly as related to exercise intolerance and postexertion malaise), alterations in sleep, the stress response, hypothalamic-pituitary axis. Understanding CFS has proved so challenging because it likely represents more than 1 underlying pathophysiology. Current studies and guidelines are attempting to stratify or subgroup patients to address this possibility.

Clinical Manifestations

The dominant symptom expressed by adolescents and adults is a substantial reduction or impairment in the ability to engage in preillness levels of activity, accompanied by fatigue (see Fig. 147.1). In younger children, who often do not spontaneously report symptoms, exertion induces behavioral changes, manifested by a lack of their usual energy and reduced participation in activities. In adolescents, fatigue and postexertion malaise may lead to decreased participation in school, family activities, and social exchange.

Cognitive impairment includes reported difficulties in concentrating, which are common and indicated by reduced participation in school, difficulty keeping up with homework, and drop in grades. Sleep may be impaired, and nonrestorative sleep is common. Other sleep complaints include difficulty falling asleep and staying asleep, whereas diagnosed sleep disorders, including restless legs syndrome, parasomnias, and sleep apnea, are less common. Myalgia and arthralgia may accompany fatigue and altered sleep. Sore throat and cervical lymph node tenderness can occur but may be part of an inciting illness. Adolescents also have increased reports of headache, abdominal pain, nausea, and sensitivity to light and sound with amplified pain.

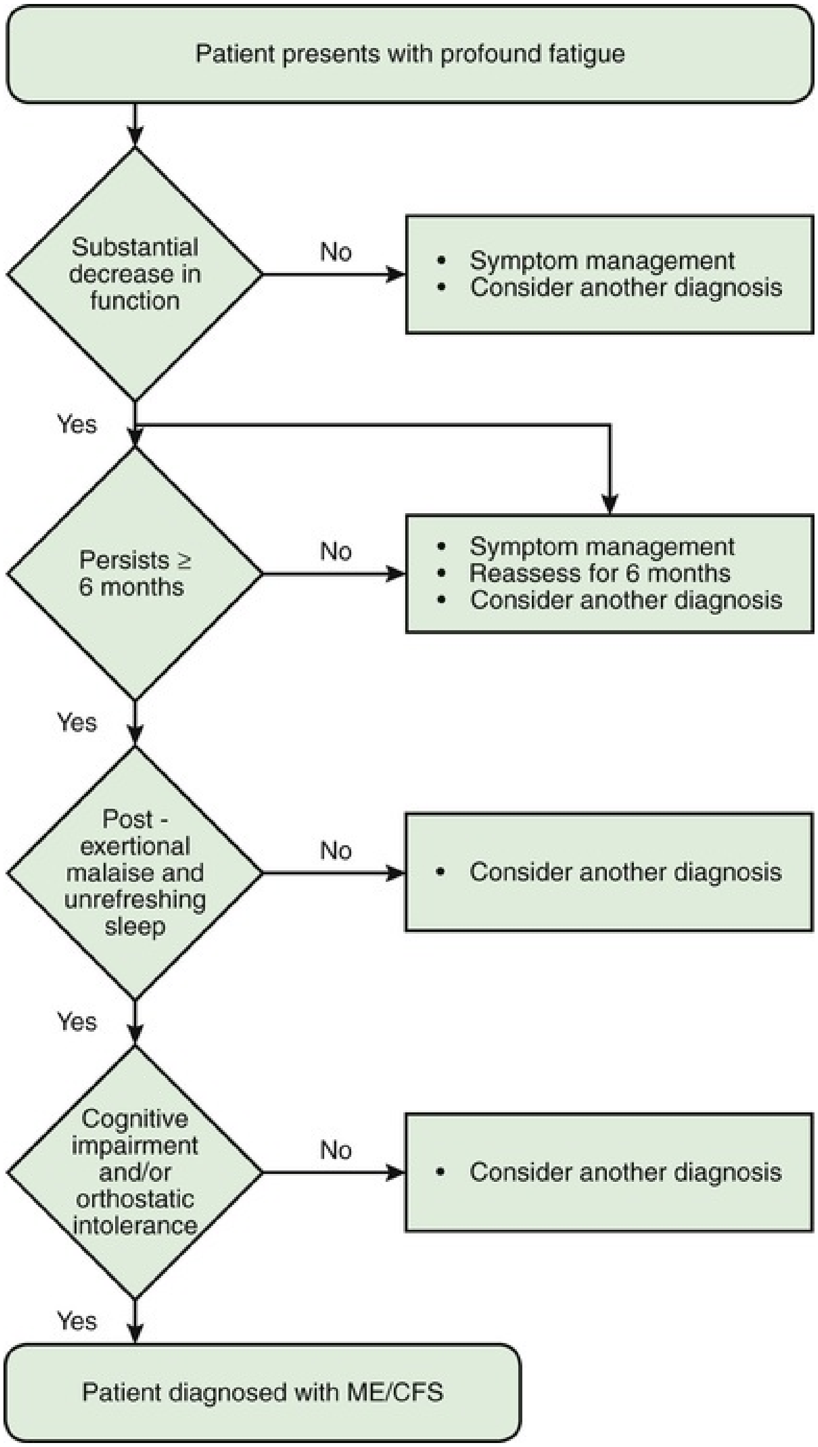
Patients diagnosed with CFS in primary care practices are more likely to report abrupt onset of their symptoms, often as part of an initial virus-like illness, whereas gradual onset is more common in those identified in population-based studies. School absenteeism is a major social issue. In one study, two thirds of adolescents missed >2 wk over a 6 wk observation period, and one third required home tutoring. Unlike school phobia, inactivity due to CFS persists on the weekends and during holidays the same as it does during the school week.

Although fatigue and accompanying symptoms are subjective, the magnitude of impairment of each component can be measured by questionnaires addressing pain and function or, in the case of suspected orthostatic instability, by recording routine supine and standing heart rate and blood pressure measurement's. Fatigue cannot be dismissed as a minor ailment. It generally manifests as lassitude, profound tiredness, intolerance of exertion with easy fatigability, and general malaise.

Abnormal physical examination findings are conspicuously absent, providing both reassurance and consternation for the patient, family, and physician. The presence of “alarm symptoms” such as weight loss, chest pain with exertion, paresthesia, dry mouth and eyes, fevers, diarrhea, cough, night sweats, and rash is uncommon and warrants consideration of a diagnosis other than CFS.

Diagnosis

There are no pathognomonic signs or diagnostic tests for CFS. The diagnosis is clinically defined based on inclusion and exclusion criteria (Fig. 147.2). The diagnostic criteria are applicable to adults and adolescents >11 yr old because of the current requirement for a self-generated history. Whereas duration of symptoms is 3- 6 mo, depending on age, symptom management should not wait until this criterion is met.



Patient presents with profound fatigue
Substantial decrease in function
No
Symptom management
Consider another diagnosis
Yes
Persists ≥ 6 months
No
Symptom management
Reassess for 6 months
Consider another diagnosis
Yes
Post - exertional malaise and unrefreshing sleep
No
Consider another diagnosis
Yes
Cognitive impairment and/or orthostatic intolerance
No
Consider another diagnosis
Yes
Patient diagnosed with ME/CFS

FIG. 147.2 **Diagnostic algorithm for myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS). (From Institute of Medicine: *Beyond myalgic encephalomyelitis/chronic fatigue syndrome: redefining an illness,* Washington, DC, 2015, National Academies Press.)**

CFS is difficult to diagnose in children, who may have difficulty describing their symptoms and articulating their concerns. Sole reliance on parental history can be fraught with confusion because parents may also struggle to interpret their children's symptoms and feelings in providing accurate historical information. A combination of child and parent reporting is most effective. It is important to document the child's activity levels and worsening of symptoms after physical or mental endeavors. Changes in participation in hobbies and family or other social activities can help identify the impact of CFS on function.

The diagnosis of CFS can be established only after other medical and psychiatric causes of fatigue and other symptoms, many of which are treatable, have been excluded. These include medical conditions presenting with chronic symptoms, such as hypothyroidism, adrenal insufficiency, respiratory and food allergies, sleep apnea, narcolepsy, substance abuse, posttraumatic stress disorder, adverse drug reactions, and obesity. A previously diagnosed medical condition with incomplete or uncertain resolution that may explain fatigue needs be considered.

Certain illnesses (e.g., fibromyalgia), amplified pain, and depression share similar symptoms with CFS but are not exclusionary diagnoses. These should be considered in the differential diagnosis in select cases. There is concern that CFS might be mistaken for readily identifiable psychiatric disorders such as anxiety and mood disorders, but evidence supports differences in their clinical presentation from CFS. CFS should not be diagnosed in persons with prior diagnosis of major depressive disorder with psychotic or melancholic features, bipolar affective disorders, schizophrenia of any subtype, delusional disorders of any subtype, dementia of any subtype, eating disorder of any type, or alcohol or other substance abuse within 2 yr before the onset of the chronic fatigue or any time thereafter.

Although evaluation of each patient should be individualized, initial laboratory evaluation should be limited to screening laboratory testing sufficient to provide reassurance of the lack of significant medical illness. Further evaluation should be directed primarily toward excluding treatable illnesses that may be suggested by the history, symptoms, signs, or physical exam findings present in specific patients.

Management

Management of CFS is based on relief of the core and most disruptive symptoms in the individual patient. The diagnostic criterion of 6 mo duration of illness should not delay evaluation and symptom management, since these may be initiated as soon as the child or adolescent presents with a CFS-like picture. Problems with sleep can be addressed by encouraging patients to adopt good sleep habits using standard sleep hygiene techniques. It may be beneficial to refer the patient to a sleep medicine specialist for the identification and treatment of sleep disorders and disturbances. Once pain is found not to be related to other specific disease of illness, nonpharmacologic treatment is indicated.

One of the nonpharmacologic approaches to pain management, **cognitive-behavioral therapy** (CBT), may also assist patient in managing and coping with CFS. Through explanation and changes in perception of the illness, CBT may help patients and their families develop coping skills and provide emotional support. Improved methods of coping may allow some improved function while living with the illness. Comorbid psychiatric conditions such as anxiety require appropriate evaluation and intervention. Guided graded-exercise therapy may be beneficial and added to CBT.

While the overall goal is to help patients with CFS tolerate activity, children and adolescents with CFS should limit physical or mental efforts that result in aggravated symptoms. Return to school should be initiated gradually and systematically with the goal return to full-time attendance. Home tutoring, cyberschool, and partial attendance can be interim steps. Parents and clinicians can work with teachers and school administrators to define appropriate expectations for attendance and performance for children with CFS. Because of the crucial importance of learning socialization skills, even brief attendance in school or participation in school activities should be encouraged, remembering that too rapid remobilization usually exacerbates symptoms and should be avoided.

Continued **empathy and support** by the treating physician are crucial in maintaining a physician–parent–patient relationship that is conducive to managing this illness. Careful attention must be directed to family dynamics to identify and resolve family problems or psychopathology that may be contributing to children's perception of their symptoms.

Prognosis

The natural history of CFS is highly variable, and patients and families understand that the symptoms will wax and wane. Children and adolescents with CFS appear to have a more optimistic outcome than adults, typically with an undulating course of gradual improvement over several years. Overall, a good functional outcome has been reported in up to 80% of patients. Poor prognostic factors include gradual onset, increased school absenteeism, lower socioeconomic status, chronic maternal health problems, and untreated comorbid individual and family psychiatric disorders. Favorable prognostic factors include patient control of the rehabilitation program, with continuing support from health professionals and family members, and improvement in orthostatic intolerance.

Chapter 148 Evaluation of Suspected Immunodeficiency

CHAPTER 148

Evaluation of Suspected Immunodeficiency

Kathleen E. Sullivan, Rebecca H. Buckley

Primary care physicians must have a high index of suspicion to diagnose immune system defects early enough to institute appropriate treatment before irreversible damage develops. Diagnosis can be difficult because most affected patients do not have abnormal physical features. The most typical manifestation of immunodeficiency in children is *recurrent sinopulmonary infections.* Although infections are common in children in general, an infection exceeding the expected frequency and usually involving multiple sites can suggest immunodeficiency. A single, severe, opportunistic, or unusual infection can also be the presentation of an immunodeficiency (Table 148.1). Increasingly recognized is the co-occurrence of autoimmune disease or inflammatory conditions and recurrent infections. Newborn screening for T-cell lymphopenia has been instituted in most states; this has led to the identification of some infants with immunodeficiency before any clear manifestations but is limited to T-cell deficiencies. Additional clues to immunodeficiency include failure to thrive with or without chronic diarrhea, persistent infections after receiving live vaccines, and chronic oral or cutaneous candidiasis (Tables 148.2 and 148.3).

Table 148.1

Predisposition to Specific Infections in Humans

PATHOGEN	PRESENTATION	AFFECTED GENE/CHROMOSOMAL REGION	COMMENTS
BACTERIA			
Streptococcus pneumoniae	Invasive disease	*IRAK4*, MyD88, *C1QA*, *C1QB*, *C1QC*, C4A^{+} C4B,	Also susceptible to other encapsulated bacteria

		C2, C3	
Neisseria	Invasive disease	C5, C6, C7, C8A, C8B, C8G, C9, properdin	Recurrent disease common
Burkholderia cepacia	Invasive disease not pulmonary colonization	*CYBB, CYBA, NCF1, NCF2*	Also susceptible to staphylococcal and fungal infections
Nocardia	Invasive disease	*CYBB, CYBA, NCF1, NCF2*	Also susceptible to staphylococcal and fungal infections
Mycobacteria	Usually nontuberculous mycobacteria	IL12B, IL12RB1, IKBKG, IFNGR1, IFNGR2, STAT1 (loss of function)	Also susceptible to *Salmonella typhi* infections
VIRUSES			
Herpes simplex virus	Herpes simplex encephalitis	*TRAF3, TRIF, TBK, UNC93B1, TLR3,* STAT1	Age of onset is typically outside the neonatal period.
Epstein-Barr virus	Severe infectious mononucleosis, hemophagocytic syndrome	*SH2DIA, XIAP, ITK, CD27, PRF1, STXBP2, UNC13D, LYST, RAB27A, STX11, AP3B1*	Fulminant infectious mononucleosis, malignant and nonmalignant lymphoproliferative disorders, dysgammaglobulinemia, autoimmunity
Papillomavirus	Warts	*RHOH, EVER1, EVER2, CXCR4, DOCK8, GATA2, STK4, SPINK5*	Warts are often progressive despite therapy.
Global susceptibility to viral infection	Severe, progressive viral infections	All types of severe combined immune deficiency, *IFNAR2*	Presentation depends on virus and infected organ
FUNGI			
Candida	Mucocutaneous candida	*AIRE*, STAT1 (gain of function), *CARD9*, STAT3, IL17F, IL17RC, IL17RA, *ACT1*	*AIRE* deficiency is associated with endocrinopathies, STAT1 (GOF) is associated with autoimmunity
Dermatophytes	Tissue invasion	*CARD9*	Autosomal recessive
Aspergillus	Deep infections	*CYBB, CYBA, NCF1, NCF2*	
Environmental fungi	Deep infections	*CYBB, CYBA, NCF1, NCF2, GATA2,* STAT1 (gain of function), *CD40L*	

Table 148.2

Characteristic Clinical Patterns in Some Primary Immunodeficiencies

FEATURES	DIAGNOSIS
IN NEWBORNS AND YOUNG INFANTS (0-6 mo)	
Hypocalcemia, unusual facies and ears, heart disease	22q11.2 deletion syndrome, DiGeorge anomaly
Delayed umbilical cord detachment, leukocytosis, recurrent infections	Leukocyte adhesion defect
Persistent thrush, failure to thrive, pneumonia, diarrhea	Severe combined immunodeficiency
Bloody stools, draining ears, atopic eczema	Wiskott-Aldrich syndrome
IN INFANTS AND YOUNG CHILDREN (6 mo to 5 yr)	
Recurrent staphylococcal abscesses, staphylococcal pneumonia with pneumatocele formation, coarse facial features, pruritic dermatitis	Hyper-IgE syndrome, PGM3 deficiency

Persistent thrush, nail dystrophy, endocrinopathies	Autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia
Short stature, fine hair, severe varicella	Cartilage hair hypoplasia with short-limbed dwarfism
Oculocutaneous albinism, recurrent infection, hemophagocytic syndrome	Chédiak-Higashi syndrome, Griscelli syndrome, Hermansky-Pudlak syndrome

Table 148.3

Clinical Aids to the Diagnosis of Immunodeficiency

Suggestive of B-Cell Defect (Humoral Immunodeficiency)

- Recurrent bacterial infections of the upper and lower respiratory tracts
- Recurrent skin infections, meningitis, osteomyelitis secondary to encapsulated bacteria *(Streptococcus pneumoniae. Haemophilus influenzae. Staphylococcus aureus. Neisseria meningitidis)*
- Paralysis after vaccination with live-attenuated poliovirus
- Reduced levels of immunoglobulins

Suggestive of T-Cell Defect (Combined Immunodeficiency)

- Systemic illness after vaccination with any live virus or bacille Calmette-Guérin (BCG)
- Unusual life-threatening complication after infection with benign viruses (giant cell pneumonia with measles; varicella pneumonia)
- Chronic oral candidiasis after age 6 mo
- Chronic mucocutaneous candidiasis
- Graft-versus-host disease after blood transfusion
- Reduced lymphocyte counts for age
- Low levels of immunoglobulins
- Absence of lymph nodes and tonsils
- Small thymus
- Chronic diarrhea
- Failure to thrive
- Recurrent infections with opportunistic organisms

Suggestive of Macrophage Dysfunction

Disseminated atypical mycobacterial infection, recurrent Salmonella infection
Fatal infection after BCG vaccination

Congenital Syndromes With Immunodeficiency

Ataxia-telangiectasia: ataxia, telangiectasia
Autoimmune polyglandular syndrome: hypofunction of 1 or more endocrine organs, chronic mucocutaneous candidiasis
Cartilage-hair hypoplasia: short-limbed dwarfism, sparse hair, neutropenia
Wiskott-Aldrich syndrome: thrombocytopenia, male gender, eczema
Chédiak–Higashi syndrome: oculocutaneous albinism, nystagmus, recurrent bacterial infections, peripheral neuropathies
DiGeorge syndrome (22q deletion syndrome): unusual facies, heart defect, hypocalcemia

Suggestive of Asplenia

Heterotaxia. complex congenital heart disease, Howell-Jolly bodies on blood smear, sickle cell anemia

From Kliegman RM, Lye PS, Bordini BJ, ET AL, editors: *Nelson pediatric symptom-based diagnosis*, Philadelphia, 2018, Elsevier, p 750.

With >300 distinct primary immunodeficiencies, in order to focus the diagnostic approach and appropriate testing. it is often useful to consider 5 categories: T-cell disorders, B-cell and antibody disorders, complement disorders, phagocytic disorders, and natural killer cell disorders (Table 148.4 and Fig. 148.1).

Table 148.4

Characteristic Features of Primary Immunodeficiency

CHARACTERISTIC	PREDOMINANT T-CELL DEFECT	PREDOMINANT B-CELL DEFECT	GRANULOCYTE DEFECT	CYTOLYTIC DEFECT	COM DEF
Age at onset of	Early onset, usually	Onset after maternal	Early onset most	Childhood onset	Onse

infection	2-6 mo	antibodies diminish, usually after 5-7 mo, later childhood to adulthood	frequently	generally	
Specific pathogens involved	Bacteria: common gram-positive and gram-negative bacteria and mycobacteria	Bacteria: pneumococci, streptococci, staphylococci, *Haemophilus*, *Campylobacter*, *Mycoplasma*	Bacteria: staphylococci, *Serratia*, *Salmonella*, mycobacteria	None usually	Bact enca orga C2, (FP, C3, C8,
	Viruses: CMV, EBV, adenovirus, parainfluenza 3, varicella, enterovirus	Viruses: enterovirus*	None generally	CMV, EBV	None
	Fungi: *Candida* and *Pneumocystis jiroveci*	Fungi and parasites: *Giardia*, Cryptosporidia	Fungi and parasites: *Candida*, *Nocardia*, *Aspergillus*	None generally	None
Affected organs	Extensive mucocutaneous candidiasis, lungs, failure to thrive, protracted diarrhea	Recurrent sinopulmonary infections, chronic gastrointestinal symptoms, malabsorption, arthritis, enteroviral meningoencephalitis*	Skin: abscesses, impetigo, cellulitis Lymph nodes: suppurative adenitis Oral cavity: gingivitis, mouth ulcers Internal organs: abscesses, osteomyelitis	Hemophagocytic syndrome can affect any organ.	Deep infec
Special features	Graft-vs-host disease caused by maternal engraftment or nonirradiated blood transfusion Postvaccination disseminated BCG or varicella Autoimmunity common in mild-moderate T-cell defects	Autoimmunity Lymphoreticular malignancy: lymphoma, thymoma	Prolonged attachment of umbilical cord, poor wound healing		SLE Glo (C3), hem synd MC

[*] X-linked (Bruton) agammaglobulinemia.

BCG, Bacille Calmette-Guérin; CMV, cytomegalovirus; EBV, Epstein-Barr virus; SLE, systemic lupus erythematosus.

FIG. 148.1 **Diagnostic testing algorithm for primary immunodeficiency diseases. Common clinical scenarios are listed at the *top.* The 1st tier of testing is listed below each category between the *dark lines.* The 2nd tier of testing is located below the 2nd *dark line.* CBC, Complete blood count; DHR, dihydrorhodamine; MAI, *Mycobacterium avium-intracellulare* infection.**

The initial evaluation of immunologic function includes a thorough history, physical examination, and family history (Table 148.5). Over 10 immunodeficiencies are X-linked, and a growing number are autosomal dominant with variable expressivity and/or incomplete penetrance. Close attention to physical signs of autoimmune disease or end-organ effects from recurrent infections should be noted. The history of infections should include the age of onset, severity, involved locations, and assessment of the underlying microbial cause. Viral, bacterial, fungal, and mycobacterial infections all require distinct arms of the immune system for eradication; therefore identification of microbiologic causes of infection can be extremely helpful in defining the deficiency states in people with primary immunodeficiencies.

Table 148.5

Special Physical Features Associated With Immunodeficiency Disorders

CLINICAL FEATURES	**DISORDERS**
DERMATOLOGIC	
Eczema	Wiskott-Aldrich syndrome, IPEX, hyper-IgE syndromes, hypereosinophilia syndromes, IgA deficiency
Sparse and/or hypopigmented hair	Cartilage-hair hypoplasia, Chédiak-Higashi syndrome, Griscelli syndrome
Ocular telangiectasia	Ataxia-telangiectasia
Oculocutaneous albinism	Chédiak-Higashi syndrome
Severe dermatitis	Omenn syndrome
Erythroderma	Omenn syndrome, SCID, graft-vs-host disease, Comel-Netherton syndrome
Recurrent abscesses with pulmonary pneumatoceles	Hyper-IgE syndromes
Recurrent organ granulomas or abscesses, lung, liver, and rectum especially	CGD
Recurrent abscesses or cellulitis	CGD, hyper-IgE syndrome, leukocyte adhesion defect
Cutaneous granulomas	Ataxia telangiectasia, SCID, CVID, RAG deficiency
Oral ulcers	CGD, SCID, congenital neutropenia
Periodontitis, gingivitis, stomatitis	Neutrophil defects
Oral or nail candidiasis	T-cell immune defects, combined defects (SCIDs); mucocutaneous candidiasis; hyper-IgE syndromes; IL-12, -17, -23 deficiencies; *CARD9* deficiency; STAT1 deficiency
Vitiligo	B-cell defects, mucocutaneous candidiasis
Alopecia	B-cell defects, mucocutaneous candidiasis
Chronic conjunctivitis	B-cell defects
EXTREMITIES	
Clubbing of nails	Chronic lung disease caused by antibody defects
Arthritis	Antibody defects, Wiskott-Aldrich syndrome, hyper-IgM syndrome
ENDOCRINOLOGIC	
Hypoparathyroidism	DiGeorge syndrome, mucocutaneous candidiasis
Endocrinopathies (autoimmune)	Mucocutaneous candidiasis
Diabetes, hypothyroid	IPEX and IPEX-like syndromes
Growth hormone deficiency	X-linked agammaglobulinemia
Gonadal dysgenesis	Mucocutaneous candidiasis
HEMATOLOGIC	
Hemolytic anemia	B- and T-cell immune defects, ALPS
Thrombocytopenia, small platelets	Wiskott-Aldrich syndrome
Neutropenia	Hyper-IgM syndrome, Wiskott-Aldrich variant, CGD
Immune thrombocytopenia	B-cell immune defects, ALPS
SKELETAL	
Short-limb dwarfism	Short-limb dwarfism with T- and/or B-cell immune defects
Bony dysplasia	ADA deficiency, cartilage-hair hypoplasia

ADA, Adenosine deaminase; ALPS, autoimmune lymphoproliferative syndrome; CGD, chronic granulomatous disease; CVID, common variable immunodeficiency; IPEX, X-linked immune dysfunction enteropathy polyendocrinopathy; SCID, severe combined immunodeficiency.

From Goldman L, Ausiello D: *Cecil textbook of medicine,* ed 22, Philadelphia, 2004, Saunders, p 1599.

Most immunologic defects can be excluded at minimal cost with the proper choice of screening tests, which should be broadly informative, reliable, and cost-effective (Table 148.6 and Figs. 148.2 and 148.3). A complete blood count

(CBC) with differential is the initial study if neutropenia is a consideration but is less recognized as a screening test for T-cell defects. Lymphopenia is seen the majority of T-cell defects. If an infant's neutrophil count is persistently elevated in the absence of any signs of infection, a leukocyte adhesion deficiency should be suspected. Normal lymphocyte counts are higher in infancy and early childhood than later in life (Fig. 148.4). Knowledge of normal values for absolute lymphocyte counts at various ages in infancy and childhood is crucial in the detection of T-cell defects. Additional clues from the CBC include absence of Howell-Jolly bodies, which argues against congenital asplenia. Normal platelet size or count excludes Wiskott-Aldrich syndrome. When immunodeficiency is suspected, obtaining IgG, IgA, IgM, and IgE levels can be a useful strategy, since antibody defects are the most common type of immunodeficiency. Immunoglobulin levels must be interpreted within the context of age-specific normative data.

Table 148.6

Initial Screening Immunologic Testing of the Child With Recurrent Infections

Complete Blood Count, Differential, and Erythrocyte Sedimentation Rate

Absolute lymphocyte count (normal result rules against T-cell defect)
Absolute neutrophil count (normal result rules against congenital or acquired neutropenia and [usually] both forms of leukocyte adhesion deficiency, in which elevated counts are present even between infections)
Platelet count (normal result excludes Wiskott-Aldrich syndrome)
Howell-Jolly bodies (absence rules against asplenia)
Erythrocyte sedimentation rate (normal result indicates chronic bacterial or fungal infection unlikely)

Screening Tests for B-Cell Defects

IgG, IgA, IgM (low in most antibody defects)
Isohemagglutinins (low in agammaglobulinemia)
Antibody titers tetanus, diphtheria, *Haemophilus influenzae* , and

pneumococcus (low in most antibody defects)

Screening Tests for T-Cell Defects

Absolute lymphocyte count (normal result indicates T-cell defect unlikely)

Flow cytometry to examine for the presence of naïve T cells ($CD3^+$ $CD45RA^+$ cells)

Screening Tests for Phagocytic Cell Defects

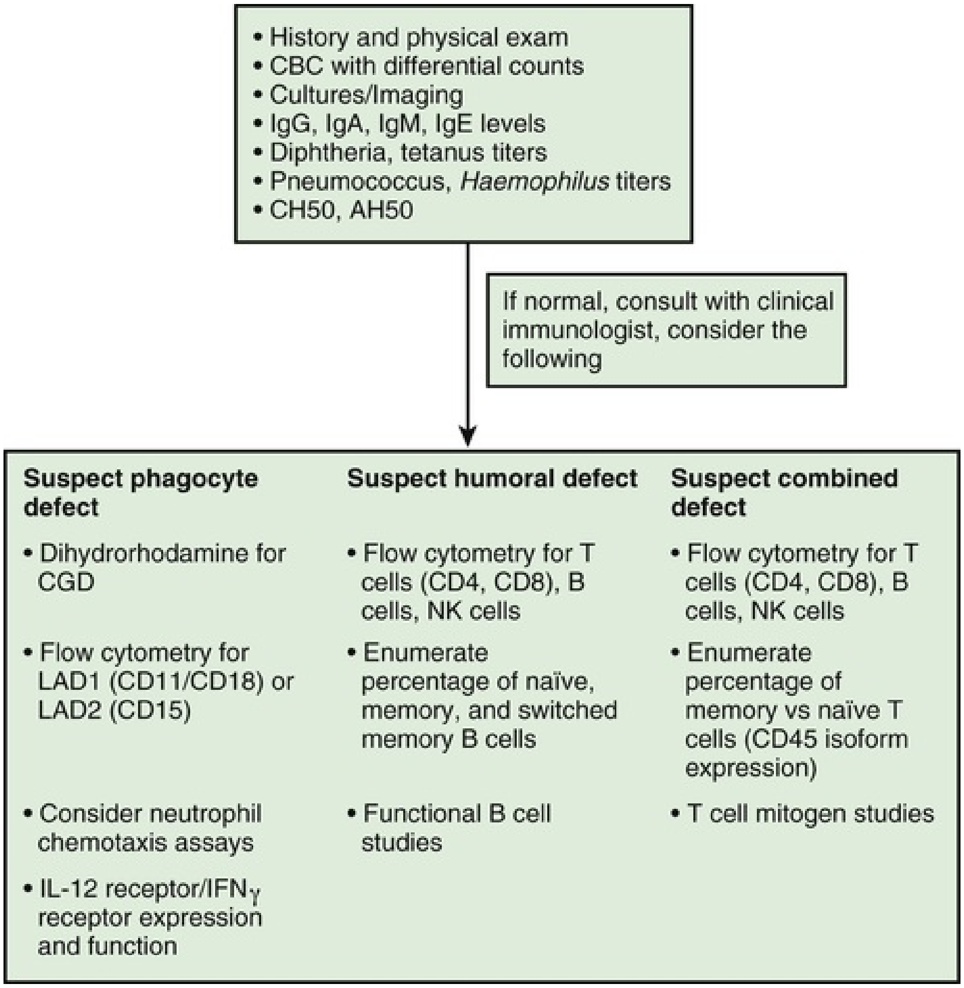
Microscopy (abnormal in some neutropenias)

Respiratory burst assay (abnormal in chronic granulomatous disease)

Screening Test for Complement Deficiency

CH_{50} (nearly absent in classical pathway and terminal component deficiencies)

AH_{50} (nearly absent in alternative pathway and terminal component deficiencies)



• History and physical exam
• CBC with differential counts
• Cultures/Imaging
• IgG, IgA, IgM, IgE levels
• Diphtheria, tetanus titers
• Pneumococcus, *Haemophilus* titers
• CH50, AH50
If normal, consult with clinical immunologist, consider the following
Suspect phagocyte defect
• Dihydrorhodamine for CGD
• Flow cytometry for LAD1 (CD11/CD18) or LAD2 (CD15)
• Consider neutrophil chemotaxis assays
• IL-12 receptor/IFN$_\gamma$ receptor expression and function
Suspect humoral defect
• Flow cytometry for T cells (CD4, CD8), B cells, NK cells
• Enumerate percentage of naïve, memory, and switched memory B cells
• Functional B cell studies
Suspect combined defect
• Flow cytometry for T cells (CD4, CD8), B cells, NK cells
• Enumerate percentage of memory vs naïve T cells (CD45 isoform expression)
• T cell mitogen studies

FIG. 148.2 Initial workup and follow-up studies of patients with suspected immunodeficiency. Consultation with a clinical immunologist is recommended to guide advanced testing and interpret results. CBC, Complete blood count; CGD, chronic granulomatous disease; LAD, leukocyte adhesion defect; NK, natural killer cell; IL, interleukin; IFN, interferon. (From Kliegman RM, Lye PS, Bordini BJ, et al, editors: *Nelson pediatric symptom-based diagnosis,* Philadelphia, 2018, Elsevier, p 753.)

FIG. 148.3 Algorithm for evaluating the most common deficiencies of cell-mediated immunity. ADA, Adenosine deaminase; PNP, purine nucleoside phosphorylase. (From Leung DYM, Szefler SJ, Bonilla FA, et al, editors: *Pediatric allergy: principles and practice,* ed 3, St Louis, 2016, Elsevier, p 68.)

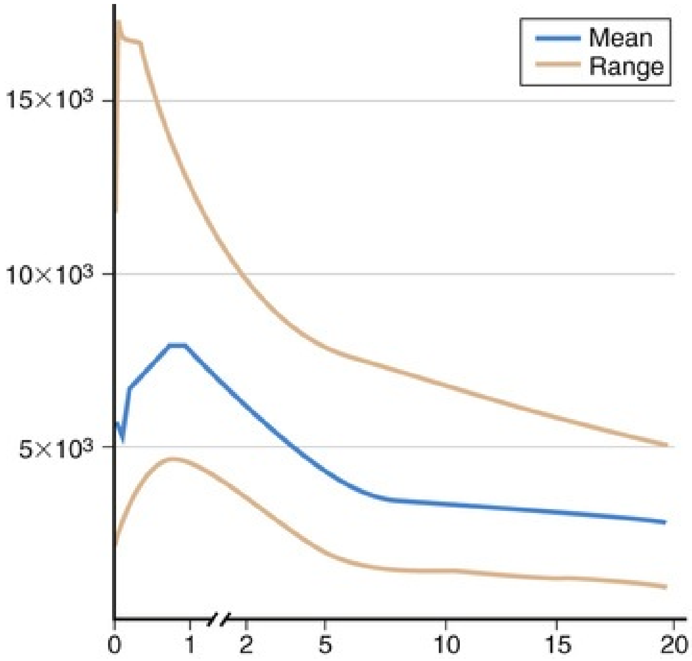

FIG. 148.4 Absolute lymphocyte counts in a normal individual during maturation. (Data graphed from Altman PL: *Blood and other body fluids.* Prepared under the auspices of the Committee on Biological Handbooks, Washington, DC, 1961, Federation of American Societies for Experimental Biology.)

Advanced Testing

Additional testing should be focused based on the phenotype and suspected category of immune deficiency (Table 148.7 ; see Figs. 148.2 and 148.3). For patients with recurrent sinopulmonary infections in whom an antibody defect is suspected, further attention to antibody testing may be revealing. In addition to Ig levels, responses to vaccines should also be pursued in this setting. A small but significant subset of patients with antibody deficiencies will have normal Ig levels but abnormal function, as detected by poor responses to vaccines. When hypogammaglobulinemia is identified, it is important to determine whether it is primary or secondary. Patients receiving corticosteroids or who have protein-losing states (nephrosis, protein-losing enteropathy) often have low serum IgG concentrations but produce normal responses to vaccines. Thus, if Ig levels are low, it is crucial before starting immune globulin replacement therapy that antibody titers to vaccines are measured. Antibody titers are not interpretable after the patient has received a blood transfusion, fresh-frozen plasma, or immune globulin therapy.

Table 148.7

Laboratory Tests in Immunodeficiency

SCREENING TESTS	ADVANCED TESTS	RESEARCH/SPECIAL TESTS
B-CELL DEFICIENCY		
IgG, IgM, IgA, and IgE levels	B-cell enumeration (CD19 or CD20)	Advanced B-cell phenotyping
Isohemagglutinin titers		Biopsies (e.g., lymph nodes)
Ab response to vaccine antigens (e.g., tetanus, diphtheria, pneumococci, *Haemophilus influenzae*)	Ab responses to boosters or to new vaccines	Ab responses to special antigens (e.g., bacteriophage φX174), mutation analysis
T-CELL DEFICIENCY		
Lymphocyte count	T-cell subset enumeration (CD3, CD4, CD8)	Advanced flow cytometry
Chest x-ray examination for thymic size*	Proliferative responses to mitogens, antigens, allogeneic cells	Enzyme assays (e.g., ADA, PNP)
TRECs	22q11.2 deletion analysis	Mutation analysis T-cell activation studies
PHAGOCYTIC DEFICIENCY		
WBC count, morphology	Adhesion molecule assays (e.g., CD11b/CD18, selectin ligand)	Mutation analysis Macrophage functional testing
Respiratory burst assay	Mutation analysis	
COMPLEMENT DEFICIENCY		
CH_{50} activity	AH_{50} , activity	Specific component assays

* In infants only.

Ab, Antibody; ADA, adenosine deaminase; C, complement; CH, hemolytic complement; G6PD, glucose-6-phosphate dehydrogenase; HLA, human leukocyte antigen; Ig, immunoglobulin; MPO, myeloperoxidase; NADPH, nicotinamide adenine dinucleotide phosphate; PNP, purine nucleoside phosphorylase; TRECs, T-cell receptor rearrangement excision circle; WBC, white blood cell; φX, phage antigen.

One useful test for B-cell function is to determine the presence and titer of **isohemagglutinins** , or natural antibodies to type A and B red blood cell polysaccharide antigens. This test measures predominantly IgM antibodies. Isohemagglutinins may be absent normally in the first 2 yr of life and are always absent if the patient is blood type AB.

Because most infants and children are immunized with diphtheria-tetanus-pertussis (dTP), conjugated *Haemophilus influenzae* type b, and pneumococcal conjugate vaccine, it is often informative to test for specific antibodies to diphtheria, tetanus, *H. influenzae* polyribose phosphate, and pneumococcal antigens. If the titers are low, measurement of antibodies to diphtheria or tetanus toxoids before and 2-8 wk after a pediatric dTP or dT booster is helpful in assessing the capacity to form IgG antibodies to protein antigens. To evaluate a patient's ability to respond to polysaccharide antigens, antipneumococcal antibodies can be measured before and 4-8 wk after immunization with 23-valent unconjugated pneumococcal polysaccharide vaccine in patients ≥2 yr old. Antibodies detected in these tests are of the IgG isotype. These antibody studies can be performed in several different laboratories, but it is important to choose a reliable laboratory and to use the same laboratory for pre- and postimmunization titers.

Patients with defective B-cell maturation due to a class-switching defects produce neither IgA nor IgG antibodies normally. IgM is normal or elevated. Vaccine responses are uniformly low. If antibody responses to vaccines are normal and the IgG level is low, studies should be performed to evaluate the possible loss of immunoglobulins through the urinary or gastrointestinal tract (nephrotic syndrome, protein-losing enteropathies, intestinal lymphangiectasia). Another common confounder is the use of rituximab or corticosteroids, leading to hypogammaglobulinemia. Very high serum concentrations of 1 or more Ig classes suggest HIV infection, chronic granulomatous disease, chronic inflammation, or autoimmune lymphoproliferative syndrome.

IgG subclass measurements are seldom helpful in assessing immune function in young children with recurrent infections. They are strongly developmentally regulated with highly variable production in early childhood. It is difficult to know the biologic significance of the various mild to moderate deficiencies of IgG subclasses, particularly when completely asymptomatic individuals have been described as totally lacking IgG1, IgG2, IgG4, and/or IgA1 because of Ign heavy-chain gene deletions. Many healthy children have been described as having low levels of IgG2 but normal responses to polysaccharide antigens when immunized. In older children and adults, a low IgG2 maybe an antecedent finding before evolving into **common variable immunodeficiency (CVID).** Specific vaccine responses are usually much more useful than IgG subclass determinations.

Patients found to be **agammaglobulinemic** should have their blood B cells enumerated by flow cytometry using dye-conjugated monoclonal antibodies to B-cell–specific CD antigens (usually CD19 or CD20). Normally, approximately 5–10% of circulating lymphocytes are B cells. B cells are absent in X-linked agammaglobulinemia (XLA) and in several very rare autosomal recessive conditions, but they are usually present in CVID, IgA deficiency, and hyper-IgM syndromes. This distinction is important, because children with hypogammaglobulinemia from XLA and CVID can have different clinical problems, and the 2 conditions clearly have different inheritance patterns. Patients with CVID have more problems with autoimmune diseases and lymphoid hyperplasia. Molecular testing for XLA and other B-cell defects (see Chapter 150.1) is indicated in cases without a family history to aid genetic counseling.

T cells and T cell subpopulations can be enumerated by flow cytometry using dye-conjugated monoclonal antibodies recognizing CD antigens present on T cells (i.e., CD2, CD3, CD4, and CD8). This is a particularly important test to perform on any infant who is lymphopenic, because $CD3^+$ T cells usually constitute 70% of peripheral lymphocytes. Regardless of molecular type, infants with SCID are unable to produce T cells, so are lymphopenic at birth. The flow cytometry for infants suspected of having SCID should also include monoclonal antibodies to naïve (CD45RA) and memory (CD45RO) T cells. In normal infants, >95% of the T cells are $CD45RA^+$ (naïve) T cells. If the infant has SCID, there could be transplacentally transferred maternal T cells detected by flow cytometry, but they would be predominantly $CD45RO^+$ T cells. SCID is a pediatric emergency that can be successfully treated by hematopoietic stem cell transplantation in more than 90% of cases if diagnosed before serious, untreatable infections develop. Normally, there are about twice as many $CD4^+$ (helper) T cells as there are $CD8^+$ (cytotoxic) T cells. Because some severe immunodeficiencies have phenotypically normal T cells, tests of T-cell function can be helpful. T cells can be stimulated directly with **mitogens** such as phytohemagglutinin, concanavalin A, or pokeweed mitogen. After 3-5 days of incubation with the mitogen, the proliferation of T cells is measured. Other stimulants that can be used to assess T-cell function in the same type of assay include antigens (*Candida,* tetanus toxoid) and allogeneic cells.

Natural killer (NK) cells can be enumerated by flow cytometry using monoclonal antibodies to NK-specific CD antigens, CD16 and CD56. NK function is assessed by killing of target cells and flow cytometry for CD107a, a marker of degranulation.

Chronic granulomatous disease should be suspected if a patient has recurrent staphylococcal abscesses or fungal infections. It can be evaluated by screening tests measuring the neutrophil respiratory burst after phorbol ester stimulation. **Leukocyte adhesion defects** (LAD) can be easily diagnosed by flow cytometric assays of blood lymphocytes or neutrophils, using monoclonal antibodies to CD18 or CD11 (LAD1) or to CD15 (LAD2). **Neutrophil defects** are most often associated with neutropenia or morphologic abnormalities visible by microscopy. Therefore, a combination of a CBC with differential, microscopic evaluation, and the flow cytometric approaches previously described often yields a diagnosis. The same is not true for **macrophage defects** , which are usually associated with susceptibility to mycobacteria, and testing requires advanced functional analyses or sequencing.

When invasive infection with encapsulated organisms or *Neisseria* leads to a suspicion of a complement defect, a **CH_{50} test** should be obtained. This bioassay measures the intactness of the entire complement pathway and yields abnormal results if classical pathway or terminal components are missing. Genetic deficiencies in the complement system often have a CH_{50} that is almost absent, although the most frequent cause of a slightly low CH50 is improper transport of the specimen. Complement proteins are highly labile and must be transported on ice. Specific factor assays are available at reference laboratories. Rare causes of neisserial susceptibility include alternative pathway defects, and the test for these deficiencies is the **AH_{50} test.** Identifying the specific component deficiency in the mode of inheritance is important for genetic counseling. Properdin deficiency is X-linked, and other deficiencies are autosomal recessive or autosomal dominant.

CHAPTER 149

Lymphocyte Development and Function

Kathleen E. Sullivan, Rebecca H. Buckley

Defense against infectious agents is secured through a combination of anatomic physical barriers, including the skin, mucous membranes, mucous blanket, and ciliated epithelial cells, and the components of the immune system. The **immune system** of vertebrates integrates 2 fundamental response mechanisms. **Innate (natural) immunity** is rapid and utilizes receptors encoded in the germline. The innate defenses comprise cell-intrinsic responses to viral infections, leukocyte responses to pathogens, and soluble mediators such as complement proteins. **Acquired (adaptive) immunity** is specific to T and B cells. These cells undergo DNA recombination to generate receptors and require an education process to minimize autoreactive cells. In addition, there are lymphocyte subsets that are innate in nature and either do not require DNA recombination or utilize a single recombination event to generate a monospecific receptor.

Lymphopoiesis in the Fetus

Pluripotential hematopoietic stem cells first appear in the yolk sac at 2.5-3 wk of gestational age, migrate to the fetal liver at 5 wk gestation, and later reside in the bone marrow, where they remain throughout life (Fig. 149.1). Lymphoid stem cells develop and differentiate into T, B, or natural killer (NK) cells, depending on the organs or tissues to which the stem cells traffic. Development of the **primary lymphoid organs** —thymus and bone marrow—begins during the middle of the 1st trimester of gestation and proceeds rapidly. Development of the **secondary lymphoid organs** —spleen, lymph nodes, tonsils, Peyer patches, and lamina propria—soon follows. These organs serve as sites of differentiation of T, B, and NK lymphocytes from stem cells throughout life. Both the initial organogenesis and the continued cell differentiation result from the interaction of a vast array of lymphocytic and microenvironmental cell surface molecules and proteins secreted by the involved cells. **Clusters of differentiation (CD)** refer to cellular protein (Table 149.1), whereas **cytokines** and **chemokines** refer to soluble mediators of immune function (Table 149.2).

Table 149.1

CD Classification of Some Lymphocyte Surface Molecules

CD Classification of Some Lymphocyte Surface Molecules

CD NUMBER	TISSUE/LINEAGE	FUNCTION
CD1	Cortical thymocytes; Langerhans cells	Lipid antigen presentation to TCRγδ cells
CD2	T and NK cells	Binds LFA-3 (CD58); alternative pathway of T-cell activation
CD3	T cells	TCR associated; transduces signals from TCR
CD4	T-helper cell subset	Receptor for HLA class II antigens; associated with p56 *Ick* tyrosine kinase
CD7	T and NK cells and their precursors	Mitogenic for T lymphocytes
CD8	Cytotoxic T-cell subset; also on 30% of NK cells	Receptor for HLA class I antigens; associated with p56 *Ick* tyrosine kinase
CD10	B-cell progenitors	Peptide cleavage
CD11a	T, B, and NK cells	With CD18, ligand for ICAMs 1, 2, and 3
CD11b, c	NK cells	With CD18, receptors for C3bi
CD16	NK cells	FcR for IgG
CD19	B cells	Regulates B-cell activation
CD20	B cells	Mediates B-cell activation
CD21	B cells	C3d, also the receptor for EBV; CR2
CD25	T, B, and NK cells	Mediates signaling by IL-2
CD34	Stem cells	Binds to L -selectin
CD38	T, B, and NK cells and monocytes	Associates with hyaluronic acid
CD40	B cells and monocytes	Initiates isotype switching in B cells when ligated
CD44	Bone marrow stromal and many other cells	Matrix adhesion molecule
CD45	All leukocytes	Tyrosine phosphatase that regulates lymphocyte activation; CD45R0 isoform on memory T cells, CD45RA isoform on naïve T cells
CD56	NK cells	Mediates NK homotypic adhesion
CD62L	Marker for recent thymic emigrants Also found on other leukocytes	Cell adhesion molecule
CD69	T cells and NK cells	Early activation marker
CD73	T and B cells	Associates with AMP
CD80	B cells	Co-stimulatory with CD28 on T cells to upregulate high-affinity IL-2 receptor
CD86	B cells	Co-stimulatory with CD28 on T cells to upregulate high-affinity IL-2 receptor
CD117	Pro-B cells, double-negative thymocytes	Receptor for stem cell factor
CD127	T cells	Mediates IL-7 signaling
CD132	T, B, and NK cells	Mediates signaling by IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21
CD154	Activated CD4$^+$ T cells	Ligates CD40 on B cells and initiates isotype switching
CD278	T cells	Interacts with B7-H2

AMP, Adenosine monophosphate; EBV, Epstein-Barr virus; ICAMs, intracellular adhesion molecules; IL, interleukin; LFA, leukocyte function–activating antigen; NK, natural killer; TCR, T-cell receptor.

Table 149.2

Common Cytokines

CATEGORY	CYTOKINE	FUNCTION
Interferons	IFN-α	Antiviral defense
	IFN-β	Antiviral defense
	IFN-γ	Antiviral defense
Innate responses	TNF	Regulates endothelial adhesion molecules for recruitment of neutrophils; activates macrophages for killing
	IL-1β	Drives the inflammatory response, fever
	IL-12	Polarizes T cells toward Th1; activates NK cells
Lymphocyte regulation	IL-2	Key growth factor for T cells
	IL-4	Polarizes T cells toward Th2
	IL-6	Growth factor for B cells
	IL-7	T-cell homeostatic factor
	IL-10	Growth factor for B cells, immunosuppressive
	IL-12	Polarizes T cells toward Th1, activates NK cells
	IL-17	Polarizes T cells toward Th17, stimulates antimicrobial peptide expression
	IL-21	Supports B-cell class switching

IL, Interleukin; NK, natural killer; Th, T-helper cell; TNF, tumor necrosis factor.

T-Cell Development and Differentiation

The primitive thymic rudiment is formed from the ectoderm of the 3rd branchial cleft and endoderm of the 3rd branchial pouch at 4 wk gestation. Beginning at 7-8 wk, the right and left rudiments fuse in the midline. Bloodborne T-cell precursors from the fetal liver then begin to colonize the perithymic mesenchyme at 8 wk gestation and move into the thymus at 8.0-8.5 wk. The earliest cells to enter the thymus are found in the subcapsular region and do not express CD3, CD4, CD8, or either type of T-cell receptor (TCR). These lymphoid cell precursors are triggered to proliferate and become thymocytes through interactions with the thymic stroma. The cells are arrested at this stage until they productively rearrange the β-chain locus of the TCR. The β chain then pairs with the surrogate pre-T α chain. This tests the function of the β chain, and if signaling occurs, β-chain rearrangement ceases. CD4 and CD8 are then expressed simultaneously (i.e., they are double-positive thymocytes). Fetal cortical thymocytes are among the most rapidly dividing cells in the body and increase in number by 100,000-fold within 2 wk after stem cells enter the thymus. As these cells proliferate and mature, they migrate deeper into the thymic cortex. The double-positive thymocytes begin efficient rearrangement of the α-chain locus. TCR gene rearrangement occurs by a process in which large, noncontiguous blocks of DNA are spliced together. **V (variable)** , **D (diversity)** , and **J (joining)** blocks exist in families of minimally different segments. Random combinations of the segments account for much of the enormous diversity of TCRs that enables humans to recognize millions of different antigens. TCR gene rearrangement requires the presence of **recombinase-activating genes** , *RAG1* and *RAG2,* as well as other recombinase components.

As immature cortical thymocytes begin to express TCRs, the processes of positive and negative selection take place. **Positive selection** occurs in immature thymocytes, recognizing major histocompatibility complex (MHC) antigens present on cortical thymic epithelial cells. Some cells are selected to mature into CD4 or CD8 single-positive cells. **Negative selection** occurs next in the thymic medulla on medullary thymic epithelial cells. Autoreactive T cells undergo apoptosis and die. T cells begin to emigrate from the thymus to the spleen, lymph nodes, and appendix at 11-12 wk of embryonic life and to the tonsils by 14-15 wk. They leave the thymus via the bloodstream and are distributed throughout the body, with the heaviest concentrations in the paracortical areas of lymph nodes, the periarteriolar areas of the spleen, and the thoracic lymph duct. Recent thymic emigrants co-express the CD45RA isoforms and CD62L (L -selectin).

Rearrangement of the TCR locus during intrathymic T-cell development results in the excision of DNA and the excised elements form circular episomes as a by-product. These **TCR recombination excision circles** can be detected in T cells that are recent thymic emigrants. TCR recombination excision circles detected in dried-blood spots collected from infants shortly after birth is the test used for newborn screening for severe combined immunodeficiency (SCID). By 12 wk gestation, T cells can proliferate in response to plant lectins, such as phytohemagglutinin and concanavalin A. Antigen-specific T cells have been found by 20 wk gestation. **Hassall corpuscles (bodies),** which are swirls of terminally differentiated medullary epithelial cells, are first seen in the thymic medulla at 16-18 wk of embryonic life.

B-Cell Development and Differentiation

B-cell development begins in the fetal liver by 7 wk gestation. Fetal liver CD34 stem cells are seeded to the bone marrow of the clavicles by 8 wk of embryonic life and to that of the long bones by 10 wk (see Fig. 149.1). As B cells differentiate from primitive stem cells, they proceed through stages that are marked by the sequential rearrangement of immunoglobulin gene segments to generate a diverse repertoire of antigen receptors. The early **pro-B cell** is the first descendent of the pluripotential stem cell committed to B-lineage development, and in this stage the heavy chain locus rearranges first. In the early pro-B cell, D-J rearrangements are made on both chromosomes. In the late pro-B cell, the V segment rearranges to a D-J gene segment. The next stage is the **pre-B cell** , during which immunoglobulin (Ig) light-chain genes are rearranged. The **pre-B cell** is distinguished by the expression of cytoplasmic μ heavy chains but no **surface** IgM (sIgM), because Ig light chains are not yet produced. Next is the **immature B-cell** stage, during which the light-chain genes have already been rearranged, and sIgM but not sIgD is expressed. Immature B cells leave the bone marrow for secondary lymphoid organs. The last stage of antigen-independent B-cell development is the **mature naïve B cell,** which co-expresses both sIgM and sIgD. Pre-B cells can be found in fetal liver at 7 wk gestation, sIgM+ and sIgG+ B cells at 7-11 wk, and sIgD+ and sIgA+ B cells by 12-13 wk. By 14 wk of embryonic life, the percentage of circulating lymphocytes bearing sIgM and sIgD is the same as in cord blood and slightly higher than in the blood of adults.

Antigen-dependent stages of B-cell development are those that develop after the mature B cell is stimulated by antigen in secondary lymphoid organs**.** Once antigen stimulation has occurred, the mature B cells can become memory B cells or plasmablasts. Both outcomes require the presence of T-cell help.

There are 5 **immunoglobulin isotypes** , which are defined by unique heavy chains: IgM, IgG, IgA, IgD, and IgE. IgG and IgM, the only complement-fixing isotypes, are the most important immunoglobulins in the blood and other internal body fluids for protection against infectious agents. IgM is confined primarily to the intravascular compartment because of its large size, whereas IgG is present in all internal body fluids. IgA is the major protective immunoglobulin of external secretions—in the gastrointestinal, respiratory, and urogenital tracts—but it is also present in the circulation. IgE, present in both internal and external body fluids, has a major role in host defense against parasites. Because of high-affinity IgE receptors on basophils and mast cells, however, IgE is the principal mediator of allergic reactions of the immediate type. The significance of IgD is still not clear. There are also **immunoglobulin subclasses** , including 4 subclasses of IgG (IgG1, IgG2, IgG3, and IgG4) and 2 subclasses of IgA (IgA1 and IgA2). These subclasses each have different biologic roles. Secreted IgM and IgE have been found in as young as 10 wk gestation, and IgG as early as 11-12 wk.

Even though these B-cell developmental stages have been described in the context of B-cell ontogeny in utero, it is important to recognize that the process of B-cell development from pluripotential stem cells goes on throughout postnatal life. Plasma cells are not usually found in lymphoid tissues of a fetus until about 20 wk gestation, and then only rarely, because of the sterile environment of the uterus. Intestinal lymphoid development occurs relatively late. Peyer patches have been found in significant numbers by the 5th intrauterine mo, and plasma cells have been seen in the lamina propria by 25 wk gestation. Before birth there may be primary follicles in lymph nodes, but secondary follicles are usually not present.

A human fetus begins to receive significant quantities of maternal IgG transplacentally at around 12 wk gestation, and the quantity steadily increases until, at birth, cord-blood serum contains a concentration of IgG comparable to or greater than that of maternal serum. IgG is the only class to cross the placenta to any significant degree. All 4 IgG subclasses cross the placenta, but IgG2 does so least well. A small amount of IgM (10% of adult levels) and a few nanograms of IgA, IgD, and IgE are normally found in cord blood serum. Because none of these proteins crosses the placenta, they are presumed to be of fetal origin. These observations suggest that certain antigenic stimuli normally cross the placenta to provoke responses, even in uninfected fetuses. Some atopic infants occasionally have IgE antibodies to antigens, such as egg white, to which they have had no known exposure during postnatal life, suggesting that synthesis of these antibodies could have been induced in the fetus by antigens ingested by the mother.

Natural Killer–Cell Development

NK cell activity is found in human fetal liver cells at 8-11 wk of gestation. NK lymphocytes are also derived from bone marrow precursors. Thymic processing is not necessary for NK-cell development, although NK cells have been found in the thymus. After release from bone marrow, NK cells enter the circulation or migrate to the spleen, with very few NK cells in lymph nodes. In normal individuals, NK cells represent 8–10% of lymphocytes. Certain tissues harbor large numbers of NK cells.

Unlike T and B cells, NK cells do not rearrange antigen receptor genes during their development but are defined by their functional capacity to mediate non–antigen-specific cytotoxicity. NK cells have killer inhibitory receptors that recognize certain MHC antigens and inhibit the killing of self tissues. NK-activating receptors recognize stress protein, and the balance of activating and inhibitory receptor engagement determines the action of the NK cells. If a viral infection drives down MHC class I expression, the loss of inhibitory function drives cytotoxicity. High levels of stress proteins, typically seen in viral infections, can also activate cytotoxicity.

Lymphocyte Choreography

The main functions of T cells are to signal B cells to make antibody, to kill virally infected cells or tumor cells, and to activate macrophages for intracellular killing. The subset of **regulatory T cells** (Tregs), is critical in the prevention of autoimmune responses. T cells are activated by antigen presented by **antigen-presenting cells (APCs)** . These are usually dendritic cells, macrophages, or B cells. For high-affinity binding of T cells to APCs, several molecules on T cells, in addition to TCRs, bind to molecules on APCs or target cells. The CD4 molecule binds directly to MHC class II molecules on APCs. CD8 on cytotoxic T cells binds the MHC class I molecule on the target cell. Lymphocyte function–associated antigen 1 (**LFA-1**) on the T cell binds a protein called **ICAM-1** (intracellular adhesion molecule 1), designated **CD54** , on APCs. CD2 on T cells binds LFA-3 (CD58) on the APCs. With the adhesion of T cells to APCs (the immunologic synapse), **T-helper (Th)** cells are stimulated to make interleukins and upregulate cell surface molecules, such as the CD40 ligand (CD154), that provide help for B cells, and cytotoxic T cells are stimulated to kill their targets. A key safety net to ensure appropriate activation of T cells in the setting of a true threat is the requirement for co-stimulation of the T cells. APCs that have encountered a pathogen express CD80 and CD86. Engagement of these molecules provides the 2nd, co-stimulatory, signal. Without co-stimulation, the T cell will be rendered *anergic*, or nonfunctional.

In the **primary antibody response** , native antigen is carried to a lymph node draining the site, captured by complement, taken up by specialized cells called **follicular dendritic cells (FDCs)** , and expressed on their surfaces. Mature B cells bearing sIgM specific for that antigen then bind to the antigen on the surfaces of the FDCs. If the affinity of the B-cell sIgM antibody for the antigen present on the FDCs is sufficient, and if other signals are provided by activated T cells, the B cell develops into a memory B cells or antibody-producing plasma cell. The signals from activated T cells include several cytokines (IL-4, IL-5, IL-

6, IL-10, IL-13, and IL-21) that they secrete (see Table 149.2) and a surface T-cell molecule, the CD40 ligand or CD154, which, on contact of the activated $CD4^+$ T cell with the B cell, binds to CD40 on the B-cell surface. Binding of CD40 on B cells by CD154 on T cells in the presence of certain cytokines causes the B cells to undergo proliferation and to initiate immunoglobulin synthesis. In the primary immune response, only IgM antibody is usually made, and most of it is of relatively low affinity. Some B cells become memory B cells during the primary immune response. The **secondary antibody response** occurs when these memory B cells again encounter that antigen. Developing memory B cells switch their Ig genes so that IgG, IgA, and/or IgE antibodies of higher affinity are formed on a secondary exposure to the same antigen. Plasma cells form, just as in the primary response; however, many more cells are rapidly generated, and IgG, IgA, and IgE antibodies are made. In addition, genetic changes in Ig genes (somatic hypermutation) lead to increased affinity of those antibodies.

The exact pattern of isotype response to antigen in normal individuals varies, depending on the type of antigen and the cytokines present in the microenvironment. Both class switching and somatic hypermutation are completely dependent on T-cell help. Thus, T cells represent a kind of gatekeeper for specific antibody production.

Postnatal Lymphocyte Behavior

Virtually all T cells in cord blood bear the CD45RA (naïve) isoform, and a dominance of CD45RA over CD45RO T cells persists during childhood. After mid-adulthood, the CD45RO (memory) T cells predominate. CD4 T cells can be further subdivided according to the cytokines they produce when activated. **Th1 cells** produce interleukin (IL)-2 and interferon (IFN)-γ, which promote cytotoxic T-cell or delayed hypersensitivity types of responses, whereas **Th2 cells** produce IL-4, IL-5, IL-6, IL-13, and IL-21 (see Table 149.2), which promote B-cell responses and allergic sensitization, **Th17** cells produce IL-17, and **Tregs** produce IL-10 (Fig. 149.2). Differentiation into these memory subsets is dictated by the cytokine milieu regulating specific transcription factors and epigenetic changes. In vivo, these subsets are largely stable but in some circumstances can change to a different subset. The importance of these subsets is that memory cells respond to antigen more quickly and are primed to produce the cytokines most likely to drive pathogen clearance.

APC, Antigen-presenting cell; IFN, interferon; IL, interleukin; Th, T-helper cell; TFH, follicular helper T cell; TGF, transforming growth factor; TNF, tumor necrosis factor.

Newborn infants have increased susceptibility to infections with gram-negative organisms because IgM antibodies, powerful **opsonins** that enhance phagocytosis, do not cross the placenta. The other major opsonin, C3b, is also lower in newborn serum than in adults. These factors probably account for impaired phagocytosis of some organisms by newborn polymorphonuclear cells. Maternally transmitted IgG antibodies serve quite adequately for most gram-positive bacteria, and IgG antibodies to viruses offer protection against those agents. Because there is a relative deficiency of the IgG2 subclass in infancy, antibodies to capsular polysaccharide antigens may be deficient. Because premature infants have received less maternal IgG by the time of birth than full-term infants, their serum opsonic activity is low for all types of organisms.

Neonates begin to synthesize antibodies of the IgM class at an increased rate very soon after birth in response to the immense antigenic stimulation of their new environment. Premature infants appear to be as capable of doing this as are full-term infants. At about 6 days after birth, the serum concentration of IgM rises sharply. This rise continues until adult levels are achieved by approximately 1 yr of age. Cord serum from noninfected normal newborns does not contain detectable IgA. Serum IgA is normally first detected at around the 13th day of postnatal life but remains low throughout infancy. Cord serum contains an IgG concentration comparable to or greater than that of maternal serum. Maternal

IgG gradually disappears during the 1st 6-8 mo of life, while the rate of infant IgG synthesis increases (IgG1 and IgG3 faster than IgG2 and IgG4 during the 1st yr) until adult concentrations of total IgG are reached and maintained by 7-8 yr. IgG1 and IgG4 reach adult levels first, followed by IgG3 at 10 yr and IgG2 at 12 yr. The serum IgG level in infants usually reaches a low point at about 3-4 mo of postnatal life. The rate of development of IgE generally follows that of IgA.

After adult concentrations of each of the 3 major immunoglobulins are reached, these levels remain remarkably constant for a normal individual. The capacity to produce specific antibodies to protein antigens is intact at birth, but infants cannot usually produce antibodies to polysaccharide antigens until after 2 yr of age unless the polysaccharide is conjugated to a protein carrier, as is the case for the conjugate *Haemophilus influenzae* type b and *Streptococcus pneumoniae* vaccines.

The percentage of NK cells in cord blood is usually lower than in the blood of children and adults, but the absolute number of NK cells is approximately the same because of the higher lymphocyte count. The capacity of cord blood NK cells to mediate target lysis in either NK-cell assays or antibody-dependent cellular cytotoxicity assays is about two-thirds that of adults.

Lymphoid Organ Development

Lymphoid tissue is proportionally small but rather well developed at birth and matures rapidly in the postnatal period. The thymus is largest relative to body size during fetal life and at birth is ordinarily two-thirds its mature weight, which it attains during the 1st yr of life. It reaches its peak mass, however, just before puberty, then gradually involutes thereafter. By 1 yr of age, all lymphoid structures are mature histologically. Absolute lymphocyte counts in the peripheral blood also reach a peak during the 1st yr of life (see Fig. 149.2). The spleen, however, gradually accrues its mass during maturation and does not reach full weight until adulthood. The mean number of Peyer patches at birth is one-half the adult number, and gradually increases until the adult mean number is exceeded during adolescent years.

Inheritance of Abnormalities in T-, B-, and NK-Cell Development

More than 300 immunodeficiency syndromes have been described. Specific molecular defects have been identified for most diseases. Most are recessive traits with X-linked, autosomal dominant loss of function, and autosomal dominant gain of function also is seen. Defects include those associated with absence of a cell type, either a lineage (e.g., absence of T cells in SCID), absence of a subset of cells (e.g., absence of Tregs in immune dysregulation, polyendocrinopathy, X-linked syndrome), or dysfunction of a cell (e.g., the hemophagocytic lymphohistiocytosis disorders). In some cases, multiple cell types are affected, and in some syndromes, excess of a certain cell type or function disrupts the critical balance needed for immune homeostasis.

CHAPTER 150

Primary Defects of Antibody Production

Kathleen E. Sullivan, Rebecca H. Buckley

Of the primary immunodeficiency diseases, those affecting antibody production are the most prevalent. Selective absence of IgA is the most common defect, with rates ranging from 1 in 333 to 1 in 18,000 persons among different races and ethnicities. Patients with antibody deficiency are usually recognized because they have recurrent infections with encapsulated bacteria, predominantly in the upper and lower respiratory tracts. Some individuals with selective IgA deficiency or infants with transient hypogammaglobulinemia may have few or no infections. These conditions have a complex and likely polygenic inheritance, as do the common variable immunodeficiency (CVID) syndromes. The gene defects for many primary antibody deficiency disorders have been identified (Table 150.1) and localized (Fig. 150.1). Sometimes the defect is not in the B cell itself but in T cells, which are required for complete B-cell function. Some disorders are caused by unknown factors or are secondary to an underlying disease or its treatment (Table 150.2).

Table 150.1

Genetic Basis of the Most Common Primary Antibody Deficiency Disorders

GENE	PHENOTYPE	DISORDER
BAFFR	CVID	Hypogammaglobulinemia
CD19	CVID	Hypogammaglobulinemia
CD20	CVID	Hypogammaglobulinemia
CD21	CVID	Hypogammaglobulinemia
CD81	CVID	Hypogammaglobulinemia
CTLA4	CVID	Hypogammaglobulinemia, pronounced lymphoproliferation and autoimmunity
ICOS	CVID	Hypogammaglobulinemia, autoimmunity, neoplasia

LRBA	CVID	Hypogammaglobulinemia, pronounced lymphoproliferation and autoimmunity
NFKB2	CVID	Hypogammaglobulinemia, autoimmunity
NFKB1	CVID	Hypogammaglobulinemia, autoimmunity
PIK3CD	CVID	Hypogammaglobulinemia, adenopathy
PI3KR1 (AD)	CVID	Hypogammaglobulinemia
TNFRSF13B	CVID	Hypogammaglobulinemia, low penetrance of disease
Unknown	CVID	Hypogammaglobulinemia, autoimmunity Majority of patients with CVID have no known gene defect.
Unknown	IgG subclass deficiency	Variable association with infection
Unknown	Specific antibody deficiency	Normal immunoglobulin levels with poor vaccine responses
Unknown	Transient hypogammaglobulinemia of infancy	Vaccine responses are usually preserved, and most children outgrow this by age 3 yr.
Unknown	Selective IgA deficiency	Low or absent IgA; low concentrations of all immunoglobulins and of switched memory B cells in CVID
BLNK	Agammaglobulinemia	Absence of antibody production, lack of B cells
BTK	Agammaglobulinemia	Absence of antibody production, lack of B cells, X-linked agammaglobulinemia
CD79A	Agammaglobulinemia	Loss of the Igα required for signal transduction, absence of antibody production, lack of B cells
CD79B	Agammaglobulinemia	Loss of the Igβ required for signal transduction, absence of antibody production, lack of B cells
IGHM	Agammaglobulinemia	Loss of the Ig heavy chain, absence of antibody production, lack of B cells
IGLL1	Agammaglobulinemia	Loss of the surrogate light chain, absence of antibody production, lack of B cells
PI3KR1 (AR)	Agammaglobulinemia	Loss of signal transduction through the B-cell receptor, absence of antibody production, lack of B cells
TCF3	Agammaglobulinemia	Loss of a key transcription factor for B-cell development, absence of antibody production, lack of B cells
AID	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies
CD40	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies, *Pneumocystis* and *Cryptosporidium* susceptibility
CD154	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies, *Pneumocystis* and *Cryptosporidium* susceptibility
INO80	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies
MSH6	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies, malignancy
UNG	Class switch defect	Failure to produce IgG, IgA, and IgE antibodies
SH2D1A	X-linked lymphoproliferative disease	Various phenotypes including hypogammaglobulinemia
XIAP	X-linked lymphoproliferative disease	Various phenotypes including hypogammaglobulinemia
CD27	EBV lymphoproliferation	Memory B-cell deficiency Hypogammaglobulinemia
NEMO	Anhidrotic ectodermal dysplasia with immunodeficiency	Phenotype highly variable but includes specific antibody deficiency and CVID

FIG. 150.1 The pre-B cell receives proliferation and differentiation signals through the pre–B-cell receptor (BCR) and the co-receptors Igα and Igβ. Signaling from the pre-BCR involves the immunoreceptor tyrosine-based activation motifs (ITAMs) of the co-receptors Igα and Igβ, which scaffold and activate the tyrosine kinase SYK. SYK either activates the extracellular signal–regulated kinase (ERK) pathway or phosphorylates (P) (together with LYN) the adaptor protein B-cell linker (BLNK) and Bruton tyrosine kinase (BTK), leading to the activation of phospholipase Cγ2 (PLCγ2) and the phosphoinositide-3 kinase (PI3K) pathway. Defects in this pathway affect the pre-BCR (in Cμ or pseudo light-chain λ5), the pre-BCR signal transduction molecules Igα and Igβ, the downstream molecules BTK, BLNK, and PI3K, components of the co-stimulatory CD19 complex (CD19, CD21, and CD81), and the B-cell marker CD20. The BCR triggers the canonical nuclear factor-κB (NF-κB) pathway through the scaffolding protein CARD11 and activation of the IκB kinase (IKK) complex (comprising IKKα, IKKβ, and NEMO [NF-κB essential modulator]). IKK activation leads to the phosphorylation and degradation of NF-κB inhibitor-α (IκBα) and the subsequent release of the p50-p65 NF-κB heterodimer, which then translocates to the nucleus to regulate gene transcription (*not shown*). Following antigen binding to antigen receptors (e.g., BCR), endoplasmic reticulum Ca^{2+} stores are depleted, STIM1 is activated, and ORAI1 Ca^{2+} release-activated Ca^{2+} channels open, resulting in store-operated Ca^{2+} entry. This influx results in activation of the transcription factor NFAT (nuclear factor of activated T cell). The *dashed arrows* indicate downstream signaling events. ER, Endoplasmic reticulum; PAD, primary antibody deficiency; PtdIns(4,5)P_2 , phosphatidylinositol-4,5-bisphosphate; PtdIns(3,4,5)P_3 , phosphatidylinositol-3,4,5-trisphosphate. Table 150.2

Other Conditions Associated With Humoral Immunodeficiency

GENETIC DISORDERS	
T-cell defects	Most T-cell defects can have a secondary deficit in immunoglobulin.
Complex syndromes	Transcobalamin II deficiency and hypogammaglobulinemia, Wiskott-Aldrich syndrome, ataxia telangiectasia, etc.
Chromosomal anomalies	Chromosome 18q− syndrome 22q11.2 deletion Trisomy 8, trisomy 21
SYSTEMIC DISORDERS	
Malignancy	Chronic lymphocytic leukemia Immunodeficiency with thymoma T-cell lymphoma
Metabolic or physical loss	Immunodeficiency caused by hypercatabolism of immunoglobulin
	Immunodeficiency caused by excessive loss of immunoglobulins and lymphocytes
ENVIRONMENTAL EXPOSURES	
Drug induced	Antimalarial agents Captopril Carbamazepine Glucocorticoids Fenclofenac Gold salts Imatinib Penicillamine Phenytoin Sulfasalazine
Infectious diseases	Congenital rubella Congenital infection with cytomegalovirus Congenital infection with *Toxoplasma gondii* Epstein-Barr virus Human immunodeficiency virus

X-Linked Agammaglobulinemia

Patients with X-linked agammaglobulinemia (**XLA**), or **Bruton agammaglobulinemia** , have a profound defect in B-lymphocyte development resulting in severe hypogammaglobulinemia, an absence of circulating B cells, small to absent tonsils, and no palpable lymph nodes.

Genetics and Pathogenesis

The abnormal gene in XLA maps to q22 on the long arm of the X chromosome and encodes the B-cell protein tyrosine kinase **Btk** (Bruton tyrosine kinase). Btk is a member of the Tec family of cytoplasmic protein tyrosine kinases and is expressed at high levels in all B-lineage cells, including pre-B cells. Some pre-B cells are found in the bone marrow, but the percentage of peripheral blood B lymphocytes is <1%. The percentage of T cells is increased, ratios of T-cell subsets are normal, and T-cell function is intact. The thymus is normal.

Seven **autosomal recessive defects** have also been shown to result in **agammaglobulinemia with an absence of circulating B cell** s (see Table 150.1), including mutations in the genes encoding (1) the μ heavy chain gene; (2) the Igα and (3) Igβ signaling molecules; (4) B-cell linker adaptor protein (BLNK); (5) the surrogate light chain, λ5/14.1; (6) leucine-rich repeat-containing 8 (LRRC8); and (7) the p85α subunit of phosphatidylinositol-3 kinase. These are rare but are clinically indistinguishable from the X-linked form.

Clinical Manifestations

Most boys afflicted with XLA remain well during the first 6-9 mo of life by virtue of maternally transmitted IgG antibodies. Thereafter, they acquire infections with extracellular pyogenic organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae,* unless they are given prophylactic antibiotics or immunoglobulin therapy. Infections include sinusitis, otitis media, pneumonia, or, less often, sepsis or meningitis. Infections with *Mycoplasma* are also particularly problematic. Chronic fungal infections are seen; *Pneumocystis jiroveci* pneumonia rarely occurs. Viral infections are usually handled normally, with the exceptions of hepatitis viruses and enteroviruses. There were several examples of **paralysis** when live polio vaccine was administered to these patients, and chronic, eventually fatal, central nervous system (CNS) infections with various echoviruses and coxsackieviruses have occurred in a significant number of patients. An enterovirus-associated **myositis** resembling dermatomyositis has also been observed. **Neutropenia** , typically seen at diagnosis when infected, can be associated with *Pseudomonas* or staphylococcal infections.

Diagnosis

The diagnosis of XLA should be suspected if **lymphoid hypoplasia** is found on physical examination (minimal or no tonsillar tissue and no palpable lymph nodes), and serum concentrations of IgG, IgA, IgM, and IgE are far below the 95% confidence limits for appropriate age- and race-matched controls; total immunoglobulins are usually <100 mg/dL. Levels of natural antibodies to type A and B red blood cell polysaccharide antigens (isohemagglutinins) and antibodies to antigens given during routine immunizations are abnormally low in XLA, whereas they are typically normal in transient hypogammaglobulinemia of infancy. Flow cytometry is an important test to demonstrate the **absence of circulating B cells** , which will distinguish XLA from most types of CVID, the hyper-IgM syndrome, and transient hypogammaglobulinemia of infancy.

Common Variable Immunodeficiency

CVID is a syndrome characterized by hypogammaglobulinemia. Serum IgG must be <2 standard deviations below the age-adjusted norms, with low IgA and or IgM levels. CVID patients may appear similar clinically to those with XLA in the types of infections experienced and bacterial etiologic agents involved, except that enterovirus meningoencephalitis is rare in patients with CVID (Table 150.3). In contrast to XLA, the sex distribution in CVID is almost equal, the age at onset is later, and infections may be less severe. CVID is the most common of the antibody defects.

Table 150.3

Main Phenotypes of Primary Antibody Deficiencies

PHENOTYPE	MAIN CLINICAL FEATURES	MAIN B-CELL FEATURES
Agammaglobulinemia	Bacterial infections (in respiratory tract) and enterovirus infections	Absence of CD19 B cells
Combined variable immunodeficiency (CVID)	Bacterial infections (in respiratory tract and gut), autoimmunity, cancer, and increased risk of granuloma	Highly variable; may see decreased memory B cells
Class switch defects	Bacterial and opportunistic infections	Decreased frequency of memory B cells
Selective IgA deficiency	Most often asymptomatic	Normal
IgG subclass deficiency	Frequent bacterial infections; diagnosis after age 2 yr	B-cell subsets normal
Selective polysaccharide antibody deficiency	Bacterial infections (after age 2 yr)	Normal IgG (including IgG2 and IgG4) levels, normal B-cell subsets

Genetics and Pathogenesis

CVID is a phenotypic diagnosis with a polygenic inheritance in most cases.

Genes known to produce the CVID phenotype when mutated include *ICOS* (inducible co-stimulator) deficiency, *SH2DIA* (responsible for X-linked lymphoproliferative disease [XLP]), *CD19*, *CD20*, *CD21*, *CD81*, *BAFF-R* (B-cell–activating factor of the tumor necrosis factor family of receptors), *TACI* (transmembrane activator, calcium modulator, and cyclophilin ligand interactor). These mutations in aggregate account for <10% of all cases of CVID. With rare exceptions, management of CVID does not depend on a genetic diagnosis. In the setting of atypical infections or autoimmunity, pursuing a genetic diagnosis can be useful because some genetic etiologies can have a poor prognosis and transplantation should be considered.

Despite normal numbers of circulating B cells in many patients and the presence of lymphoid cortical follicles, blood B cells from CVID patients do not differentiate normally into immunoglobulin-producing cells. They may have a deficiency of switched memory B cells.

Clinical Manifestations

The serum immunoglobulin and antibody deficiencies in CVID are associated with recurrent sinopulmonary infections. Repeated pulmonary infections may produce bronchiectasis. Sepsis and meningitis with encapsulated bacteria occur more frequently than in the general population. Patients with recurrent infections as their only manifestation typically have a normal life expectancy and do well with immunoglobulin replacement. The presence of autoimmune disease or lymphoproliferation confers a poor prognosis. Patients with CVID often have autoantibody formation and normal-sized or enlarged tonsils and lymph nodes; about 25% of patients have splenomegaly. CVID has also been associated with a spruelike enteropathy with or without nodular lymphoid hyperplasia of the intestine. Other autoimmune diseases include alopecia areata, hemolytic anemia, thrombocytopenia, gastric atrophy, achlorhydria, and pernicious anemia. Lymphoid interstitial pneumonia, intestinal lung disease, pseudolymphoma, B-cell lymphomas, amyloidosis, and noncaseating sarcoid-like granulomas of the lungs, spleen, skin, and liver also occur. There is an increased risk of lymphomas.

Selective IgA Deficiency

An isolated absence or near absence (<5 mg/dL) of serum and secretory IgA is the most common well-defined immunodeficiency disorder, with a disease frequency as high as 0.33% in some populations. Patients may be asymptomatic or may develop sinopulmonary or gastrointestinal (GI) infections (especially *Giardia*). IgA deficiency is also associated with celiac disease and autoimmune disorders. The diagnosis cannot be made until about 4 yr of age, when IgA levels should be matured to adult levels.

The basic defect resulting in IgA deficiency is unknown. Phenotypically normal blood B cells are present. This defect also often occurs in pedigrees containing individuals with CVID. Indeed, IgA deficiency may evolve into CVID. IgA deficiency is noted in patients treated with the same drugs associated with producing CVID (phenytoin, D -penicillamine, gold, and sulfasalazine), suggesting that environmental factors may trigger this disease in a genetically susceptible person.

Clinical Manifestations

Infections occur predominantly in the respiratory, GI, and urogenital tracts. Bacterial agents responsible are the same as in other antibody deficiency syndromes. Intestinal giardiasis is common. Serum concentrations of other immunoglobulins are usually normal in patients with selective IgA deficiency, although IgG2 (and other) subclass deficiency has been reported.

Serum antibodies to IgA are reported in as many as 44% of patients with selective IgA deficiency. These antibodies can cause nonhemolytic transfusion reactions. Washed erythrocytes (frozen blood would have this done routinely) or blood products from other IgA-deficient individuals should be administered to patients with IgA deficiency. Many intravenous immune globulin (IVIG) preparations contain sufficient IgA to cause reactions. However, administration of IVIG, which is >99% IgG, is not indicated because most IgA-deficient patients make IgG antibodies normally.

IgG Subclass Deficiencies

Some patients have deficiencies of 1 or more of the 4 subclasses of IgG despite normal or elevated total IgG serum concentration. Some patients with absent or very low concentrations of IgG2 also have IgA deficiency. Other patients with IgG subclass deficiency have gone on to develop CVID, suggesting that the presence of IgG subclass deficiency may be a marker for more generalized immune dysfunction. The biologic significance of the numerous moderate deficiencies of IgG subclasses that have been reported is difficult to assess. IgG subclass measurement is not cost-effective in evaluating immune function in the child with recurrent infection. The more relevant issue is a patient's capacity to make specific antibodies to protein and polysaccharide antigens, because profound deficiencies of antipolysaccharide antibodies have been noted even in the presence of normal concentrations of IgG2. IVIG should not be administered to patients with IgG subclass deficiency unless they are shown to have a deficiency of antibodies to a broad array of antigens.

Immunoglobulin Heavy- and Light-Chain Deletions

Some completely asymptomatic individuals have been documented to have a total absence of IgG1, IgG2, IgG4, and/or IgA1 as a result of gene deletions. These patients illustrate the importance of assessing specific antibody formation before deciding to initiate IVIG therapy in IgG subclass–deficient patients.

Transient Hypogammaglobulinemia of Infancy

A common laboratory finding in infants, transient hypogammaglobulinemia represents developmental delay in the production of immunoglobulin. It is thought to occur in as many as 1 : 1000 children. Most infants begin to produce IgG in the 1st 3 mo of life, and the quantity produced increases throughout infancy. For reasons incompletely understood, a small number of infants either begin late or do not increases their production as expected. This condition will resolve with no intervention but represents a source of diagnostic confusion. A key distinction is that responses to vaccines are usually preserved in this condition, whereas in the others, responses will be low to absent.

Class Switch Defects

The **hyper-IgM syndrome** is genetically heterogeneous and characterized by normal or elevated serum IgM levels associated with low or absent IgG, IgA, and IgE serum levels, indicating a defect in the class switch recombination (CSR) process. Causative mutations have been identified in the CD40 ligand gene on the X chromosome and 3 genes on autosomal chromosomes: the activation-induced cytidine deaminase (**AID**) gene, the uracil DNA glycosylase gene (**UNG**), and the **CD40** gene on chromosome 20. Distinctive clinical features permit presumptive recognition of the type of mutation in these patients, thereby aiding proper choice of therapy. All such patients should undergo molecular analysis to ascertain the affected gene for purposes of genetic counseling, carrier detection, and decisions regarding definitive therapy.

X-Linked Hyper-IgM Caused by Mutations in CD40 Ligand Gene

X-linked hyper IgM is caused by mutations in the gene that encodes the CD40 ligand (CD154, CD40L), which is expressed on activated T-helper (Th) cells. Boys with this syndrome have very low serum concentrations of IgG and IgA, with a usually normal or sometimes elevated concentration of polyclonal IgM; may or may not have small tonsils; usually have no palpable lymph nodes; and often have profound neutropenia.

Genetics and Pathogenesis

The B cells are actually normal in this condition; the defect is in the T cells. CD40L is the ligand for CD40, which is present on B cells and monocytes. CD40L is upregulated on activated T cells. Mutations result in an inability to signal B cells to undergo isotype switching, and thus the B cells produce only IgM. The failure of T cells to interact with B cells through this receptor-ligand pair also causes a failure of upregulation of the B-cell and monocyte surface molecules CD80 and CD86 that interact with CD28/CTLA4 on T cells, resulting in failure of “crosstalk” between immune system cells.

Clinical Manifestations

Similar to patients with XLA, boys with the CD40 ligand defect become symptomatic during the 1st or 2nd yr of life with recurrent pyogenic infections, including otitis media, sinusitis, pneumonia, and tonsillitis. They have marked susceptibility to *P. jiroveci* pneumonia and can be neutropenic. Lymph node histology shows only abortive germinal center formation with severe depletion and phenotypic abnormalities of follicular dendritic cells. These patients have normal numbers of circulating B lymphocytes, but a decreased frequency of CD27+ memory B cells. Circulating T cells are also present in normal number and in vitro responses to mitogens are normal, but there is decreased antigen-specific T-cell function. In addition to opportunistic infections such as *P. jiroveci* pneumonia, there is an increased incidence of extensive verruca vulgaris lesions, *Cryptosporidium* enteritis, subsequent liver disease, and an increased risk of malignancy.

Treatment

Because of the poor prognosis, the treatment of choice is an HLA-identical hematopoietic stem cell transplant at an early age. Alternative treatment for this condition is monthly infusion of IVIG. In patients with severe neutropenia, the use of granulocyte colony-stimulating factor has been beneficial.

Autosomal Recessive Hyper-IgM

Genetics and Pathogenesis

In contrast to patients with the CD40L defect, B cells from these patients are not able to switch from IgM-secreting to IgG-, IgA-, or IgE-secreting cells, even when co-cultured with normal T cells. The defects are all B cell intrinsic. The most common autosomal recessive defect in a gene that encodes AID. AID deaminates cytosine into uracil in targeted DNA, which is followed by uracil removal by UNG. Severely impaired CSR was found in 3 hyper-IgM patients reported to have UNG deficiency. Their clinical characteristics were similar to those with AID deficiency, with increased susceptibility to bacterial infections and lymphoid hyperplasia. Histologic examination of the enlarged lymph nodes reveals the presence of giant germinal centers (5-10 times > normal) filled with highly proliferating B cells. Autosomal recessive hyper-IgM can be caused by defects in CD40. Clinical manifestations included recurrent sinopulmonary infections, *P. jiroveci* pneumonia, and *Cryptosporidium parvum* infections, very similar to the manifestations seen in X-linked hyper IgM syndrome.

Clinical Manifestations

Concentrations of serum IgG, IgA, and IgE are very low in AID, UNG, and CD40 deficiencies. In contrast to the CD40 ligand defect, however, the serum

IgM concentration in patients with AID deficiency is usually markedly elevated and polyclonal. Patients with AID and UNG mutations have lymphoid hyperplasia, are generally older at age at onset, do not have susceptibility to *P. jiroveci* pneumonia, often do have isohemagglutinins, and are much less likely to have neutropenia unless it occurs on an autoimmune basis. They have a tendency, however, to develop autoimmune and inflammatory disorders, including diabetes mellitus, polyarthritis, autoimmune hepatitis, hemolytic anemia, immune thrombocytopenia, Crohn disease, and chronic uveitis.

Treatment and Prognosis

With early diagnosis and monthly infusions of IVIG, as well as good management of infections with antibiotics, patients with AID and UNG mutations generally have a more benign course than do boys with the CD40L or CD40 defects. CD40 deficiency is rare but appears to mimic the manifestations of CD40L quite closely.

X-Linked Lymphoproliferative Disease

There are two types of X-linked lymphoproliferative disease (Table 150.4). They have distinct clinical features but share a susceptibility to **Epstein-Barr virus (EBV)** and the development of **hemophagocytic lymphohistiocytosis (HLH)** .

Table 150.4

Features of SAP (SH2D1A) and XIAP Deficiency

FEATURE	SAP DEFICIENCY (XLP)	XIAP DEFICIENCY
CLINICAL MANIFESTATIONS		
HLH	Yes	Yes
Hypogammaglobulinemia	Yes	Yes
Lymphoma	Yes	No
Aplastic anemia	Yes	No
Vasculitis	Yes	No
GENETICS		
Causative gene	*SH2D1A*	*XIAP*
Genetic locus	Xq25	Xq25
Encoded protein	SAP	XIAP
Effect of mutation	Reduced, absent protein expression	Reduced, absent or truncated protein
IMMUNE CELL FUNCTIONS		

Natural killer T (NKT) cell cytotoxicity/degranulation	Reduced	Normal
NKT cell number (blood)	Absent	Variable
Restimulation-induced death	Reduced	Increased
Memory B-cell numbers	Reduced	Not reported
TREATMENT OPTIONS		
HLH	Immunosuppression and/or chemotherapy (etoposide) Consideration of rituximab	Immunosuppression and/or chemotherapy (etoposide)
Humoral deficiency	Intravenous IgG infusions	Consider rituximab for EBV-positive cases Intravenous IgG infusions
Lymphoma	Standard chemotherapy	
Curative therapy	Stem cell transplantation	Stem cell transplantation

EBV, Epstein-Barr virus; HLH, hemophagocytic lymphohistiocytosis; SAP, SLAM-associated protein; XIAP, X-linked inhibitor of apoptosis protein.

From Rezaei N, Mahmoudi E, Aghamohamadi A, et al: X-linked lymphoproliferative syndrome: a genetic condition typified by the triad of infection, immunodeficiency and lymphoma, *Br J Haematol* 152:14, 2010.

Genetics and Pathogenesis

The defective gene in **XLP type I** was localized to Xq25, cloned, and the gene product was initially named SAP (SLAM-associated protein), but is now known officially as SH2D1A. SLAM (signaling lymphocyte activation molecule) is an adhesion molecule that is upregulated on both T and B cells with infection and other stimulation. The absence of SH2D1A can lead to an uncontrolled cytotoxic T-cell immune response to EBV. The SH2D1A protein associates permissively with 2B4 on natural killer (NK) cells; thus selective impairment of 2B4-mediated NK-cell activation also contributes to the immunopathology of XLP.

XLP type 2 is caused by a mutation in *XIAP* (X-linked inhibitor of apoptosis protein). Disease manifestations are similar to XLP. The precise role of this protein in the susceptibility to EBV has not been elucidated.

Clinical Manifestations

Affected males are usually healthy until they acquire EBV infection. The mean age of presentation is <5 yr. There are 3 major clinical phenotypes: (1) fulminant, often fatal, infectious mononucleosis (50% of cases); (2) lymphomas, predominantly involving B-lineage cells (25%); and (3) acquired hypogammaglobulinemia (25%). A less common manifestation is CNS vasculitis. There is a marked impairment in production of antibodies to the EBV nuclear antigen, whereas titers of antibodies to the viral capsid antigen have ranged from absent to greatly elevated. XLP has an unfavorable prognosis. Unless there is a family history of XLP, diagnosis before the onset of complications is difficult because affected individuals are asymptomatic initially.

In 2 pedigrees reported, boys in one arm of each pedigree were diagnosed with CVID, whereas those in the other arms had fulminant infectious mononucleosis. The family members with CVID never gave a history of infectious mononucleosis. All affected members of each pedigree had the same distinct *SH2D1A* mutation, however, despite the different clinical phenotypes. Because the *SH2D1A* mutation was the same but the phenotype varied in these families, XLP should be considered in all males with a diagnosis of CVID, particularly if there is more than 1 male family member with this phenotype.

150.1

Treatment of B-Cell Defects

Kathleen E. Sullivan, Rebecca H. Buckley

Except for the CD40 ligand defect and XLP, for which stem cell transplantation is recommended, judicious use of antibiotics to treat documented infections and regular administration of immunoglobulin are the only effective treatments for primary B-cell disorders. The most common forms of replacement therapy are either intravenous or subcutaneous immune globulin (IVIG or SCIG). Broad antibody deficiency should be carefully documented before such therapy is initiated. The rationale for the use of IVIG or SCIG is to provide missing antibodies, not to raise the serum IgG or IgG subclass level. The development of safe and effective immunoglobulin preparations is a major advance in the treatment of patients with severe antibody deficiencies, although it is expensive and there have been national shortages. Almost all commercial preparations are isolated from normal plasma by the Cohn alcohol fractionation method or a modification of it. Cohn fraction II is then further treated to remove aggregated IgG. Additional stabilizing agents such as sugars, glycine, and albumin are added to prevent reaggregation and protect the IgG molecule during lyophilization. The ethanol used in preparation of immunoglobulin inactivates HIV, and an organic solvent/detergent step inactivates hepatitis B and C viruses. Some preparations are also nanofiltered to remove infectious agents. Most commercial lots are produced from plasma pooled from 10,000 to 60,000 donors and therefore contain a broad spectrum of antibodies. Each pool must contain adequate levels of antibody to antigens in various vaccines, such as tetanus and measles. However, there is no standardization based on titers of antibodies to more clinically relevant organisms, such as *S. pneumoniae* and *H. influenzae* type b.

The IVIG and SCIG preparations available in the United States have similar efficacy and safety. Rare transmission of hepatitis C virus has occurred in the past, but this has been resolved by the additional treatment step. There has been no documented transmission of HIV by any of these preparations. *IVIG or SCIG at a dose of 400 mg/kg per month* achieves trough IgG levels close to the normal range. Higher doses are indicated in patients with chronic or severe respiratory infections. Systemic reactions may occur, but rarely are these true anaphylactic reactions. Neutropenia associated with B-cell defects has responded to granulocyte colony-stimulating factor.

CHAPTER 151

Primary Defects of Cellular Immunity

Kathleen E. Sullivan, Rebecca H. Buckley

Defects in cellular immunity, historically referred to *T-cell defects,* comprise a large number of distinct immune deficiencies. The manifestations usually include prolonged viral infections, opportunistic fungal or mycobacterial infections, and a predisposition to autoimmunity. To facilitate conceptualization of this large and complex category, this chapter describes immunodeficiencies where the defect primarily affects T cells and those where the defect alters function of many cell types. Chapter 152.1 describes severe combined immunodeficiency (SCID). These disorders are further approached clinically by considering whether or not nonhematologic features are present.

Chromosome 22Q11.2 Deletion Syndrome

Chromosome 22q11.2 deletion syndrome is the most common of the T-cell disorders, occurring in about 1 in 3,000 births in the United States. Chromosome 22q11.2 deletion disrupts development of the 3rd and 4th pharyngeal pouches during early embryogenesis, leading to hypoplasia or aplasia of the thymus and parathyroid glands. Other structures forming at the same age are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, congenital heart disease (conotruncal, atrial, and ventricular septal defects), a short philtrum of the upper lip, hypertelorism, an antimongoloid slant to the eyes, mandibular hypoplasia, and posteriorly rotated ears (see Chapters 98 and 128). The diagnosis is often first suggested by hypocalcemic seizures during the neonatal period.

Genetics and Pathogenesis

Chromosome 22q11.2 deletions occur with high frequency because complex repeat sequences that flank the region represent a challenge for DNA polymerase. This condition is inherited in an autosomal dominant fashion and occurs with comparable frequency in all populations. Within the deleted region, haplosufficiency for the TBX1 transcription factor appears to underlie the majority of the phenotype. The phenotype is highly variable; a subset of patients has a phenotype that has also been called **DiGeorge syndrome** , **velocardiofacial syndrome** , or **conotruncal anomaly face syndrome** .

Variable hypoplasia of the thymus occurs in 75% of the patients with the deletion, which is more frequent than total aplasia; aplasia is present in <1% of patients with 22q11.2 deletion syndrome. Slightly less than half of patients with complete thymic aplasia are hemizygous at chromosome 22q11.2. Approximately 15% are born to diabetic mothers. Another 15% of infants have no identified risk factors. Approximately one third of infants with complete DiGeorge syndrome have **CHARGE association** (*c* oloboma, *h* eart defect, choanal *a* tresia, growth or developmental *r* etardation, *g* enital hypoplasia, and *e* ar anomalies including deafness). Mutations in the chromodomain helicase DNA-binding protein 7 (CHD7) gene on chromosome 8q12.2 are found in approximately 60–65% of individuals with CHARGE syndrome; a minority have mutations in *SEMA3E* .

Absolute lymphocyte counts are usually only moderately low for age. The CD3 T-cell counts are variably decreased in number, corresponding to the degree of thymic hypoplasia. Lymphocyte responses to mitogen stimulation are absent, reduced, or normal, depending on the degree of thymic deficiency. Immunoglobulin levels are often normal, but there is an increased frequency of IgA deficiency, low IgM levels, and some patients develop progressive hypogammaglobulinemia.

Clinical Manifestations

Children with partial thymic *hypoplasia* may have little trouble with infections and grow normally. Patients with thymic *aplasia* resemble patients with SCID in their susceptibility to infections with low-grade or opportunistic pathogens, including fungi, viruses, and *Pneumocystis jiroveci* , and to graft-versus-host disease from nonirradiated blood transfusions. Patients with complete DiGeorge syndrome can develop an atypical phenotype in which oligoclonal T-cell populations appear in the blood associated with rash and lymphadenopathy. These atypical patients appear phenotypically similar to patients with **Omenn syndrome** or maternal T-lymphocyte engraftment.

It is critical to ascertain in a timely manner whether an infant has thymic aplasia, because this disease is fatal without treatment. A T-cell count should be obtained on all infants born with primary hypoparathyroidism, CHARGE syndrome, and conotruncal cardiac anomalies with syndromic features. Some infants are being identified by newborn screening for SCID and when 22q11.2 deletion is suspected, a calcium level should be obtained at the time of T-cell evaluation. The 3 manifestations with the highest morbidity in early infancy are profound immunodeficiency, severe cardiac anomaly, and seizures from hypocalcemia. Thus an early focus on these concerns is warranted even before the diagnosis is confirmed. Affected patients may develop autoimmune cytopenias, juvenile idiopathic arthritis, atopy, and malignancies (lymphomas).

Treatment

The immunodeficiency in thymic aplasia is correctable by cultured unrelated **thymic tissue transplants** . Some infants with thymic aplasia have been given nonirradiated unfractionated bone marrow or peripheral blood transplants from a human leukocyte antigen–identical sibling, with subsequent improved immune function because of adoptively transferred T cells. Infants and children with low T-cell counts but not low enough to consider transplantation should be monitored for evolution of immunoglobulin defects. Infections in these patients are multifactorial. Their anatomy may not favor drainage of secretions; they have a higher rate of atopy, which may complicate infections; and their host defense may allow persistence of infections. Interventions range from hand hygiene, probiotics, prophylactic antibiotics, and risk management to immunoglobulin replacement for those who have demonstrated defective humoral immunity.

T-Cell Activation Defects

T-cell activation defects are characterized by the presence of normal or elevated numbers of blood T cells that appear phenotypically normal but fail to proliferate or produce cytokines normally in response to stimulation with mitogens, antigens, or other signals delivered to the TCR, owing to defective signal transduction from the TCR to intracellular metabolic pathways (Fig. 151.1). These patients have problems similar to those of other T-cell–deficient individuals, and some with severe T-cell activation defects may clinically resemble SCID patients (Table 151.1). In some cases, susceptibility to a single pathogen or a limited number of pathogens dominates the clinical phenotype. Susceptibility to Epstein-Barr virus, cytomegalovirus, and papillomavirus is common in this set of T-cell defects. Most individuals with significant T-cell activation defects will require a hematopoietic stem cell transplant. Although each infection may be manageable early in life, the long-term prognosis is not favorable in many of these conditions.

Table 151.1

Genetic Basis of Primary Cellular Immunodeficiency Diseases

GENE PRODUCT	**EFFECT ON T CELLS**	**INFECTION SUSCEPTIBILITY**
Lck	↓↓ CD4 CD8	Viral infections predominantly
CD8α	↓↓ CD8 deficiency	Viral infections predominantly
ZAP-70	CD8 deficiency	Viral infections predominantly
RhoH	↓ Naïve $CD4^{+}$ cells	Warts
ITK	↓ Naïve $CD4^{+}$ cells Absence of NKT cells	Epstein-Barr virus
22q11.2 deletion	Thymic hypoplasia (DiGeorge syndrome, velocardiofacial syndrome)	Highly variable
CD3γ and ε	CD3 deficiency	Viral infections predominantly
TRAC	TCR-αβ T-cell deficiency	Similar to SCID
Coronin-1A	↓↓ CD4 ↓↓ CD8	Similar to SCID
MST1/STK4	↓ Naïve T cells Low number of recent thymic emigrants, restricted T-cell repertoire	Warts
AIRE	APECED, chronic mucocutaneous candidiasis, parathyroid and adrenal autoimmunity	Candida
TBX1	Thymic hypoplasia	Similar phenotype with 22q11.2 deletion

AIRE, Autoimmune regulator; APECED, autoimmune polyendocrinopathy-candidiasis–ectodermal dysplasia; Ig, immunoglobulin; ITK, IL-2–inducible tyrosine kinase deficiency; MST1, macrophage-stimulating factor 1; NKT, natural killer T; RhoH, Ras homology family member H; SCID, severe combined immunodeficiency; STK4, serine threonine kinase 4; TCR, T-cell receptor; TRAC, T-cell receptor α chain constant region; ZAP-70, zeta-associated protein 70.

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis (**CMC**) is a syndrome characterized by impaired immune responsiveness to *Candida.* Some of the known gene defects with CMC have **autoimmune polyendocrinopathy syndrome type 1** (**APS1** , or autoimmune polyendocrinopathy-candidiasis–ectodermal dystrophy [**APECED**]). One of the other genetic types of CMC is associated with autoimmunity and predisposition to other infections (*STAT1* gain-of-function mutations). However, most of the specific genetic types of CMC have isolated susceptibility to *Candida* . These types of CMC relate to defects in the Th17 cell pathway. Autosomal recessive deficiency in the interleukin-17 receptor A (IL-17RA) chain, and an autosomal dominant deficiency of the cytokine IL-17F are both associated with predisposition to *Candida* . Other immunodeficiencies in which *Candida* occurs in the context of other infections also affect the Th17 cells. Another CMC genetic type, caused by mutations in *CARD9* , has a strong predisposition to *Candida* but also to other fungi.

Although the underlying gene defects are varied, the clinical presentation of CMC is usually similar. Symptoms can begin in the 1st mo of life or as late as the 2nd decade. The disorder is characterized by chronic and severe *Candida* skin and mucous membrane infections. Patients rarely develop systemic *Candida* disease, except as noted below. Topical antifungal therapy can provide limited improvement early in the course of the disease, but systemic courses of azoles are usually necessary; antifungal resistance often develops later in life. The infection usually responds temporarily to treatment, but it is not eradicated and recurs. Patients with *CARD9* gene mutations have a more severe fungal susceptibility than typical CMC patients. Two described patients with *CARD9* mutations had fungal sepsis in addition to CMC; deep tissue dermatophyte infections were also present.

Autoimmune Polyendocrinopathy-Candidiasis–Ectodermal Dysplasia

Patients with this syndrome present with CMC and autoimmune polyendocrinopathy, usually developing hypoparathyroidism and Addison disease before adulthood. Additional features include male and female hypogonadism, chronic active hepatitis, alopecia, vitiligo, pernicious anemia, enamel hypoplasia, type 1 diabetes, asplenia, malabsorption, interstitial nephritis, hypothyroidism, hypopituitarism, and Sjögren syndrome. APECED, or APS1, is caused by a mutation in the autoimmune regulator *(AIRE)* gene (see Table 151.1). The gene product, AIRE, is expressed at high levels in purified human thymic medullary stromal cells and is thought to regulate the cell surface expression of tissue-specific proteins such as insulin and thyroglobulin. Expression of these self proteins allows for the negative selection of autoreactive T cells during their development. Failure of negative selection results in organ-specific autoimmune destruction.

CHAPTER 152

Immunodeficiencies Affecting Multiple Cell Types

Jennifer R. Heimall, Jennifer W. Leiding, Kathleen E. Sullivan, Rebecca H. Buckley

The manifestations of immune deficiencies that affect multiple cell types range from profound to mild; these conditions can present with severe infection, recurrent infections, unusual infections, or autoimmunity. The most profound disorder is severe combined immunodeficiency. Other combined immunodeficiencies include defects of innate immunity and defects leading to immune dysregulation; the latter category is typically associated with profound autoimmunity. Combined immunodeficiencies are characterized by a predisposition to viral infections, and the innate immunodeficiencies are susceptible to a range of bacteria.

152.1

Severe Combined Immunodeficiency

Kathleen E. Sullivan, Rebecca H. Buckley

Keywords

SCID

newborn screening
lymphoid development

Severe combined immunodeficiency (**SCID**) is caused by diverse genetic mutations that lead to absence of T- and B-cell function. Patients with this group of disorders have the most severe immunodeficiency.

Pathogenesis

SCID is caused by mutations in genes crucial for lymphoid cell development (Table 152.1 and Fig. 152.1). All patients with SCID have very small thymuses that contain no thymocytes and lack corticomedullary distinction or Hassall corpuscles. The thymic epithelium appears histologically normal. Both the follicular and the paracortical areas of the spleen are depleted of lymphocytes. Lymph nodes, tonsils, adenoids, and Peyer patches are absent or extremely underdeveloped.

Genetic Basis of SCID and SCID Variants

DISEASE	INHERITANCE	PRESUMED PATHOGENESIS	ADDITIONAL FEATURES	TREATMENT
Reticular dysgenesis	AR	Impaired mitochondrial energy metabolism and leukocyte differentiation	Severe neutropenia, deafness. Mutations in adenylate kinase 2	GCSF, HSCT
Adenosine deaminase deficiency	AR	Accumulation of toxic purine nucleosides	Neurologic, hepatic, renal, lung, and skeletal and bone marrow abnormalities	HSCT, PEG-ADA, gene therapy
IL-2Rγ deficiency	X-linked	Abnormal signaling through by IL-2 receptor and other receptors containing γc (IL-4, -7, -9, -15, -21)	None	HSCT
Jak3 deficiency	AR	Abnormal signaling downstream of γc	None	HSCT
RAG1 and RAG2 deficiency	AR	Defective V(D)J recombination	None	HSCT
Artemis deficiency	AR	Defective V(D)J recombination, radiation sensitivity	*DCLERE1C* gene defects	HSCT
DNA-PK deficiency	AR	Defective V(D)J recombination	None	HSCT
DNA ligase IV	AR	Defective V(D)J recombination, radiation sensitivity	Growth delay, microcephaly, bone	HSCT

deficiency			marrow abnormalities, lymphoid malignancies	
Cernunnos-XLF	AR	Defective V(D)J recombination, radiation sensitivity	Growth delay, microcephaly, birdlike facies, bone defects	HSCT
CD3δ deficiency	AR	Arrest of thymocytes differentiation at $CD4^-$ $CD8^-$ stage	Thymus size may be normal	HSCT
CD3ε deficiency	AR	Arrest of thymocytes differentiation at $CD4^-$ $CD8^-$ stage	γ/δ T cells absent	HSCT
CD3ζ deficiency	AR	Abnormal signaling	None	HSCT
IL-7Rα deficiency	AR	Abnormal IL-7R signaling	Thymus absent	HSCT
CD45 deficiency	AR		None	HSCT
Coronin-1A deficiency	AR	Abnormal T-cell egress from thymus and lymph nodes	Normal thymus size. Attention deficit disorder.	HSCT

AR, Autosomal recessive; GCSF, granulocyte colony-stimulating factor; HSCT, hematopoietic stem cell transplantation; IL, interleukin; Jak3, Janus kinase 3; PEG-ADA, polyethylene glycol-modified adenosine deaminase; RAG1, RAG2, recombinase-activating genes 1 and 2; V(D)J, variable, diversity, joining domains.

(Adapted from Roifman, CM. Grunebaum E: Primary T-cell immunodeficiencies. In Rich RR, Fleisher TA, Shearer WT, et al, editors: *Clinical immunology,* ed 4. Philadelphia, 2013, Saunders, pp 440–441).

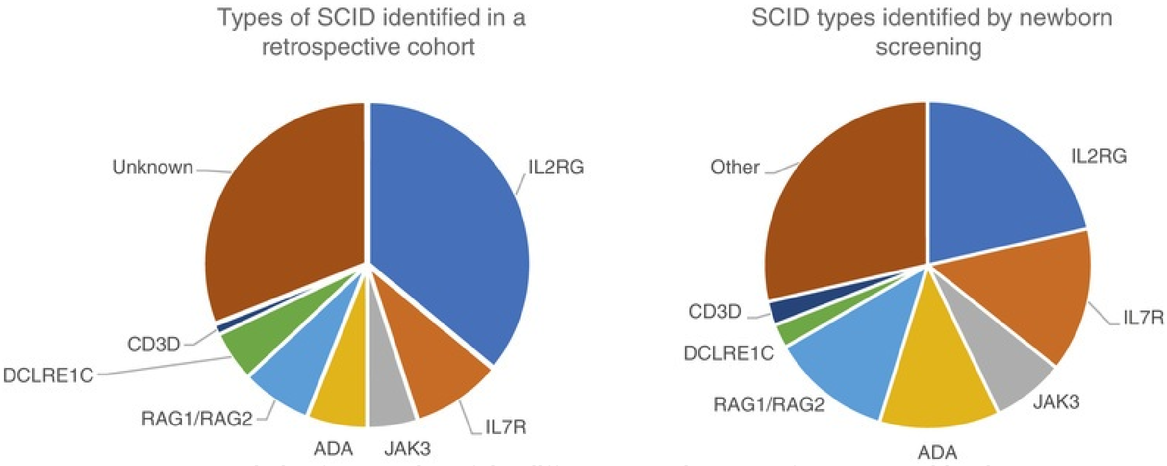

FIG. 152.1 **Relative frequencies of the different genetic types of severe combined immunodeficiency (SCID). ADA, Adenosine deaminase; IL-7R, interleukin 7 receptor; JAK, Janus kinase; RAG, recombinase-activating gene.**

Clinical Manifestations

SCID is included in the newborn screening program in many states. Thus, infants are identified prior to symptoms, which has dramatically improved the survival of infants with SCID. A few genetic types of SCID are not detected by newborn screening, and there are a few states where newborn screening for SCID is not yet performed.

When infants with SCID are not detected through newborn screening, they most often present with **infection** . Diarrhea, pneumonia, otitis media, sepsis, and cutaneous infections are common presentations. Infections with a variety of opportunistic organisms, either through direct exposure or immunization, can lead to death. Potential threats include *Candida albicans, Pneumocystis jiroveci* , parainfluenza 3 virus, adenovirus, respiratory syncytial virus (RSV), rotavirus vaccine, cytomegalovirus (CMV), Epstein-Barr virus (EBV), varicella-zoster virus, measles virus, MMRV (measles, mumps, rubella, varicella) vaccine, or bacille Calmette-Guérin (BCG) vaccine. Affected infants also lack the ability to reject foreign tissue and are therefore at risk for severe or fatal **graft-versus-host disease (GVHD)** from T lymphocytes in nonirradiated blood products or maternal immunocompetent T cells that crossed the placenta while the infant was in utero. This devastating presentation is characterized by expansion of the allogeneic cells, rash, hepatosplenomegaly and diarrhea. A 3rd presentation is often called **Omenn syndrome** , in which a few cells generated in the infant expand and cause a clinical picture similar to GVHD (Fig. 152.2). The difference in this case is that the cells are the infant's own cells.

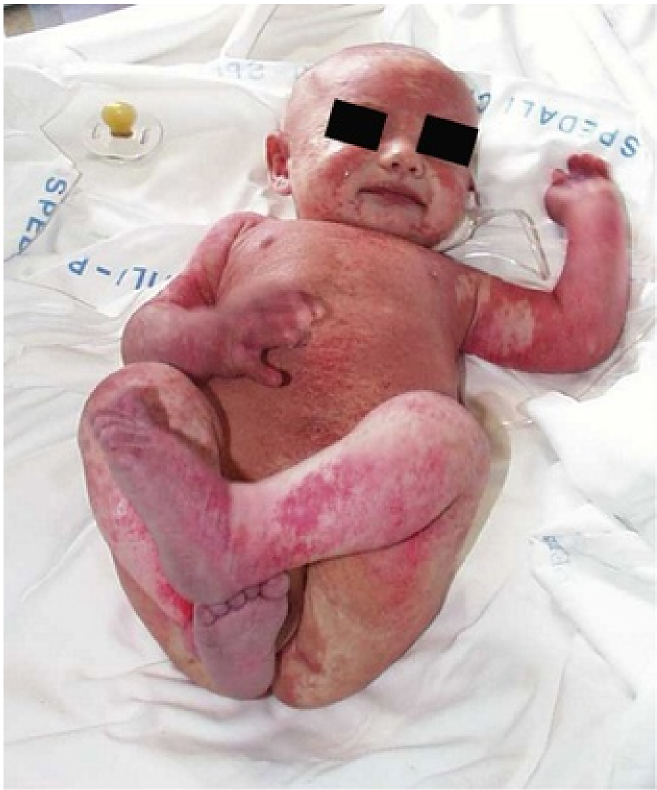

FIG. 152.2 **Typical clinical features in an infant with Omenn syndrome. Note generalized erythroderma with scaly skin, alopecia, and edema. (From Leung DYM, Szefler SJ, Bonilla FA, et al, editors: *Pediatric allergy: principles and practice,* ed 3, Philadelphia, 2016, Saunders, p 82).**

A key feature of SCID is that almost all patients will have a low lymphocyte count. A combination of opportunistic infections and a persistently low lymphocyte count is an indication to test for SCID. The diagnostic strategy both for symptomatic infants and those detected by newborn screening is to perform flow cytometry to quantitate the T, B, and natural killer (NK) cells in the infant. The CD45RA and CD45RO markers can be helpful to distinguish maternal engraftment and Omenn syndrome. T-cell function is also often assessed by measuring proliferative responses to stimulation.

All genetic types of SCID are associated with profound immunodeficiency. A small number have other associated features or atypical features that are important to recognize. Adenosine deaminase (ADA) deficiency can be associated with pulmonary alveolar proteinosis and chondroosseous dysplasia. Adenylate kinase 2 (AK2) deficiency causes a picture referred to as **reticular dysgenesis** where neutrophils, myeloid cells, and lymphocytes are all low. This condition is also often associated with deafness.

Treatment

SCID is a true pediatric immunologic emergency. Unless immunologic reconstitution is achieved through hematopoietic stem cell transplantation (**HSCT**) or gene therapy, death usually occurs during the 1st yr of life and almost invariably before 2 yr of age. *HSCT in an infant prior to infection is associated with a 95% survival rate.* ADA-deficient SCID and X-linked SCID have been treated successfully with gene therapy. Early trials of gene therapy were associated with a risk of malignancy, but this has not been seen in trials with new vectors. ADA-deficient SCID can also be treated with repeated injections of polyethylene glycol–modified bovine ADA (**PEG-ADA**), although the immune reconstitution achieved is not as effective as with stem cell or gene therapy.

Genetics

The 4 most common types of SCID are the X-linked form, caused by mutations in *CD132* ; autosomal recessive *RAG1* and *RAG2* deficiencies; and *ADA* deficiency. Additional forms are listed in Table 152.1 . For X-linked SCID and ADA deficiency, gene therapy exists, but genetic counseling is the most compelling reason for genetic sequencing to identify the gene defect. Several specific gene defects are associated with increased sensitivity to radiation and chemotherapy, and their early identification can lead to a better transplant experience.

Sequencing is often done by requesting a SCID gene panel. There are certain laboratory features that predict specific gene defects. When both T cells and B cells are low, often a gene encoding a protein involved in V(D)J recombination is the cause. Similarly, certain cytokine receptor defects are associated with specific lymphocyte phenotypes.

Hypomorphic mutations in genes most often associated with SCID can lead to varied phenotypes. This condition is often referred to as *leaky SCID,* referring to the mutation being "leaky" for some lymphocyte development. Leaky phenotypes range from the dramatic Omenn syndrome phenotype to later-onset immunodeficiency, granulomas, and autoimmunity.

152.2

Combined Immunodeficiency

Kathleen E. Sullivan, Rebecca H. Buckley

Keywords

cartilage-hair hypoplasia
Wiskott-Aldrich syndrome
lymphopenia

Combined immunodeficiency (**CID**) is distinguished from SCID by the presence of low but not absent T-cell function. CID is a syndrome of diverse genetic causes. Patients with CID have recurrent or chronic pulmonary infections, failure to thrive, oral or cutaneous candidiasis, chronic diarrhea, recurrent skin infections, gram-negative bacterial sepsis, urinary tract infections, and severe varicella in infancy. Although they usually survive longer than infants with SCID, they fail to thrive and often die before adulthood. Neutropenia and eosinophilia are common. Serum immunoglobulins may be normal or elevated for all classes, but selective IgA deficiency, marked elevation of IgE, and elevated IgD levels occur in some cases. Although antibody-forming capacity is impaired in most patients, it is not absent.

Studies of cellular immune function show lymphopenia, deficiencies of T cells, and extremely low but not absent lymphocyte proliferative responses to mitogens, antigens, and allogeneic cells in vitro. Peripheral lymphoid tissues demonstrate paracortical lymphocyte depletion. The thymus is usually small, with a paucity of thymocytes and usually no Hassall corpuscles.

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is an unusual form of **short-limbed dwarfism** with frequent and severe infections. It occurs with a high frequency among the Amish and Finnish people.

Genetics and Pathogenesis

CHH is an autosomal recessive condition. Numerous mutations that cosegregate with the CHH phenotype have been identified in the untranslated RNase MRP (*RMRP*) gene. The RMRP endoribonuclease consists of an RNA molecule bound to several proteins and has at least 2 functions: cleavage of RNA in mitochondrial DNA synthesis and nucleolar cleaving of pre-RNA. Mutations in *RMRP* cause CHH by disrupting a function of *RMRP* RNA that affects multiple organ systems. In vitro studies show decreased numbers of T cells and defective T-cell proliferation because of an intrinsic defect related to the G1 phase, resulting in a longer cell cycle for individual cells. NK cells are increased in number and function.

Clinical Manifestations

Clinical features include short, pudgy hands; redundant skin; hyperextensible joints of hands and feet but an inability to extend the elbows completely; and fine, sparse, light hair and eyebrows. Infections range from mild to severe. Associated conditions include deficient erythrogenesis, Hirschsprung disease, and an increased risk of malignancies. The bones radiographically show scalloping and sclerotic or cystic changes in the metaphyses and flaring of the costochondral junctions of the ribs. Some patients have been treated with HSCT.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked recessive disorder characterized by atopic dermatitis, thrombocytopenic purpura with normal-appearing megakaryocytes but small defective platelets, and susceptibility to infection.

Genetics and Pathogenesis

The Wiskott-Aldrich syndrome protein (WASP) binds CDC42H2 and Rac, members of the Rho family of guanosine triphosphatases. WASP controls the assembly of actin filaments required for cell migration and cell-cell interactions.

Clinical Manifestations

Patients often have prolonged bleeding from the circumcision site or bloody diarrhea during infancy. The thrombocytopenia is not initially caused by antiplatelet antibodies. **Atopic dermatitis** and **recurrent infections** usually develop during the 1st yr of life. *Streptococcus pneumoniae* and other bacteria having polysaccharide capsules cause otitis media, pneumonia, meningitis, and sepsis. Later, infections with agents such as *P. jiroveci* and the herpesviruses become more frequent. Infections, bleeding, and EBV-associated malignancies are major causes of death.

Patients with this defect uniformly have an impaired humoral immune response to polysaccharide antigens, as evidenced by absent or greatly diminished isohemagglutinins, and poor or absent antibody responses after immunization with polysaccharide vaccines. The predominant immunoglobulin pattern is a low serum level of IgM, elevated IgA and IgE, and a normal or slightly low IgG concentration. Because of their profound antibody deficiencies, these patients should be given immunoglobulin replacement regardless of their serum levels of the different immunoglobulin isotypes. Percentages of T cells are moderately reduced, and lymphocyte responses to mitogens are variably depressed.

Treatment

Good supportive care includes appropriate nutrition, immunoglobulin replacement, use of killed vaccines, and aggressive management of eczema and associated cutaneous infections. HSCT is the treatment of choice when a high-quality matched donor is available and is usually curative. Gene-corrected autologous HSCT has resulted in sustained benefits in 6 patients.

Ataxia-Telangiectasia

Ataxia-telangiectasia is a complex syndrome with immunologic, neurologic, endocrinologic, hepatic, and cutaneous abnormalities.

Genetics and Pathogenesis

The ataxia-telangiectasia mutation (*ATM*) gene encodes a protein critical for responses to DNA damage. Cells from patients, as well as from heterozygous carriers, have increased sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities.

In vitro tests of lymphocyte function have generally shown moderately depressed proliferative responses to T- and B-cell mitogens. Percentages of CD3 and CD4 T cells are moderately reduced, with normal or increased percentages of CD8 and elevated numbers of γ/δ T cells. The thymus is very hypoplastic, exhibits poor organization, and lacks Hassall corpuscles.

Clinical Manifestations

The most prominent clinical features are progressive **cerebellar ataxia, oculocutaneous telangiectasias, chronic sinopulmonary disease** , a high incidence of malignancy, and variable humoral and cellular immunodeficiency. Ataxia typically becomes evident soon after these children begin to walk and progresses until they are confined to a wheelchair, usually by age 10-12 yr. The telangiectasias begin to develop at 3-6 yr. The most frequent humoral immunologic abnormality is the selective absence of IgA, which occurs in 50–80% of these patients. IgG2 or total IgG levels may be decreased, and specific antibody titers may be decreased or normal. Recurrent sinopulmonary infections occur in approximately 80% of these patients. Although common viral infections have not usually resulted in untoward sequelae, fatal varicella has occurred. The malignancies associated with ataxia-telangiectasia are usually of the lymphoreticular type, but adenocarcinomas also occur. Unaffected carriers of mutations have an increased incidence of malignancy.

Therapy in ataxia-telangiectasia is supportive.

Autosomal Dominant Hyper-IgE

Syndrome

This syndrome is associated with early-onset atopy and recurrent skin and lung infections.

Genetics and Pathogenesis

The autosomal dominant hyper-IgE syndrome is caused by heterozygous mutations in the gene encoding signal transducer and activator of transcription 3 (STAT-3). These mutations result in a dominant negative effect. The many clinical features are caused by compromised signaling downstream of the interleukin (IL)-6, type I interferon, IL-22, IL-10 and epidermal growth factor (EGF) receptors.

Clinical Manifestations

The characteristic clinical features are staphylococcal abscesses, pneumatoceles, osteopenia, and unusual facial features. There is a history from infancy of recurrent staphylococcal abscesses involving the skin, lungs, joints, viscera, and other sites. Persistent pneumatoceles develop as a result of recurrent pneumonia. Patients often have a history of sinusitis and mastoiditis. *Candida albicans* is the 2nd most common pathogen. Allergic respiratory symptoms are usually absent. The pruritic dermatitis that occurs is not typical atopic eczema and does not always persist. There can be a prominent forehead, deep-set wide-spaced eyes, a broad nasal bridge, a wide fleshy nasal tip, mild prognathism, facial asymmetry, and hemihypertrophy, although these are most evident in adulthood. In older children, delay in shedding primary teeth, recurrent fractures, and scoliosis occur.

These patients demonstrate an **exceptionally high serum IgE concentration** ; an elevated serum IgD concentration; usually normal concentrations of IgG, IgA, and IgM; pronounced blood and sputum eosinophilia; and poor antibody and cell-mediated responses to neoantigens. Traditionally, IgE levels >2000 IU/mL confirm the diagnosis. However, IgE levels may fluctuate and even decrease in adults. In neonates and infants with the pruritic pustular dermatosis, IgE levels will be elevated for age and are usually in the 100s. In vitro studies show normal percentages of blood T, B, and NK lymphocytes, except for a decreased percentage of T cells with the memory (CD45RO) phenotype and an absence or deficiency of T-helper type 17 (Th17) cells. Most patients have normal T-lymphocyte proliferative responses to mitogens but very low or absent responses to antigens or allogeneic cells from family members. Blood, sputum, and histologic sections of lymph nodes, spleen, and lung cysts show striking eosinophilia. Hassall corpuscles and thymic architecture are normal. Therapy is generally directed at prevention of infection using antimicrobials and immunoglobulin replacement.

DOCK8 Deficiency

Deficiency of DOCK8 (dedicator of cytokinesis 8) is an autosomal recessive condition that most often presents with impressively severe eczema in infancy and toddlerhood. **Cutaneous viral infections** and **susceptibility to CMV, EBV, and cryptosporidia** are common (Fig. 152.3). The infectious susceptibility tends to worsen over time, as do the laboratory features of immune dysfunction, most often low T-cell counts and poor proliferative function. Although these patients can survive to adulthood without transplantation, they suffer many complications and their quality of life is often poor. For this reason, most patients are now transplanted early in life to avoid the later complications.

152.3

Defects of Innate Immunity

Jennifer R. Heimall, Kathleen E. Sullivan

Keywords

TLR
NK cells
mycobacteria

The innate immune system is the earliest responding feature of host defense in vertebrates. Components include the physical barrier function of the skin and mucosal surfaces, complement, neutrophils, macrophages, dendritic cells (DCs), NK cells, and their associated cytokines. The activation of innate immunity is critically reliant on a group of **pattern recognition receptors (PRRs)** that respond to host infections or tissue damage within minutes. These receptors are all germline encoded and are therefore able to be expressed in all cells, where they serve as critical monitors for the presence of **pathogen-associated molecular patterns (PAMPs)** .

Interferon-γ Receptors 1 and 2, IL-12 Receptor β_1 , and IL-12P40 Defects

Among the best-described defects of innate immunity are those associated with susceptibility to nontuberculous mycobacteria. These defects are associated with abnormalities in the interferon-gamma (IFN-γ)–IL-12 signaling axis.

Pathogenesis

Interleukin-12 is a cytokine secreted by macrophages, neutrophils, and DCs in response to infection with mycobacterial and other microbes. IL-12 then binds to receptors on NK cells and T cells to stimulate secretion of IFN-γ. IFN-γ is critical in the activation of phagocyte secretion of tumor necrosis factor alpha (TNF-α) and destruction of the phagocytosed microbe. IFN-γ activates phagocytes via binding of IFN-γ receptor 1 (IFN-γR1) which is found in a homodimerized form associated with Janus-associated kinase-1 (Jak1) that recruits and binds IFN-γ receptor 2 (IFN-γR2) which is associated with Janus-associated kinase-2 (Jak2). Jak1 and Jak2 are then transphosphorylated, which leads to phosphorylation of IFN-γR1 and subsequent docking of signal transducer and activator of transcription 1 (STAT1). Phosphorylated STAT1 then homodimerizes and translocates to the cell nucleus to induce gene transcription. Deficiency of any of these components has a significant impact on phagocyte activation.

Clinical Manifestations

IFN-γR1 deficiency leads to impaired IFN-γ binding and signaling and inability to form mature granulomas and indicates a risk of **susceptibility to *Mycobacteria*** species and *Salmonella* . There are both autosomal recessive (AR) and autosomal dominant (AD) forms of this defect. In the AR form are both partial and complete defects. In the complete AR form, patients present with early onset of disseminated *Mycobacteria*, and some have been reported to present with nontyphoid *Salmonella* or *Listeria monocytogenes* . Treatment should be directed at the presenting infection, with multiple antimicrobial agents used without interruption. HSCT has been used once mycobacterial disease is controlled but requires conditioning to permit the myeloid engraftment necessary to correct the underlying disease. In the partial AR form, IFN-γR1 deficiency remains associated with disseminated *Mycobacteria* and S*almonella* infections but is managed with symptomatic treatment of infections and consideration of IFN-γ therapy to induce higher serum IFN-γ levels. The AD form is also a partial defect in IFN-γ signaling and most often presents with *Mycobacteria* osteomyelitis, although *Salmonella* and *Histoplasma* infections have also been described. Similar to the partial AR defect, these patients are able to be managed with antimicrobial therapy of infections and supplemental IFN-γ injections. Deficiency of IFN-γR2 is an AR defect that also has partial and complete forms. The complete form is a phenocopy to complete IFN-γR1, presenting with early-onset, severe, and disseminated mycobacterial infections. Treatment involves uninterrupted multidrug therapy for the infections and consideration for HSCT. A partial form of IFN-γR2 also presents with mild but potentially disseminated *Mycobacteria* or *Salmonella* infections, which can be controlled with antibiotic therapy that can be stopped once the infection is resolved.

Deficiencies of the IL-12 receptor (IL-12R) components have also been described as inherited in an AR fashion, with defects in both the IL-12p40 chain as well as the shared IL-12/IL-23Rβ_1 , causing impaired IFN-γ secretion and resultant susceptibility to *Mycobacteria* and *Salmonella.* Both forms of IL-12R defects are characterized by relatively mild disease, with some ability to form granulomatous lesions in response to *Mycobacteria* infections. These defects can usually be managed with antimicrobials and supplemental IFN-γ. Partial defects in STAT1, inherited in an AD fashion, are associated with *Mycobacteria* susceptibility, whereas complete AR defects in STAT1 are associated with mycobacterial susceptibility as well as defects in responses to IFN-α and IFN-β, leading to fulminant herpesvirus infections. Other defects associated with poor production of IFN-γ leading to increased *Mycobacteria* susceptibility include AR inherited defects in **ISG-15** , which is associated with *Mycobacteria*-induced brain calcifications, and **RORγC** deficiency, which leads to a lack of IL-17–producing T cells, in addition to lack of IFN-γ production. RORγC defects are associated with an increased risk of candidiasis in addition to *Mycobacteria* infections. Defects in **Tyk2** , inherited in an AR fashion, generally present with susceptibility to intracellular bacteria, fungi and viruses. AD mutations in interferon regulatory factor 8 (*IRF8*) are also associated with impaired IL-12 production by the CD1-DCs, leading to increased risk of recurrent mycobacterial infection, which can be treated with antimicrobial therapy.

IL-1R–Associated Kinase 4 Deficiency and Myeloid Differentiation Factor 88

Toll-like receptors (**TLRs**) are the best described of the PRRs in humans, and deficiencies almost uniformly cause infection susceptibility.

Pathogenesis

Among those expressed on the cell surface, TLRs 1, 2, and 6 bind lipoproteins and are important in defense to bacteria and fungi, TLR4 binds lipopolysaccharides and has an important role in defense from gram-negative bacteria as well as the fusion protein of RSV. TLR5 binds flagellin, found in many bacterial organisms. The remaining TLRs (3, 7, 8, and 9) are expressed intracellularly, respond to nucleic acids and are initiators for the host response for viral defense. When bound to their PAMP, TLRs activate an intracellular signaling cascade that in most cases utilizes myeloid differentiation primary response gene 88 (MyD88) and IL-1R–associated kinase 4 (IRAK4). TLR4 also signals using the Toll/IL-1R domain-containing adaptor-inducing interferon-B (TRIF). Both MyD88 and TRIF can lead to activation of the nuclear factor (NF)-κB pathway via the IKK complex to induce proinflammatory cytokine production. The IKK complex is composed of IKKα and IKKβ, and IKKγ (NF-κB essential modulator, or NEMO).

Clinical Manifestations

IRAK4 and *MYD88* deficiencies have identical features and are associated with deep infections such as pneumonia, meningitis, or sepsis with encapsulated organisms early in life. The main organisms recovered from patients are *Staphylococcus aureus* , *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa.* This is one of the few types of immunodeficiency where clostridial infections are also seen with increased frequency. Most patients have an improved infection risk after adolescence. Therapy has generally focused on education of parents and clinicians to the life-threatening nature of the infections with encouragement of timely cultures and empirical antibiotic use. These patients may have a **blunted febrile response** , and clinical features of infection may be subtle.

Among the first-described defects of TLR signaling were X-linked mutations in *NEMO* , which causes a broad range of clinical manifestations, with most demonstrating a poor inflammatory response. NEMO is typically considered in the category of combined immunodeficiency because of its impact on both innate and adaptive immune responses. Severely affected patients may present with disseminated *Mycobacteria* infections, severe infections from encapsulated organisms such as *S. pneumoniae* or other opportunistic infections. In addition to the infectious phenotype, these patients characteristically have conical or peg-shaped teeth, hypohydrosis, and hypotrichosis from anhidrotic ectodermal dysplasia (EDA). Patients should be treated with immunoglobulin replacement, antibiotic prophylaxis with trimethoprim/sulfamethoxazole, azithromycin, and/or penicillin VK. HSCT is a treatment consideration, but myeloid lineage engraftment is needed to fully correct the underlying immunodeficiency.

Natural Killer Cell Deficiency

NK cells are the major lymphocytes of the innate immune system. NK cells recognize virally infected and malignant cells and mediate their elimination. Individuals with absence or functional deficiencies of NK cells are rare, and they typically have susceptibility to the herpesviruses (including varicella-zoster virus, herpes simplex virus (HSV), CMV, and EBV) as well as papillomaviruses. A number of gene defects are associated with these isolated abnormalities in NK cells. Autosomal recessive CD16 gene mutations were described in 3 separate families and altered the first immunoglobulin-like domain of this important NK cell activation receptor. Patients with these mutations have NK cells that are functionally impaired and have clinical susceptibility to **herpesviruses** . AD deficiency of NK cells occurs in individuals with mutations in the **GATA2 transcription factor** . These patients also have cytopenias and very low numbers of monocytes. They have extreme susceptibility to **human papillomavirus** (HPV) as well as mycobacteria, the latter presumably from the monocytic defect. They are at risk for alveolar proteinosis, myelodysplasia, and leukemia. AR mutations in the *MCM4* gene have been identified in a cohort of patients who had growth failure and susceptibility to herpesviruses. Therapeutically, patients should be maintained on antiviral prophylaxis, and HSCT has been successful in certain cases.

Defects in Innate Responses to Viral

Infection

Defects in both the JAK-STAT signaling pathways and the TLR signaling pathways have been implicated in patients with increased susceptibility to severe viral infections. AR defects in STAT1 cause a complete lack of response to INF-γ and IFN-α/β, affecting the function of T and NK cells as well as monocytes, leading to disseminated mycobacterial infections as well as severe herpesvirus infections, including recurrent **HSV encephalitis** and EBV-driven lymphoproliferative disease. In these patients, lifelong antibiotic therapy to protect from *Mycobacteria* and antiviral therapy for herpesviruses is recommended, and HSCT should be considered. Defects in STAT2, inherited in an AR fashion, lead to poor T- and NK-cell responses to IFN-α and IFN-β, leading to increased viral susceptibility, in particular development of **disseminated vaccine strain measles** with central nervous system (CNS) involvement despite development of normal vaccine titers. The interferon response factor 7 (IRF7) is important in induction of IFN-α/β via the both the MyD88-dependent and independent pathways of TLR signaling. AR defects in IRF7 have been associated with severe respiratory distress with influenza A infection in a patient with otherwise normal vaccine responses and T- and B-cell populations.

HSV-1 encephalitis has been associated with a group of defects in TLR signaling that lead to decreased production of IFN-α/β/λ causing impaired immunity to HSV-1 but not other viral infections. The first described was deficiency of UNC93B1, a protein involved in trafficking of the TLRs 7 and 9 and inherited in an AR fashion. Subsequently, defects in TLR3 and TRIF as well as the other TLR pathway signaling molecules tumor necrosis factor (TNF), receptor–associated factor 3 (TRAF3), and tank-binding kinase 1 (TBK1) were described to lead to decreased production of IFN-α/β/λ and an associated risk of sporadic HSV-1 encephalitis that can be recurrent. The symptoms were controlled with acyclovir prophylaxis.

Defects in Innate Responses to Fungi

Although **chronic mucocutaneous candidiasis (CMC)** can be seen in association with CID, T-cell disorders, and hyper-IgE syndromes, there are also innate defects known to cause CMC (see Chapter 151). The most common include AD gain-of-function mutations in *STAT1* , where an increased response to IFN-α/β/γ leads to decreased Th17 differentiation. In addition to CMC, these patients also have increased susceptibility to bacterial, fungal, and HSV viral infections; autoimmunity; and enteropathy. Patients with CMC are managed with antifungal, antibacterial, and acyclovir prophylaxis, and HSCT should be considered as a treatment option. Mutations in the IL-17RA and IL-17F have also been described to increase risk of CMC; IL-17RA and IL-17F deficiencies are also associated with *S. aureus* folliculitis, likely from impaired skin β-defensin production. Treatment includes **fluconazole** and sulfamethoxazole/trimethoprim prophylaxis. TRAF3-interacting protein 2 (TRAF3IP2) interacts with IL-17RA on binding of IL-17; AR mutations in TRAF3IP2 have been described in patients with CMC, blepharitis, folliculitis, and macroglossia. CMC is also seen in 25% of patients with IL-12RB1 and IL12p40 defects. Invasive fungal infections, including invasive **dermatophyte infections** and *Candida* brain abscesses, have been seen in addition to CMC in patients with AR inherited defects in CARD9. CARD9 leads to NF-κB–induced cytokine production in response to fungal PAMPS that bind to C-type lectin receptors, including Dectin 1, Dectin 2, and MINCLE. Both granulocyte-macrophage colony-stimulating factor (GM-CSF) and G-CSF have been successfully used to control refractory brain lesions, and once identified, these patients should be maintained on fluconazole prophylaxis.

Treatment of Cellular or Combined Immunodeficiency

Kathleen E. Sullivan, Rebecca H. Buckley

Good supportive care, including prevention and treatment of infections, is critical while patients await more definitive therapy (Table 152.2). Having knowledge of the pathogens causing disease with specific immune defects is also useful.

Table 152.2

Infection in the Host Compromised by B- and T-Cell Immunodeficiency Syndromes

From Stiehm ER, Ochs HD, Winkelstein JA: *Immunologic disorders in infants and children* , ed 5, Philadelphia, 2004, Saunders.

Transplantation of major histocompatibility complex (MHC)–compatible sibling or rigorously T-cell–depleted haploidentical (half-matched) parental hematopoietic stem cells is the treatment of choice for patients with fatal T-cell or combined T- and B-cell defects. The major risk to the recipient from transplants of bone marrow or peripheral blood stem cells is GVHD from donor T cells. Patients with less severe forms of cellular immunodeficiency, including some forms of CID, Wiskott-Aldrich syndrome, cytokine deficiency, and MHC antigen deficiency, reject even HLA-identical marrow grafts unless chemoablative treatment is given before transplantation. Several patients with these conditions have been treated successfully with hematopoietic stem cell transplantation after conditioning.

More than 90% of patients with primary immunodeficiency transplanted with HLA-identical related marrow will survive with immune reconstitution. T-cell–depleted haploidentical-related marrow transplants in patients with primary immunodeficiency have had their greatest success in patients with SCID, who do not require pretransplant conditioning or GVHD prophylaxis. Of patients with SCID, 92% have survived after T-cell–depleted parental marrow is given soon after birth when the infant is healthy, without pretransplant chemotherapy or posttransplant GVHD prophylaxis. Bone marrow transplantation remains the most important and effective therapy for SCID. In ADA-deficient and X-linked SCID, there has been success in correcting the immune defects with ex vivo gene transfer to autologous hematopoietic stem cells. Gene therapy has also been successful in the Wiskott-Aldrich syndrome. Initial protocols of gene therapy for X-linked SCID resulted in **insertional mutagenesis** with the development of leukemic-like clonal T cells or lymphoma in some patients. Modification of the gene therapy protocol has greatly reduced the risk of insertional mutagenesis.

152.5

Immune Dysregulation With Autoimmunity or Lymphoproliferation

Jennifer W. Leiding, Kathleen E. Sullivan, Rebecca H. Buckley

Keywords

ALPS
cytopenias

IPEX

Primary immunodeficiency diseases characterized by immune dysregulation, autoimmunity, and autoinflammation are monogenic defects of the immune system. These complex multisystem diseases often have a progressive phenotype with organ-specific autoimmunity, specific infectious susceptibility, and lymphoproliferation.

Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (**ALPS**), also known as Canale-Smith syndrome, is a disorder of abnormal lymphocyte apoptosis leading to polyclonal populations of T cells (double-negative T cells), which express CD3 and α/β antigen receptors but do not have CD4 or CD8 co-receptors (CD3^{+} T-cell receptor α/β^{+} , CD4^{-} CD8^{-}). These T cells respond poorly to antigens or mitogens and do not produce growth or survival factors (IL-2). The genetic deficit in most patients is a germline or somatic mutation in the *FAS* gene, which produces a cell surface receptor of the TNF receptor superfamily (TNFRSF6), which, when stimulated by its ligand, will produce programmed cell death (Table 152.3). Persistent survival of these lymphocytes leads to immune dysregulation and autoimmunity. ALPS is also caused by other genes in the Fas pathway (*FASLG* and *CASP10*). In addition, ALPS-like disorders are associated with other mutations: RAS-associated autoimmune lymphoproliferative disorder (RALD), caspase-8 deficiency, Fas-associated protein with death domain deficiency (FADD), and protein kinase C delta deficiency (PRKCD). These disorders have varying degrees of immunodeficiency, autoimmunity, and lymphoproliferation.

Table 152-3

Revised Diagnostic Criteria for Autoimmune Lymphoproliferative Syndrome*

REQUIRED
1. Chronic (>6 months), nonmalignant, noninfectious lymphadenopathy, splenomegaly or both
2. Elevated CD3+TCRαβ+CD4-CD8- DNT cells (≥1.5% of total lymphocytes or 2.5% of CD3+ lymphocytes) in

the setting of normal or elevated lymphocyte counts
ACCESSORY
Primary
1. Defective lymphocyte apoptosis (in 2 separate assays) 2. Somatic or Germline pathogenic mutation in *FAS* , *FASLG* , or *CASP10*
Secondary
1. Elevated plasma sFasL levels (>200 pg/mL) OR elevated plasma interleukin-10 levels (>20 pg/mL) OR elevated serum or plasma vitamin B 12 levels (>1500 ng/L) OR elevated plasma interleukin-18 levels >500 pg/mL 2. Typical immunohistological findings as reviewed by an experienced hematopathologist 3. Autoimmune cytopenias (hemolytic anemia, thrombocytopenia, or neutropenia) AND elevated immunoglobulin G levels (polyclonal hypergammaglobulinemia) 4. Family history of a nonmalignant/noninfectious lymphoproliferation with or without autoimmunity

[*] A *definitive* diagnosis is based on the presence of both required criteria plus one primary accessory criterion. A *probable* diagnosis is based on the presence of both required criteria plus one secondary accessory criterion.

From Petty RE, Laxer RM, Lindsley CB, Wedderburn LR, editors: Textbook of pediatric rheumatology, ed 7, Philadelphia, 2016, Elsevier, Box 46-2.

Clinical Manifestations

ALPS is characterized by **autoimmunity, chronic persistent or recurrent lymphadenopathy** , splenomegaly, hepatomegaly (in 50%), and hypergammaglobulinemia (IgG, IgA). Many patients present in the 1st yr of life, and most are symptomatic by age 5 yr. Lymphadenopathy can be striking (Fig. 152.4). Splenomegaly may produce hypersplenism. Autoimmunity also produces anemia (Coombs-positive hemolytic anemia) or thrombocytopenia or a mild neutropenia. The lymphoproliferative process (lymphadenopathy, splenomegaly) may regress over time, but autoimmunity does not regress and is characterized by frequent exacerbations and recurrences. Other autoimmune features include urticaria, uveitis, glomerulonephritis, hepatitis, vasculitis, panniculitis, arthritis, and CNS involvement (seizures, headaches, encephalopathy).

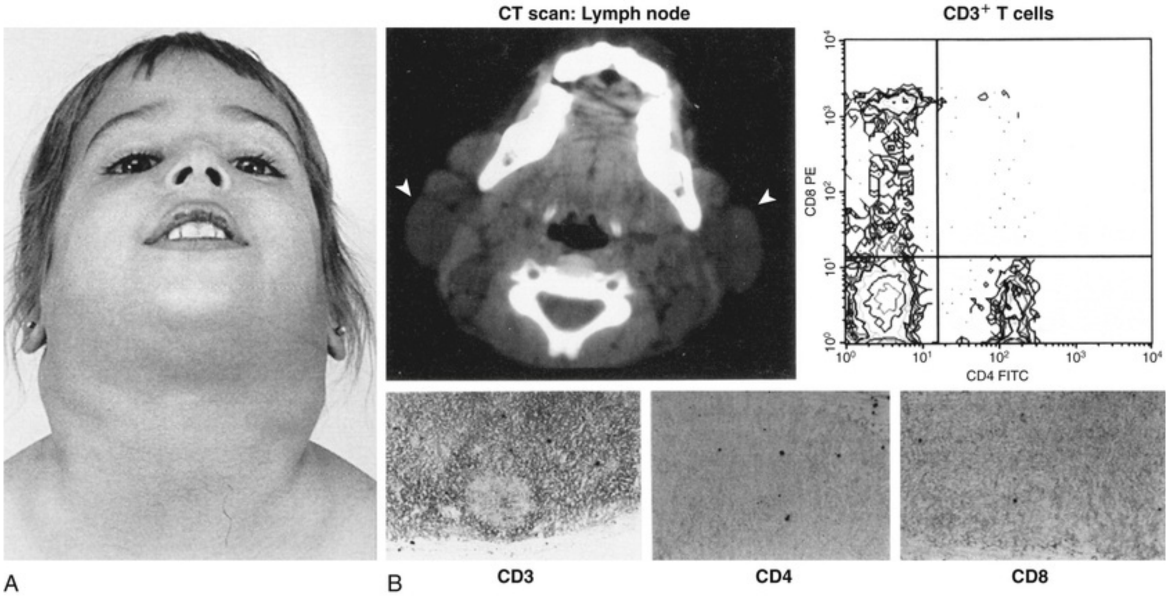

FIG. 152.4 Clinical, radiographic, immunologic, and histologic characteristics of the autoimmune lymphoproliferative syndrome. A, Front view of the National Institutes of Health patient. B, *Top middle,* a CT scan of the neck is shown demonstrating enlarged preauricular, cervical, and occipital lymph nodes. *Arrowheads* denote the most prominent lymph nodes. The *top right* panels show the flow-cytometric analysis of peripheral blood T cells from a patient with autoimmune lymphoproliferative syndrome (ALPS), with CD8 expression on the vertical axis and CD4 on the horizontal axis. The *lower left quadrant* contains CD4$^-$ CD8$^-$ (double-negative) T cells, which are usually present at <1% of T cells expressing the αβ T-cell receptor. The *bottom panels* show CD3, CD4, and CD8 staining on serial sections of a lymph node biopsy specimen from a patient with ALPS, and also show that large numbers of DNCD3$^+$ CD4$^-$ CD8$^-$ (double-negative) T cells are present in the interfollicular areas of the lymph node. (Adapted from Siegel RM, Fleisher TA: The role of Fas and related death receptors in autoimmune and other disease states, *J Allergy Clin Immunol* 103:729–738, 1999.)

Malignancies are also more common in patients with ALPS and include Hodgkin and non-Hodgkin lymphomas and solid-tissue tumors of thyroid, skin, heart, or lung. ALPS is one cause of Evan syndrome (immune thrombocytopenia and immune hemolytic anemia).

Diagnosis

Laboratory abnormalities depend on the lymphoproliferative organ response (hypersplenism) or the degree of autoimmunity (anemia, thrombocytopenia). There may be lymphocytosis or lymphopenia. Table 152.3 lists the criteria for the diagnosis. Flow cytometry helps identify the lymphocyte type (see Fig. 152.4). Functional genetic analysis for the *TNFRSF6* gene often reveals a heterozygous mutation.

Treatment

Rapamycin (sirolimus) will often control the adenopathy and autoimmune cytopenias. Malignancies can be treated with the usual protocols used in patients unaffected by ALPS. Stem cell transplantation is another possible option in treating the autoimmune manifestations of ALPS.

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

This immune dysregulation syndrome is characterized by onset within the 1st few wk or mo of life with watery diarrhea (autoimmune enteropathy), an eczematous rash (erythroderma in neonates), insulin-dependent diabetes mellitus, hyperthyroidism or more often hypothyroidism, severe allergies, and other autoimmune disorders (Coombs-positive hemolytic anemia, thrombocytopenia, neutropenia). Psoriasiform or ichthyosiform rashes and alopecia have also been reported.

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (**IPEX**) syndrome is caused by a mutation in the *FOXP3* gene, which encodes a forkhead-winged helix transcription factor *(scurfin)* involved in the function and development of CD4$^+$ CD25$^+$ regulatory T cells (Tregs). The absence of Tregs may predispose to abnormal activation of effector T cells. Dominant gain-of-function mutations in *STAT1* and other gene mutations (Table 152.4) produce an IPEX-like syndrome, also associated with compromised Tregs.

From Verbsky JW, Chatila TA: Immune dysregulation, polyendocrinopathy, enteropathy, X–linked (IPEX) and IPEX–related disorders: an evolving web of heritable autoimmune diseases, *Curr Opin Pediatr* 25:709, 2013.

Clinical Manifestations

Watery diarrhea with intestinal **villous atrophy** leads to failure to thrive in most patients. Cutaneous lesions (usually eczema) and insulin-dependent diabetes begin in infancy. Lymphadenopathy and splenomegaly are also present. Serious bacterial infections (meningitis, sepsis, pneumonia, osteomyelitis) may be related to neutropenia, malnutrition, or immune dysregulation. Laboratory features reflect the associated autoimmune diseases, dehydration, and malnutrition. In addition, serum IgE levels are elevated, with normal levels of IgM, IgG, and IgA. The diagnosis is made clinically and by mutational analysis of the *FOXP3* gene.

Treatment

Inhibition of T-cell activation by cyclosporine, tacrolimus, or sirolimus with corticosteroids is the treatment of choice, along with the specific care of the endocrinopathy and other manifestations of autoimmunity. These agents are typically used as a bridge to transplant. HSCT is the only possibility for curing IPEX.

Cytotoxic T-Lymphocyte Antigen 4 (CTLA4) Deficiency

Patients with CTLA4 deficiency have lost the ability to maintain immune tolerance, leading to a disease characterized by autoimmunity and multiorgan lymphocytic infiltration of lymphoid and nonlymphoid organs. CTLA4, also known as CD152, is a protein receptor that is expressed on activated T cells. It acts as an immune checkpoint, downregulating immune responses, on T-cell activation. CTLA4 deficiency is inherited in a haploinsufficient manner.

Autoimmune cytopenias, **lymphoid infiltration of lymphoid and nonlymphoid organs** , granulomatous disease, hypogammaglobulinemia, and recurrent respiratory infections are key features. Nonlymphoid organs most often affected with lymphoid infiltration are the brain and gastrointestinal (GI) tract. The immune phenotype of CTLA4-deficient patients includes reduced naïve T cells ($CD4^+$ $CD45RA^+$ $CD62L^+$), loss of circulating B cells, and reduced Treg expression. Treatment is symptom specific, although use of abatacept, a CTLA4-Ig fusion protein, has alleviated disease-specific symptoms in several patients. When refractory to therapy, *HSCT has led to remission of symptoms and cure of disease.*

Lipopolysaccharide (Lps)-Responsive Beige-Like Anchor Protein (LRBA) Deficiency

Homozygous mutations in *LRBA* cause a syndrome of early-onset hypogammaglobulinemia, autoimmunity, lymphoproliferation, and inflammatory bowel disease.

LRBA is a member of the pleckstrin homology-beige and Chédiak-Higashi–tryptophan–aspartic acid dipeptide (PH-BEACH-WD40) protein family. Much is unknown about the function of LRBA. However, in normal T cells, LRBA co-localizes with CTLA4 within recycling endosomes, suggesting that LRBA may play a specific role in the regulation of recycling endosomes. Homozygous mutations in *LRBA* abrogate LRBA protein expression.

Immune dysregulation consisting of enteropathy, autoimmune cytopenias, granulomatous-lymphocytic **interstitial lung disease** , **lymphadenopathy** , and hepatomegaly or splenomegaly are the most common manifestations. Other, less common symptoms of immune dysregulation include cerebral granulomas, type 1 diabetes mellitus, alopecia, uveitis, myasthenia gravis, and eczema. Growth failure occurs in many patients, complicated especially by enteropathy. Bacterial, fungal, and viral infections have been reported in about 50% of patients. The immune phenotype is variable but can consist of reduced T-cell quantities ($CD3^+$), elevated double-negative T cells ($CD3^+$ $CD4^-$ $CD8^-$), normal T-cell proliferation to mitogens and antigens, reduced Treg numbers ($CD4^+$ $CD25^+$ $FoxP3^+$), reduced NK cells ($CD56^+$), and reduced B cells ($CD19^+$). Immunoglobulin quantities are also variable, with hypogammaglobulinemia occurring most frequently.

The focus of therapy is treatment of the immunodysregulatory features with immunosuppression. Corticosteroids, immunoglobulin replacement, mycophenolate mofetil, tacrolimus, rapamycin, budesonide, cyclosporine, azathioprine, rituximab, infliximab, and hydroxychloroquine have all been used with mixed success. Abatacept has been successful in treating the immunodysregulatory features. HSCT has been successfully performed in LRBA-deficient patients as well.

Activated Phosphoinositide 3-Kinase (PI3K) δ Syndromes

These syndromes are primary immunodeficiencies that cause a spectrum of immunodeficiency, lymphadenopathy, and senescent T cells. PI3K molecules are composed of a p110 catalytic subunit (p110α, p110β, or p110δ) and a regulatory subunit (p85α, p55α, p50α, p85β, or p55γ). PI3Ks convert phosphatidylinositol 4,5-bisphosphate to phosphatidylinositol 3,4,5-triphosphate (PIP_3), an important second messenger.

Autosomal dominant gain-of-function mutations in *PIK3CD* , the gene that encodes for the catalytic unit, p110δ, leads to hyperactivated PI3Kδ signaling. AD mutations in *PI3KR*, the gene that encodes the regulatory subunit (p85α, p55α, and p50α) of PI3Ks are associated with the same phenotype. Defects in this pathway lead to a syndrome of chronic lymphoproliferation and T-cell senescence.

Early-onset respiratory tract infections, noninfectious lymphadenopathy, and hepatosplenomegaly are the most common features. A large proportion of patients develop early-onset **bronchiectasis** as a result of recurrent pneumonia. Persistent, severe, or recurrent herpesvirus infections are also common. **Lymphadenopathy** often starts in childhood and localizes to sites of infection. However, lymphadenopathy may be diffuse and is usually associated with chronic CMV or EBV viremia. **Mucosal lymphoid hyperplasia** of the respiratory and GI tracts is also frequent. Histologically, lymph nodes show atypical follicular hyperplasia. **Autoimmune cytopenias** are the most frequent autoimmune manifestation, but others include glomerulopathies, autoantibody-mediated thyroid disease, and sclerosing cholangitis. Early-onset lymphoma, as early as the 2nd yr of life, have been reported as well and are a major cause of mortality. Growth impairment affecting weight and height and developmental delay with mild cognitive impairment also may occur.

The immunophenotype consists of reduced naïve T cell (CD3$^+$ CD4$^+$) and B-cell counts (CD19$^+$) and normal NK cell counts (CD56$^+$). More specifically, reduced numbers of recent thymic emigrants (CD3$^+$ CD4$^+$ CD45RA$^+$ CD31$^+$) with increased effector memory cytotoxic T-cell counts (CD3$^+$ CD8$^+$ CCR7$^-$ CD45RA$^{+/-}$), increased transitional B cells (CD19$^+$ IgM$^+$ CD38$^+$), and reduced nonswitched memory B cells (CD19$^+$ IgD$^+$ CD27$^+$) and class-switched memory B cells (CD19$^+$ IgD$^+$ CD27$^+$) are hallmark. Immunoglobulin levels are variable, but typically there are increased serum quantities of IgM, reduced or normal IgG, and reduced or normal IgA.

Treatment is symptom specific but can include antimicrobial prophylaxis and immunoglobulin replacement. Various immunosuppressive agents (e.g., rituximab, rapamycin) have been used to treat the lymphoproliferative disease and autoimmune cytopenias that are often present. HSCT has also been successfully performed in those refractory to medical therapy.

Signal Transducer and Activator of Transcription (STAT) Pathway Defects

The Janus kinase (JAK)-STAT signal transduction pathway is used for signal transduction by type 1 and type 2 cytokine receptors within most hematopoietic cells. Cytokines bind to their cognate receptor, triggering JAK-STAT pathways, ultimately leading to the upregulation of genes involved in the immune response against many pathogens. There are 4 JAK proteins (Jak1, Jak2, Jak3, Tyk2) and 6 STATs (1-6). Mutations in several JAKs and STATs cause immunodeficiency. Table 152.5 includes diseases affecting STAT proteins characterized by immune dysregulation. Chronic immunosuppression is necessary for control of STAT defects. Ruxolitinib, a JAK-STAT inhibitor, has been used with some success. With the advent of JAK-STAT immunomodulating therapies, more treatment options will be available to patients.

Table 152.5

Defects of STAT Proteins Associated With Immunodysregulation

PROTEIN	LOF/GOF	AUTOIMMUNE OR INFLAMMATORY COMPLICATIONS	OTHER CHARACTERISTICS	IMMUNOPHENOTYPE
STAT1	GOF	IPEX-like enteropathy, enteropathy, endocrinopathy, dermatitis, cytopenias	Infections CMC Viral infections NTM Dimorphic mold Respiratory bacterial	Variable lymphopenia, hypogammaglobulinemia, abnormal T-cell function, reduced Th17 expression

Nuclear Factor-κB Pathway Defects

The NF-κB pathways consists of canonical (NF-κB1) and noncanonical (NF-κB2) pathways. On cellular activation, both pathways lead to activation and translocation of NF-κB proteins into the nucleus, where they initiate downstream inflammatory responses. Defects in many proteins in both pathways have been described. Table 152.6 describes immune defects of the NF-κB pathways that cause symptoms of immune dysregulation or autoimmunity. Treatment of NF-κB defects includes prevention of infections and replacement of immunoglobulin and has included HSCT.

Table 152.6

Defects of Nuclear Factor-κB Pathways Associated With Immune Dysregulation

PROTEIN	INHERITANCE	AUTOIMMUNE OR INFLAMMATORY COMPLICATIONS	OTHER MANIFESTATIONS	IMMUNOLOGIC PHENOTYPE

Tetratricopeptide Repeat Domain 7A (TTC7A) Deficiency

Combined immunodeficiency with T-cell and B-cell defects had long accompanied hereditary **multiple intestinal atresia** . Mutations in *TTC7A* are causative of the combined intestinal and immunologic defects. TTC7A is involved in cell cycle control, cytoskeletal organization, cell shape and polarity, and cell adhesion. Deficiency of TTC7A is inherited in an autosomal recessive manner. Multiple intestinal atresia with disruption of intestinal architecture is a universal feature. Often, early-onset severe enterocolitis occurs concurrently. Immunodeficiency with severe T-cell lymphopenia has been described; B- and NK-cell defects are variable. T-cell proliferative responses are also abnormal. Severe hypogammaglobulinemia is common. Treatment includes removal of atretic areas of the intestine and antimicrobial prophylaxis in immunodeficient patients. Bowel transplant has also been performed with some success.

Deficiency of Adenosine Deaminase 2 (DADA2)

Deficiency in ADA2 is a cause of early **vasculopathy, stroke** , and immunodeficiency. DADA2 is secondary to autosomal recessive mutations in cat-eye syndrome chromosome region 1 (*CECR1*), mapped to chromosome 22q11.1. ADA2 is important in purine metabolism converting adenosine to inosine and 2′-deoxyadenosine to 2′-deoxyinosine. The pathogenesis is not exactly known, but ADA2 is mostly secreted by myeloid cells, and deficiency leads to upregulation of proinflammatory genes and increased secretion of proinflammatory cytokines. DADA2 is characterized by chronic or recurrent inflammation with elevated acute-phase reactants and fever. Skin manifestations include livedo reticularis, maculopapular rash, nodules, purpura, erythema nodosum, Raynaud phenomenon, ulcerative lesions, and digital necrosis. CNS involvement is variable but can include transient ischemic attacks and ischemic or hemorrhagic stroke. Peripheral neuropathy is also common. GI manifestations include hepatosplenomegaly, gastritis, bowel perforation, and portal hypertension. Nephrogenic hypertension is common and can be associated with glomerulosclerosis or amyloidosis. Immunodeficiency consists of hypogammaglobulinemia and variable decreases in IgM.

Treatment with chronic long-term corticosteroids and anti-TNF-α agents have shown modest control of disease manifestations. HSCT has been successful in 2 patients as well.

Neutrophils

Thomas D. Coates

The Phagocytic Inflammatory Response

The phagocyte system includes both granulocytes (neutrophils, eosinophils, and basophils) and mononuclear phagocytes (monocytes and tissue macrophages). Neutrophils and mononuclear phagocytes share primary functions, including the defining properties of large-particle ingestion and microbial killing. Phagocytes participate primarily in the innate immune response but also help initiate acquired immunity. Mononuclear phagocytes, including tissue macrophages and circulating monocytes, are discussed in Chapter 154 .

Neutrophils provide the rapid effector arm of the innate immune system. They circulate in the bloodstream for only about 6 hr (Table 153.1), but on encountering specific chemotactic signals, they adhere to the vascular endothelium and transmigrate into tissues. There they ingest and kill microbes and release chemotactic signals to recruit more neutrophils and to attract dendritic cells and other initiators of the acquired immune response.

Table 153.1

Neutrophil and Monocyte Kinetics

NEUTROPHILS	
Average time in mitosis (myeloblast to myelocyte)	7-9 days
Average time in postmitosis and storage (metamyelocyte to neutrophil)	3-7 days
Average half-life in the circulation	6 hr
Average total body pool	6.5 × 10^8 cells/kg
Average circulating pool	3.2 × 10^8 cells/kg
Average marginating pool	3.3 × 10^8 cells/kg
Average daily turnover rate	1.8 × 10^8 cells/kg
MONONUCLEAR PHAGOCYTES	

Average time in mitosis	30-48 hr
Average half-life in the circulation	36-104 hr
Average circulating pool (monocytes)	1.8 × 10^7 cells/kg
Average daily turnover rate	1.8 × 10^9 cells/kg
Average survival in tissues (macrophages)	Months

Hematopoiesis

The hematopoietic progenitor system can be viewed as a continuum of functional compartments, with the most primitive compartment composed of very rare **pluripotential stem cells** , which have high self-renewal capacity and give rise to more mature stem cells, including cells that are committed to either lymphoid or myeloid development (Fig. 153.1). Common lymphoid progenitor cells give rise to T- and B-cell precursors and their mature progeny (see Chapter 149). Common myeloid progenitor cells eventually give rise to committed single-lineage progenitors of the recognizable precursors through a random process of lineage restriction in a stepwise process (see Chapter 473). The capacity of lineage-specific committed progenitors to proliferate and differentiate in response to demand provides the hematopoietic system with a remarkable range of response to changing requirements for mature blood cell production.

FIG. 153.1 Major cytokine sources and actions and transcription factor requirements for hematopoietic cells. Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblastoid cells, produce macrophage, granulocyte-macrophage, and granulocyte colony-stimulating factors (M-CSF, GM-CSF, G-CSF), interleukin-6 (IL-6), and probably stem cell factor (SCF) (cellular sources not precisely determined) after induction with endotoxin (macrophage) or IL-1/tumor necrosis factor (TNF) (endothelial cells and fibroblasts). T cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages, optimal development requires a combination of early-acting and late-acting factors. Transcription factors important for survival or self-renewal of stem cells are shown in *red* at the *top,* whereas stages of hematopoiesis blocked after the depletion of indicated transcription factors are shown in *red* for multipotent and committed progenitors. (From *Nathan & Oski's hematology and oncology of infancy and childhood,* ed 8, vol 2, Philadelphia, 2015, Elsevier, p 10.)

The proliferation, differentiation, and survival of immature hematopoietic progenitor cells are governed by hematopoietic growth factors, a family of glycoproteins (see Chapter 473). Besides regulating proliferation and differentiation of progenitors, these factors influence the survival and function of mature blood cells. During granulopoiesis and monopoiesis, multiple cytokines regulate the cells at each stage of differentiation from pluripotent stem cells to nondividing, terminally differentiated cells (monocytes, neutrophils, eosinophils, and basophils). As cells mature, they lose receptors for most cytokines, especially those that influence early cell development; however, they retain receptors for cytokines that affect their mobilization and function, such as granulocyte and macrophage colony-stimulating factors. Mature phagocytes also express receptors for chemokines, which help direct the cells to sites of inflammation. Chemokine receptors such as CXCR4 and its ligand SDF-1 play a key role in retention of developing myeloid cells within bone marrow.

Neutrophil Maturation and Kinetics

The process of intramedullary granulocyte maturation involves changes in nuclear configuration and accumulation of specific intracytoplasmic granules. The bone marrow microenvironment supports the normal steady-state renewal of peripheral blood neutrophils through the generation of growth and differentiation factors by stromal cells. Growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) not only stimulate cell division, but also induce the expression of transcription factors that regulate the biosynthesis of functional components of the neutrophil, such as granule proteins. The transcription factor PU.1 is essential for myelopoiesis, both as a positive regulatory element and as a suppressor of GATA1, a transcription factor that directs nonmyeloid differentiation. Other transcription factors, such as Runx1 (AML1), c-myb, CDP, C/EBPα, C/EBPγ, and MEF, are expressed in the myeloblast and promyelocyte, and some of these are required for azurophil granule protein expression. As cells enter the myelocyte stage, Runx1 and myb are downregulated, whereas PU.1 and C/EBPε expression rises to initiate terminal differentiation.

Granulocytes survive for only 6-12 hr in the circulation, and therefore daily production of 2×10^4 granulocytes/μL of blood is required to maintain a level of circulating granulocytes of 5×10^3 /μL (see Table 153.1). The relatively small peripheral blood pool includes the rapidly interchanging circulating and marginating pools; the latter provides entrance into the tissue phase, where neutrophils may survive for hours or days. The circulating pool is fed and buffered by a much larger marrow population of mature neutrophils and myeloid precursors, representing the marrow reserve and proliferating pools, respectively. Proliferation of myeloid cells, encompassing approximately 5 mitotic divisions, takes place only during the first 3 stages of neutrophil development, in myeloblasts, promyelocytes, and myelocytes. After the myelocyte stage, the cells terminally differentiate into nondividing, maturing metamyelocytes, bands, and neutrophils.

Neutrophil maturation is associated with nuclear condensation and lobulation and the sequential production of characteristic granule populations. A **myeloblast** is a relatively undifferentiated cell with a large oval nucleus, a sizable nucleolus, and a deficiency of granules. **Promyelocytes** acquire peroxidase-positive azurophilic (primary) granules, and then **myelocytes** and **metamyelocytes** acquire specific (secondary) granules; tertiary granules and secretory vesicles develop in the final stage of neutrophil maturation.

Neutrophil Function

Neutrophil responses are initiated as circulating neutrophils flowing through the postcapillary venules detect low levels of chemokines and other chemotactic substances released from a site of infection. The sequence of events as the neutrophil moves from circulating in the blood to the encounter and destruction of bacteria is carefully orchestrated by a series of biochemical events, defects of which are associated with genetic disorders of neutrophil function (Fig. 153.2). In fact, these disorders of neutrophil function lead to our understanding of the cell biology of phagocyte function. A subset of circulating neutrophils loosely adheres to the endothelium through low-affinity receptors called **selectins** and rolls along the endothelium, forming the marginated pool. Soluble effectors of inflammation trigger subtle changes in surface adhesion molecules on endothelial cells at the site of infection. The rolling of neutrophils allows more intense exposure of neutrophils to activating factors such as tumor necrosis factor or interleukin-1 (Fig. 153.2). Exposure of neutrophils to these same activating factors induces qualitative and quantitative changes in the family of β_2 -integrin adhesion receptors (the CD11/CD18 group of surface molecules), leading to tight adhesion between neutrophils and endothelial cells at the site of inflammation and ultimately to transmigration of the neutrophil into the tissue.

FIG. 153.2 **The neutrophil-mediated inflammatory response and associated neutrophil dysfunction syndromes. Circulating neutrophils loosely attach to endothelium via selectins and roll along the vessel wall until they arrive at the site of infection. Inflammatory monokines, interleukin-1 (IL-1), and tumor necrosis factor (TNF) activate endothelial cells to express E- and P-selectins. E- and P-selectins serve as counter-receptors for neutrophils sialyl Lewis X and Lewis X to cause low-avidity neutrophil rolling. Activated endothelial cells express ICAM-1, which serves as a counter-receptor for neutrophil β_2 -integrin molecules, leading to high-avidity leukocyte spreading and the start of transendothelial migration at the infection site. Neutrophils invade through the vascular basement membrane with the release of proteases and reactive oxidative intermediates, causing local destruction of surrounding tissue at sites of high concentrations of chemotactic factors, and migrate to the site of infection, where they ingest and kill the bacteria. (Modified from Kyono W, Coates TD: A practical approach to neutrophil disorders, *Pediatr Clin North Am* 49:929, 2002.)**

Once through the endothelium, the neutrophil senses the gradient of chemokines or other chemoattractants and migrates to sites of infection. **Neutrophil migration** is a complex process involving rounds of receptor engagement, signal transduction, and remodeling of the actin microfilaments composing in part the cytoskeleton. Actin polymerization-depolymerization occurs in approximately 8 sec cycles and drives cyclic extension and retraction of the actin-rich lamella at the front of the neutrophil. Receptors at the leading edge of the lamella detect the gradient of attractant and follow microorganisms, then ingest and destroy them. When the neutrophil reaches the site of infection, it recognizes pathogens by means of Fc immunoglobulin and complement receptors, Toll-like receptors, fibronectin receptors, and other adhesion molecules.

The neutrophil ingests microbes that are coated by **opsonins** , serum proteins such as immunoglobulin and complement component **C3** . The pathogens are engulfed into a closed vacuole, the **phagosome** (Fig. 153.3), where 2 cellular responses essential for optimal microbicidal activity occur concomitantly: degranulation and activation of nicotinamide-adenine dinucleotide phosphate (NADPH)–dependent oxidase. Fusion of neutrophil granule membranes with the phagosome membrane delivers potent antimicrobial proteins and small peptides into the phagosome.

On activation of phagocytic cells, the 3 cytosolic components *(red)* of the NADPH oxidase (p67 ^{phox} , p47 ^{phox} , and p40 ^{phox}), plus the small guanosine triphosphatase (GTPase) protein Rac2, are translocated to the membrane of the phagocytic vacuole. The p47 ^{phox} subunit binds to the flavocytochrome $_{b558}$ membrane component *(blue-green)* of the NADPH oxidase (gp91 ^{phox} plus p22 ^{phox}). The NADPH oxidase catalyzes the formation of superoxide by transferring an electron from NADPH to molecular oxygen (O_2), thereby forming the superoxide free radical. The unstable superoxide anion is converted to hydrogen peroxide, either spontaneously or by superoxide dismutase (SOD). H_2O_2 can follow different metabolic pathways into more potent reactive oxidants, such as OH* or HOCl) or degradation to $H_2O + O_2$. (Adapted from Stiehm ER, Ochs HD, Winkelstein JA: *Immunologic disorders in infants and children,* ed 5, Philadelphia, 2004, Saunders, p 622.)

Assembly and activation of NADPH oxidase occur at the phagosome membrane as well (see Fig. 153.3), generating large amounts of superoxide (O_2^-) from molecular oxygen, which in turn decomposes to produce hydrogen peroxide (H_2O_2) and singlet oxygen. **Myeloperoxidase,** a major azurophil granule component, catalyzes the reaction of H_2O_2 with ubiquitously present chloride ions to create hypochlorous acid (HOCl) in the phagosome. H_2O_2 and HOCl are potent microbicidal agents that break down and clear pathogens from sites of infection.

In addition, neutrophils secrete a wide variety of cytokines and chemokines that recruit more neutrophils to fight the infection, attract monocytes and macrophages that possess both microbicidal and scavenger functions, and promote antigen presentation to help initiate the adaptive immune response. Also, the reactive oxidants can inactivate chemotactic factors and may serve to terminate the process of neutrophil influx, thereby attenuating the inflammatory process. Finally, the release of reactive oxygen species, granule proteins, and cytokines can also damage local tissues, leading to the classic signs of inflammation or to more permanent impairment of tissue integrity and function.

CHAPTER 154

Monocytes, Macrophages, and Dendritic Cells

Richard B. Johnston Jr.

Mononuclear phagocytes (monocytes, macrophages) are distributed across all body tissues and play a central role in maintaining immunologic and metabolic homeostasis. They are essential for innate host defense against infection, tissue repair and remodeling, and the antigen-specific adaptive immune response. No human has been identified as having congenital absence of this cell line, probably because macrophages are required to remove primitive tissues during fetal development as new tissues develop to replace them. Monocytes and tissue macrophages in their several forms have variable morphology, surface markers, and transcriptional profiles but common functions, particularly phagocytosis (Table 154.1). Dendritic cells (DCs) are specialized derivatives of this mononuclear phagocyte system that develop from myeloid cell precursors or monocytes themselves.

Granulomas (multinucleated giant cells)

Development

Monocytes develop more rapidly during bone marrow hematopoiesis and remain longer in the circulation than do neutrophils (see Table 153.1). The **monoblast** is the first recognizable monocyte precursor, followed by the **promonocyte** , with cytoplasmic granules and an indented nucleus, and finally the fully developed monocyte with cytoplasmic granules filled with hydrolytic enzymes. The transition from monoblast to mature circulating monocyte requires about 6 days.

Three major subsets of human monocytes can be identified on the basis of surface antigens: CD14^{++} CD16^{-} *classical* monocytes that constitute the majority of total monocytes in the resting state; the more mature CD14^{++} CD16^{+} *proinflammatory* (*intermediate*) monocytes, which produce proinflammatory hormone-like factors termed **cytokines** , such as tumor necrosis factor-α (TNF-α), in response to microbial stimuli; and *nonclassical* (*regulatory)* monocytes (CD14^{+} CD16^{++}) that promote wound healing. Monocytes from these subsets migrate into tissues in response to localized inflammation or injury and provide proinflammatory host defense or antiinflammatory responses and wound healing.

Tissue (organ)-specific macrophages arise from macrophage progenitors that develop in the yolk sac and fetal liver before hematopoiesis occurs in the bone marrow. These cells maintain their population through self-renewal. Tissue macrophages can also be populated to some extent by circulating monocytes. Monocytes or macrophages at sites of active inflammation mature into proinflammatory (M1) macrophages or proresolving (M2) macrophages. In ongoing tissue injury or inflammation, many (perhaps most) of the macrophages will express a mix of the properties of the classic types.

Whether embryonic or blood derived, tissue macrophages are directed by organ-specific factors to differentiate into macrophages characteristic of that organ. Embryonic progenitors or monocytes in the liver become **Kupffer cells** that bridge the sinusoids separating adjacent plates of hepatocytes. Those at the lung airway surface become large ellipsoid **alveolar macrophages** , those in the bone become **osteoclasts** , and those in brain or retina become **microglia** . All macrophages, however, have at least 3 major functions in common: phagocytosis, presentation of antigens to lymphocytes, and enhancement or suppression of the immune response through release of a variety of potent cytokines. At sites of inflammation, monocytes and macrophages can fuse to form **multinucleated giant cells** ; these cells maintain the antimicrobial functions of macrophages.

Activation

The most important step in the maturation of tissue macrophages is the conversion from a resting to a more functionally active cell, a process driven primarily by certain cytokines and microbial products. *Macrophage activation* is a generic term, with the functional characteristics of an activated macrophage population varying with the cytokine or other stimulus (microbial, chemical) to which the population has been exposed.

Classical activation refers to a response to infection that is driven by specifically activated T-helper (Th) type 1 (Th1-type) lymphocytes and natural killer (NK) cells through their release of interferon-γ (IFN-γ). TNF-α secreted by activated macrophages amplifies their activation, as does bacterial cell wall protein or endotoxin through Toll-like receptors (TLRs). **Alternative activation** is driven by Th2-type lymphocytes through release of interleukin-4 (IL-4) and IL-13, cytokines that regulate antibody responses, allergy, and resistance to parasites. Alternatively activated macrophages may have particular functional advantages, such as in wound healing and immunoregulation. In the traditional context of host defense, the term *activated macrophage* indicates that the “classically activated” cell has an enhanced capacity to kill microorganisms or tumor cells. These macrophages are larger, with more pseudopods and pronounced ruffling of the plasma membrane, and they exhibit accelerated activity of many functions (Table 154.2). Considering the variety of macrophage activities essential to the maintenance of homeostasis, it seems likely that so-called classically activated, M1-type, and alternatively activated, M2-type, macrophages are extremes of a continuum of physiologic functions expressed by these long-lived cells in response to the specific task at hand.

Table 154.2

Upregulated Functions in Macrophages Activated in Response to Infection

Microbicidal and tumoricidal activity
Phagocytosis (of most particles) and pinocytosis

Membrane expression of MHC, CD40, TNF receptor
Antigen presentation
Secretion:
    Complement components
    Lysozyme, acid hydrolases, and cytolytic proteinases
    Collagenase
    Plasminogen activator
    Interleukins, including IL-1, IL-12, and IL-15
    TNF-α
    Interferons, including IFN-α and IFN-β
    Antimicrobial peptides (cathelicidin, defensins)
    Angiogenic factors

H_2O_2, Hydrogen peroxide; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; O_2^-, superoxide anion; TNF, tumor necrosis factor.

Classical macrophage activation is accomplished during infection with intracellular pathogens (e.g., mycobacteria, *Listeria*) through crosstalk between Th1 lymphocytes and antigen-presenting macrophages mediated by the engagement of a series of ligands and receptors on the 2 cell types, including class II major histocompatibility complex (MHC) molecules and CD40 on macrophages and CD40 ligand on Th1 cells, and through secretion of cytokines. Macrophages encountering microorganisms release IL-12, which stimulates T cells to release IFN-γ. These interactions constitute the basis of cell-mediated immunity. IFN-γ is an especially important macrophage-activating cytokine; it is currently used as a therapeutic agent.

Functional Activities

Numerous functions are upregulated when the macrophage is activated in response to infection (see Table 154.2). Of importance are the ingestion and killing of *intracellular* pathogens such as mycobacteria, *Listeria, Leishmania, Toxoplasma*, and some fungi. Killing of the ingested organisms of any kind depends heavily on products of the *respiratory burst* (e.g., hydrogen peroxide) and on nitric oxide, and release of these metabolites is enhanced in activated macrophages. Whether activated or not, splenic and hepatic macrophages are essential for clearing the bloodstream of *extracellular* pathogens such as pneumococci.

The capacity to undergo diapedesis across the endothelial wall of blood vessels and to migrate to sites of microbial invasion is essential to monocyte function. Chemotactic factors for monocytes include complement products and chemotactic peptides (**chemokines**) derived from neutrophils, lymphocytes, and other cell types. Phagocytosis of the invading organisms can then occur, influenced by the presence of opsonins for the invader (antibody, complement, mannose-binding and surfactant proteins), the inherent surface properties of the microorganism, and the state of activation of the macrophage.

Monocytes migrating to intestinal mucosa are modified by stromal factors so that they lose innate receptors for microbial products such as endotoxin, and they do not effectively produce proinflammatory cytokines. They retain, however, the capacity to ingest and kill microbes. They have been modified during evolution to allow the absence of inflammation typical of normal intestinal mucosa despite its constant exposure to huge numbers of microbes and their inflammatory by-products.

Macrophages play an essential role in the disposal of damaged and dying cells, helping resolve the inflammatory response and heal wounds. Brain microglia demonstrate these functions particularly well. In conditions such as stroke, neurodegenerative disease, and tumor invasion, these cells can become activated, surround damaged and dead cells, and clear cellular debris. Macrophages lining the sinusoids of the spleen are especially important in ingesting aged or autoantibody-coated erythrocytes or platelets; splenectomy is used to manage autoimmune cytopenias. In the process of **efferocytosis** , macrophages in inflammatory sites can recognize changes in phosphatidylserine on the membrane of neutrophils undergoing apoptosis, and these can be removed before they spill their toxic contents into the tissue. Macrophages also remove the extracellular traps exuded by inflammatory neutrophils, thus reducing the risk of autoimmunity. Macrophages can be identified early in fetal development, where they function to remove debris as one maturing embryonic tissue replaces another; in the brain, microglia prune synapses opsonized with C1q. Macrophages are also important in removing inorganic particles, such as elements of cigarette smoke, that enter the alveoli.

Macrophages are involved in the induction and expression of adaptive immune responses, including antibody formation and cell-mediated immunity. This depends on their capacity to break down foreign material, then present individual antigens on their surface as peptides or polysaccharides bound to MHC class II molecules. Monocytes, B lymphocytes, and most effectively, DCs, also present antigens to T cells for the specific immune response. Activated macrophages express increased MHC class II molecules, and antigen presentation is more effective.

The heightened capacity of activated macrophages to synthesize and release various hydrolytic enzymes and microbicidal materials contributes to their increased killing capacity (see Table 154.2). The macrophage is an extraordinarily active secretory cell shown to secrete >100 distinct substances, including cytokines, growth factors, and sterol hormones, placing it in a class with the hepatocyte. Because of the profound effect of some of these secretory products on other cells and the large number and widespread distribution of macrophages, this network of cells can be viewed as an important endocrine organ. IL-1 illustrates this point. Microbes and microbial products, burns, ischemia–reperfusion, and other causes of inflammation or tissue damage stimulate the release of IL-1, mainly by monocytes, macrophages, and epithelial cells. In turn, IL-1 elicits fever, sleep, and release of IL-6, which induces production of acute-phase proteins.

The complex relationship between mononuclear phagocytes and cancer is becoming more clear. Macrophages have been demonstrated to kill tumor cells by ingestion and by means of secreted products, including lysosomal enzymes, nitric oxide, oxygen metabolites, and TNF-α. In contrast, M2-type **tumor-associated macrophages (TAMs)** can stimulate growth of tumors through secretion of growth and angiogenic factors such as vascular endothelial growth factor (VEGF), promote metastasis, and inhibit T-cell antitumor immune responses. TAMs are currently targets of clinical trials studying attempts to reprogram them to antitumor macrophages or otherwise blunt their tumor-supportive capacity.

As traumatic damage and infection subside, the macrophage population shifts toward playing an essential role in tissue repair and healing through removal of apoptotic cells and secretion of IL-10, transforming growth factor-β, lipoxins, and the “specialized proresolving mediators,” omega-3 fatty acid–derived resolvins, protectins, and maresins.

Dendritic Cells

Dendritic cells are a type of mononuclear phagocyte found in blood, lymphoid organs, and all tissues. DCs are specialized to capture, process, and present antigens to T cells to generate adaptive immunity or tolerance to self-antigens. Human monocytes can be induced to differentiate into DCs in some circumstances, particularly inflammation. DCs express retractable dendritic (branched) extensions and potent endocytic capacity but are a heterogeneous population from the standpoint of location, surface markers, level of antigen-presenting activity, and function. Single-cell RNA sequencing has defined 6 human DC subtypes; but 2 major functional types of DCs can be identified: *conventional* DCs, which include Langerhans cells in the epithelial surfaces of skin and mucosa, dermal or interstitial DCs in subepithelial skin, and interstitial DCs in solid organs; and *plasmacytoid* DCs, sentinels for viral infection and principal source of antiviral IFN-α and IFN-β.

DCs migrating from the bloodstream enter skin, epithelial surfaces, and lymphoid organs where, as immature cells, they internalize self and foreign antigens. Microbial products, cytokines, or molecules exposed in damaged tissue (“danger signals” or “alarmins”) induce DC maturation, with upregulation of cytokine receptors and MHC class II and co-stimulatory molecules that expedite cell-cell binding. Stimulated DCs in the periphery migrate to lymphoid organs, where they continue to mature. They function there as the most potent cells that present antigens to T lymphocytes and induce their proliferation, activities that are central to the antigen-specific adaptive immune response. Macrophage IL-10 acts to suppress DC maturation during resolution of inflammation.

DCs from cancer patients have been used in an attempt to control their cancer. The patient's DCs are amplified and matured from blood monocytes or marrow progenitor cells by cytokines, exposed to antigens from the patient's tumor, then injected into the patient as a “vaccine” against the cancer.

Abnormalities of Monocyte-Macrophage or Dendritic Cell Function

Mononuclear phagocytes and neutrophils from patients with **chronic granulomatous disease (CGD)** exhibit a profound defect of phagocytic killing (see Chapter 156). The inability of affected macrophages to kill ingested organisms leads to abscess formation and characteristic granulomas at sites of macrophage accumulation beneath the skin and in the liver, lungs, spleen, and lymph nodes. IFN-γ is used to prevent infection in CGD patients and to treat the decreased bone resorption of **congenital osteopetrosis** , which is caused by decreased function of osteoclasts. Genetic deficiency of the CD11/CD18 complex of membrane adherence glycoproteins **(leukocyte adhesion defect 1),** which includes a receptor for opsonic complement component 3, results in impaired phagocytosis by monocytes (see Chapter 156).

The monocyte-macrophage system is prominently involved in **lipid storage diseases** called sphingolipidoses (see Chapter 104). In these conditions, macrophages express a systemic enzymatic defect that permits accumulation of cell debris that they normally clear. Resistance to infection can be impaired, at least partly because of impairment in macrophage function. In **Gaucher disease** , the prototype for these disorders, the enzyme glucocerebrosidase functions abnormally, allowing accumulation of glucocerebroside from cell membranes in Gaucher cells throughout the body. In all locations the Gaucher cell is an altered macrophage. These patients can be treated with infusions of the normal enzyme modified to expose mannose residues, which bind to mannose receptors on macrophages.

The cytokine IL-12 is a powerful inducer of IFN-γ production by T cells and NK cells. Individuals with inherited deficiency in macrophage receptors for IFN-γ or lymphocyte receptors for IL-12, or in IL-12 itself, undergo a severe, selective susceptibility to infection by nontuberculous mycobacteria such as *Mycobacterium avium* complex or bacille Calmette-Guérin (see Chapter 152). About half these patients have had disseminated *Salmonella* infection. These abnormalities are grouped as **defects in the IFN- γ–IL-12 axis** .

Monocyte-macrophage function has been shown to be partially abnormal in various clinical conditions. Cultured mononuclear phagocytes of newborns are more readily infected than adult cells by HIV-1 and measles virus. Macrophages from newborns release less granulocyte colony-stimulating factor (G-CSF) and

IL-6 in culture, and this deficiency is accentuated in cells from preterm infants. This finding supports the observations that G-CSF levels are significantly decreased in blood from newborns, and that the marrow granulocyte storage pool is diminished in infants, particularly preterm infants. Mononuclear cells from newborns produce less IFN-γ and IL-12 than do adult cells, and macrophages cultured from cord blood are not activated normally by IFN-γ. This combination of deficiencies would be expected to blunt the newborn's response to infection by viruses, fungi, and intracellular bacteria.

More than 100 different subtypes of the **histiocytoses** have been organized into 5 major groups based on clinical, pathologic, genetic, and other features. These rare disorders are characterized by accumulation of macrophages or DCs in tissues or organs. “Histiocyte” is a histologic term and not cell specific, but it has been retained because of its long usage to identify the classic members of this family. Familial and secondary **hemophagocytic lymphohistiocytosis** is characterized by uncontrolled activation of T cells and macrophages, with resultant fever, hepatosplenomegaly, lymphadenopathy, pancytopenia, marked elevation of serum proinflammatory cytokines, and macrophage hemophagocytosis (see Chapter 534). The familial form usually presents in the 1st yr of life. Up to 5% of children with systemic-onset juvenile rheumatoid arthritis develop an acute severe complication termed **macrophage activation syndrome** , with persistent fever (rather than typical febrile spikes), hepatosplenomegaly, pancytopenia, macrophage hemophagocytosis, and coagulopathy, which can progress to disseminated intravascular coagulation and death if not recognized (see Chapter 180).

Two genetic autoinflammatory diseases result from dysregulation of the mononuclear phagocyte–produced proinflammatory cytokine IL-1. In **neonatal-onset multisystem inflammatory disorder** , monocytes overproduce IL-1. In **deficiency of the IL-1 receptor antagonist** , normal activity levels of IL-1 go unopposed. In both conditions, patients present in the 1st few days or weeks of life with pustular or urticarial rash, bony overgrowth, sterile osteomyelitis, elevated erythrocyte sedimentation rate, and other evidence of systemic inflammation. The recombinant IL-1 receptor antagonist anakinra is effective treatment for both these disorders (Chapter 188).

CHAPTER 155

Eosinophils

Benjamin L. Wright, Brian P. Vickery

Eosinophils are distinguished from other leukocytes by their morphology, constituent products, and association with specific diseases. Eosinophils are nondividing, fully differentiated cells with a diameter of approximately 8 μm and a bilobed nucleus. They differentiate from stem cell precursors in the bone marrow under the control of T-cell–derived interleukin-3 (IL-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), and especially IL-5. Their characteristic membrane-bound specific granules stain bright pink with eosin and consist of a crystalline core made up of major basic protein (MBP) surrounded by a matrix containing the eosinophil cationic protein (ECP), eosinophil peroxidase (EPX), and eosinophil-derived neurotoxin (EDN). These basic proteins are cytotoxic for the larval stages of helminthic parasites and are also thought to contribute to much of the inflammation associated with chronic allergic diseases such as asthma (see Chapter 169).

Eosinophil MBP, ECP, and EPX are also present in large quantities in the airways of patients who have died of asthma and are thought to inflict epithelial cell damage leading to airway hyperresponsiveness, although recent studies indicate the role of these granule proteins may be more nuanced and not purely destructive. Eosinophil granule contents also contribute to eosinophilic endomyocardial disease associated with the hypereosinophilic syndrome. MBP has the potential to activate other proinflammatory cells, including mast cells, basophils, neutrophils, and platelets. Eosinophils have the capacity to generate large amounts of the lipid mediators platelet-activating factor and leukotriene C_4, both of which can cause vasoconstriction, smooth muscle contraction, and mucus hypersecretion (Fig. 155.1). Eosinophils are a source of a number of proinflammatory cytokines, including IL-1, IL-3, IL-4, IL-5, IL-9, IL-13, and GM-CSF. They have also been shown to influence T-cell recruitment and immune polarization in inflammatory settings. Thus, eosinophils have considerable potential to initiate and sustain the inflammatory response of the innate and acquired immune systems.

FIG. 155.1 **Schematic diagram of an eosinophil and its diverse properties. Eosinophils are bilobed granulocytes that respond to diverse stimuli, including allergens, helminths, viral infections, allografts, and nonspecific tissue injury. Eosinophils express the receptor for IL-5, a critical eosinophil growth and differentiation factor, as well as the receptor for eotaxin and related chemokines (CCR3). The secondary granules contain four primary cationic proteins designated eosinophil peroxidase (EPO), major basic protein (MBP), eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN). All 4 proteins are cytotoxic molecules; also, ECP and EDN are ribonucleases. In addition to releasing their preformed cationic proteins, eosinophils can release a variety of cytokines, chemokines and neuromediators and generate large amounts of LTC4. Lastly, eosinophils can be induced to express MHC class II and co-stimulatory molecules and may be involved in propagating immune responses by presenting antigen to T cells. (From Leung YM, Szefler SJ, Bomilla FA, Akdis CA, Sampson HA: *Pediatric allergy principles and practice,* ed 3, Philadelphia, 2016, Elsevier, p 42.)**

Eosinophil migration from the vasculature into the extracellular tissue is mediated by the binding of leukocyte adhesion receptors to their ligands or counterstructures on the postcapillary endothelium. Similar to neutrophils (see Fig. 153.2), transmigration begins as the eosinophil selectin receptor binds to the endothelial carbohydrate ligand in loose association, which promotes eosinophils rolling along the endothelial surface until they encounter a priming stimulus such as a chemotactic mediator. Eosinophils then establish a high-affinity bond between integrin receptors and their corresponding immunoglobulin-like ligand. Unlike neutrophils, which become flattened before transmigrating between the tight junctions of the endothelial cells, eosinophils can use unique integrins, known as very late antigens (VLA-4), to bind to vascular cell adhesion molecule (VCAM)-1, which enhances eosinophil adhesion and transmigration through endothelium. Eosinophils are recruited to tissues in inflammatory states by a group of chemokines known as **eotaxins** (eotaxin 1, 2, and 3). These unique pathways account for selective accumulation of eosinophils in allergic and inflammatory disorders. Eosinophils normally dwell primarily in tissues, especially tissues with an epithelial interface with the environment, including the respiratory, gastrointestinal (GI), and lower genitourinary tracts. The life span of eosinophils may extend for weeks within tissues.

IL-5 selectively enhances eosinophil production, adhesion to endothelial cells, and function. Considerable evidence shows that IL-5 has a pivotal role in promoting eosinophilpoeisis. It is the predominant cytokine in allergen-induced pulmonary late-phase reaction, and antibodies against IL-5 (mepolizumab, reslizumab, benralizumab), decrease sputum eosinophils and reduce exacerbations in a subset of patients with asthma. Eosinophils also bear unique receptors for several chemokines, including RANTES (regulated on activation, normal T-cell expressed and secreted), eotaxin, and monocyte chemotactic proteins 3 and 4. These chemokines appear to be key mediators in the induction of tissue eosinophilia.

Diseases Associated With Eosinophilia

The **absolute eosinophil count** (**AEC**) is used to quantify peripheral blood eosinophilia. Calculated as the white blood cell (WBC) count/µL × percent of eosinophils, it is usually <450 cells/µL and varies diurnally, with eosinophil numbers higher in the early morning and diminishing as endogenous glucocorticoid levels rise.

Many diseases with allergic, infectious, hematologic, autoimmune, or idiopathic origins are associated with moderate (AEC 1,500-5,000 cells/µL) or severe (AEC >5,000 cells/µL) eosinophilia in peripheral blood (Table 155.1). These disorders may range from mild and transient to chronic and life threatening. Importantly, blood eosinophil numbers do not always reflect the extent of eosinophil involvement in tissues and degranulation products may more accurately reflect disease activity. Because prolonged eosinophilia is associated with end-organ damage, especially involving the heart, patients with persistently elevated AECs should undergo a thorough evaluation to search for an underlying cause.

Table 155.1

Causes of Eosinophilia

Allergic Disorders

- Allergic rhinitis
- Asthma
- Acute and chronic urticaria
- Eczema
- Angioedema
- Hypersensitivity drug reactions (drug rash with eosinophilia and systemic symptoms [DRESS])
- Eosinophilic gastrointestinal disorders
- Interstitial nephritis

Infectious Diseases

Tissue-Invasive Helminth Infections

- Trichinosis
- Toxocariasis
- Strongyloidosis
- Ascariasis
- Filariasis
- Schistosomiasis
- Echinococcosis
- Amebiasis
- Malaria
- Scabies
- Toxoplasmosis

Other Infections

Pneumocystis jirovecii
Scarlet fever
Allergic bronchopulmonary aspergillosis (ABPA)
Coccidioidomycosis
Human immunodeficiency virus (HIV)

Malignant Disorders

Hodgkin disease and T-cell lymphoma
Acute myelogenous leukemia
Myeloproliferative disorders
Eosinophilic leukemia
Brain tumors

Gastrointestinal Disorders

Inflammatory bowel disease
Peritoneal dialysis
Chronic active hepatitis
Eosinophilic gastrointestinal disorders:
  Eosinophilic esophagitis
  Eosinophilic gastroenteritis
  Eosinophilic colitis

Rheumatologic Disease

Rheumatoid arthritis
Eosinophilic fasciitis
Scleroderma
Dermatomyositis
Systemic lupus erythematosus
IgG4-related disease
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis)

Immunodeficiency/Immune Dysregulation Disease

Hyperimmunoglobulin E syndromes
Wiskott-Aldrich syndrome
Graft-versus-host disease
Omenn syndrome
Severe congenital neutropenia
Autoimmune lymphoproliferative syndromes (ALPS)
Immune dysregulation, polyendocrinopathy, X-linked (IPEX)
Transplant rejection (solid organ)

Miscellaneous

Thrombocytopenia with absent radii
Hypersensitivity pneumonitis
Adrenal insufficiency
Postirradiation of abdomen
Histiocytosis with cutaneous involvement
Hypereosinophilic syndromes
Cytokine infusion
Pemphigoid

Allergic Diseases

Allergy is the most common cause of eosinophilia in children in the United States. Patients with allergic asthma typically have eosinophils in the blood, sputum, and/or lung tissue. **Hypersensitivity drug reactions** can elicit eosinophilia, and when associated with organ dysfunction (e.g., DRESS [drug rash with eosinophilia and systemic symptoms]), these reactions can be serious (see Chapter 177). If a drug is suspected of triggering eosinophilia, biochemical evidence of organ dysfunction should be sought, and if found, the drug should be discontinued. Various skin diseases have also been associated with eosinophilia, including atopic dermatitis/eczema, pemphigus, urticaria, and toxic epidermal necrolysis.

Eosinophilic gastrointestinal diseases are important emerging allergic causes of eosinophilia in tissue and, in some cases, peripheral blood (see Chapter 363). In these conditions, eosinophils are recruited to esophagus, stomach, and/or intestine, where they cause tissue inflammation and clinical symptoms such as dysphagia, food aversion, abdominal pain, vomiting, and diarrhea. Treatment options include allergen elimination diets and swallowed or inhaled corticosteroids.

Infectious Diseases

Eosinophilia is often associated with invasive infection with multicellular helminthic parasites, which are the most common cause in developing countries. Table 155.1 includes examples of specific organisms. The level of eosinophilia tends to parallel the magnitude and extent of tissue invasion, especially by larvae such as **visceral larva migrans** (see Chapter 324). Eosinophilia often *does not* occur in established parasitic infections that are well contained within tissues or are solely intraluminal in the gastrointestinal tract, such as *Giardia lamblia* and *Enterobius vermicularis* infection.

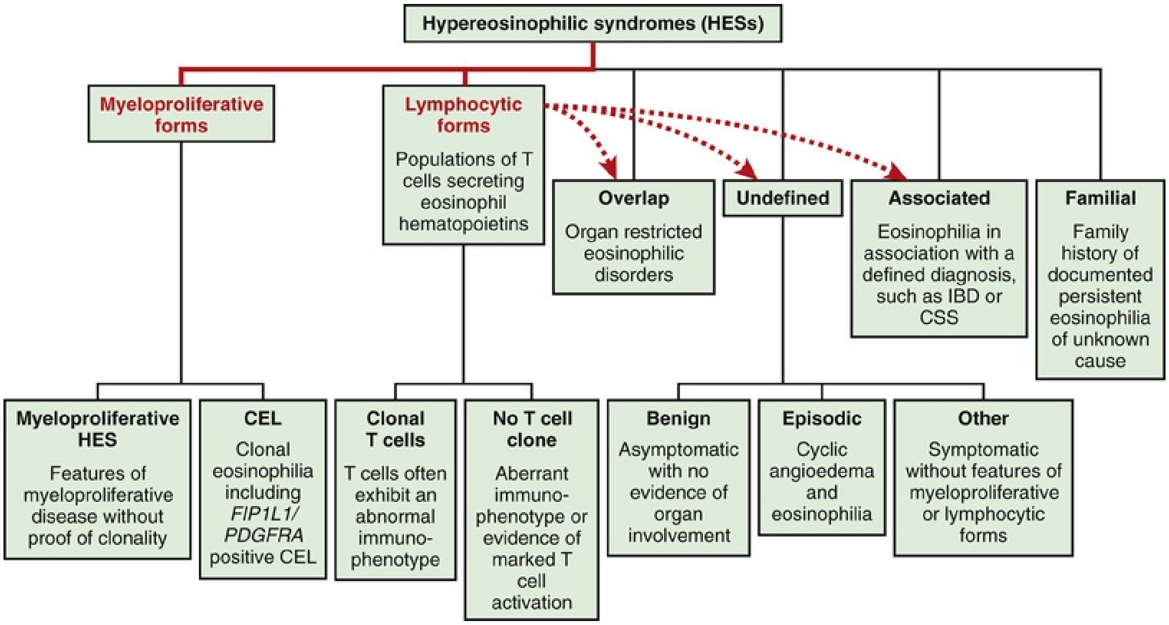
In evaluating patients with unexplained eosinophilia, the dietary history and geographic or travel history may indicate potential exposures to helminthic parasites. It is frequently necessary to examine the stool for ova and larvae at least 3 times. Additionally, the diagnostic parasite stages of many of the helminthic parasites that cause eosinophilia never appear in feces. Thus, normal results of stool examinations do not absolutely preclude a helminthic cause of eosinophilia; diagnostic blood tests or tissue biopsy may be needed. *Toxocara* causes visceral larva migrans usually in toddlers with pica (see Chapter 324). Most young children are asymptomatic, but some develop fever, pneumonitis, hepatomegaly, and hypergammaglobulinemia accompanied by severe eosinophilia. Isohemagglutinins are frequently elevated, and serology can establish the diagnosis.

Two fungal diseases may be associated with eosinophilia: aspergillosis in the form of **allergic bronchopulmonary aspergillosis** (see Chapter 264.1) and **coccidioidomycosis** (see Chapter 267) following primary infection, especially in conjunction with erythema nodosum. HIV infection can also be associated with peripheral eosinophilia.

Hypereosinophilic Syndrome

The idiopathic hypereosinophilic syndrome is a heterogeneous group of disorders characterized by sustained overproduction of eosinophils. The 3 diagnostic criteria for this disorder are (1) AEC >1,500 cells/μL persisting for 6 mo or longer or at least on 2 occasions or with evidence of tissue eosinophilia;

(2) absence of another diagnosis to explain the eosinophilia; and (3) signs and symptoms of organ involvement. The clinical signs and symptoms of hypereosinophilic syndrome can be heterogeneous because of the diversity of potential organ (pulmonary, cutaneous, neurologic, serosal, GI) involvement. Eosinophilic endomyocardial disease, one of the most serious and life-threatening complications, can cause heart failure from endomyocardial thrombosis and fibrosis. Eosinophilic leukemia, a clonal myeloproliferative variant, may be distinguished from idiopathic hypereosinophilic syndrome by demonstrating a clonal interstitial deletion on chromosome 4q12 that fuses the platelet-derived growth factor receptor-α (*PDGFRA*) and FIP1-like-1 (*FIP1L1*) genes; this disorder is treated with imatinib mesylate, a tyrosine kinase inhibitor, which helps target the fusion oncoprotein (Fig. 155.2).



Hypereosinophilic syndromes (HESs)
Myeloproliferative forms
Lymphocytic forms
Populations of T cells secreting eosinophil hematopoietins
Overlap
Organ restricted eosinophilic disorders
Undefined
Associated
Eosinophilia in association with a defined diagnosis, such as IBD or CSS
Familial
Family history of documented persistent eosinophilia of unknown cause
Myeloproliferative HES
Features of myeloproliferative disease without proof of clonality
CEL
Clonal eosinophilia including FIP1L1/PDGFRA positive CEL
Clonal T cells
T cells often exhibit an abnormal immuno-phenotype
No T cell clone
Aberrant immuno-phenotype or evidence of marked T cell activation
Benign
Asymptomatic with no evidence of organ involvement
Episodic
Cyclic angioedema and eosinophilia
Other
Symptomatic without features of myeloproliferative or lymphocytic forms

FIG. 155.2 **Revised classification of hypereosinophilic syndromes. Changes from the previous classification are indicated in *red. Dashed arrows* identify hypereosinophilic syndrome (HES) forms for which at least some patients have T-cell–driven disease. Classification of myeloproliferative forms has been simplified, and patients with HES and eosinophil hematopoietin–producing T cells in the absence of a T-cell clone are included in the lymphocytic forms of HES. CEL, Chronic eosinophilic leukemia; CSS, Churg-Strauss syndrome; IBD, inflammatory bowel disease. (From Simon HU, Rothenberg ME, Bocher BS, et al: Refining the definition of hypereosinophilic syndrome, *J Allergy Clin Immunol* 126:47, 2010.)**

Therapy is aimed at suppressing eosinophilia and is initiated with corticosteroids. Imatinib mesylate may be effective in FIP1L1-PDGFRA–negative patients. Hydroxyurea or interferon-alfa may be beneficial in patients unresponsive to corticosteroids. Specific anti–IL-5 monoclonal antibodies (mepolizumab) target this cytokine, which has a central role in eosinophil differentiation, mobilization, and activity. With therapy, the eosinophil count declines and corticosteroid doses may be reduced. For patients with prominent organ involvement who fail to respond to therapy, the mortality is about 75% after 3 yr.

Miscellaneous Diseases

Eosinophilia is observed in many patients with primary immunodeficiency syndromes, especially hyper-IgE syndrome, Wiskott-Aldrich syndrome, and Omenn syndrome (see Chapters 148 and 152). Eosinophilia is also frequently present in the syndrome of thrombocytopenia with absent radii and in familial reticuloendotheliosis with eosinophilia. Eosinophilia can be found in patients with Hodgkin disease, as well as in acute lymphoid and myeloid leukemia. Other considerations include GI disorders such as ulcerative colitis, Crohn disease during symptomatic phases, chronic hepatitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis), and adrenal insufficiency.

CHAPTER 156

Disorders of Phagocyte Function

Thomas D. Coates

Neutrophils are the first line of defense against microbial invasion. They arrive at the site of inflammation during the critical 2-4 hr after microbial invasion to contain the infection and prevent hematogenous dissemination. This well-orchestrated process is one of the most interesting stories in modern cell biology. In fact, much of our knowledge about neutrophil function derives from studies done in patients with genetic errors in neutrophil function. These critical functions and their associated disorders are depicted in Fig. 153.2 . Children with phagocytic dysfunction present at a young age with recurrent infections that often involve unusual organisms and are poorly responsive to treatment.

Primary defects of phagocytic function comprise <20% of immunodeficiencies, and there is significant overlap in the presenting signs and symptoms between phagocytic disorders and lymphocyte and humeral disorders. Children with phagocytic defects present with deep tissue infection, pneumonia, adenitis, or osteomyelitis rather than bloodstream infections (Tables 156.1 and 156.2 and Fig. 156.1). A few clinical features point to phagocyte defects rather than other immunodeficiencies, but correct diagnosis relies on highly specialized laboratory tests.

Table 156.1

Infections and White Blood Cell Defects: Features That Can Be Seen in Phagocyte Disorders

Table 156.2

Clinical Disorders of Neutrophil Function

DISORDER	ETIOLOGY	IMPAIRED FUNCTION	CLINICAL CONSEQUENCE
DEGRANULATION ABNORMALITIES			
Chédiak-Higashi syndrome (CHS)	Autosomal recessive; disordered coalescence of lysosomal granules; responsible gene is *CHSI/LYST* , which encodes a protein hypothesized to regulate granule fusion	Decreased neutrophil chemotaxis, degranulation, and bactericidal activity; platelet storage pool defect; impaired NK function, failure to disperse melanosomes	Neutropenia; recurrent pyogenic infections; propensity to develop marked hepatosplenomegaly as a manifestation of hemophagocytic syndrome
Specific granule deficiency	Autosomal recessive; functional loss of myeloid transcription factor arising from a mutation or arising from reduced expression of *Gfi-1* or *C/EBPε* , which regulates specific granule formation	Impaired chemotaxis and bactericidal activity; bilobed nuclei in neutrophils; defensins, gelatinase, collagenase, vitamin B_{12} –binding protein,	Recurrent deep-seated abscesses

		and lactoferrin	
ADHESION ABNORMALITIES			
Leukocyte adhesion deficiency 1 (LAD-1)	Autosomal recessive; absence of CD11/CD18 surface adhesive glycoproteins (β_2 -integrins) on leukocyte membranes most commonly arising from failure to express CD18 messenger RNA	Decreased binding of iC3b to neutrophils and impaired adhesion to ICAM-1 and ICAM-2	Neutrophilia; recurrent bacterial infection associated with a lack of pus formation
Leukocyte adhesion deficiency 2 (LAD-2)	Autosomal recessive; loss of fucosylation of ligands for selectins and other glycol conjugates arising from mutations of GDP-fucose transporter	Decreased adhesion to activated endothelium expressing ELAM	Neutrophilia; recurrent bacterial infection without pus
Leukocyte adhesion deficiency 3 (LAD-1 variant syndrome)	Autosomal recessive; impaired integrin function arising from mutations of *FERMT3* , which encodes kindlin-3 in hematopoietic cells; kindlin-3 binds to β-integrin and thereby transmits integrin activation	Impaired neutrophil adhesion and platelet activation	Neutrophilia, recurrent infections, bleeding tendency
DISORDERS OF CELL MOTILITY			
Enhanced motile responses; FMF	Autosomal recessive gene responsible for FMF on chromosome 16, which encodes for a protein called pyrin; pyrin regulates caspase-1 and thereby IL-1β secretion; mutated pyrin may lead to heightened sensitivity to endotoxin, excessive IL-1β production, and impaired monocyte apoptosis	Excessive accumulation of neutrophils at inflamed sites, possibly the result of excessive IL-1β production	Recurrent fever, peritonitis, pleuritis, arthritis, amyloidosis
DEPRESSED MOTILE RESPONSES			
Defects in the generation of chemotactic signals	IgG deficiencies; C3 and properdin deficiency can arise from genetic or acquired abnormalities; mannose-binding protein deficiency predominantly in neonates	Deficiency of serum chemotaxis and opsonic activities	Recurrent pyogenic infections
Intrinsic defects of the neutrophil, e.g., LAD, CHS, specific granule deficiency, neutrophil actin dysfunction, neonatal neutrophils	In the neonatal neutrophil there is diminished ability to express β_2 -integrins, and there is a qualitative impairment in β_2 -integrin function	Diminished chemotaxis	Propensity to develop pyogenic infections
Direct inhibition of neutrophil mobility, e.g., drugs	Ethanol, glucocorticoids, cyclic AMP	Impaired locomotion and ingestion; impaired adherence	Possible cause for frequent infections; neutrophilia seen with epinephrine arises from cyclic AMP release from endothelium
Immune complexes	Bind to Fc receptors on neutrophils in patients with rheumatoid arthritis, systemic lupus erythematosus, and other inflammatory states	Impaired chemotaxis	Recurrent pyogenic infections
Hyper-IgE syndrome	Autosomal dominant; responsible gene is *STAT3*	Impaired chemotaxis at times; impaired regulation of cytokine production	Recurrent skin and sinopulmonary infections, eczema, mucocutaneous candidiasis, eosinophilia,

			retained primary teeth, minimal trauma fractures, scoliosis, and characteristic facies
Hyper-IgE syndrome–AR	Autosomal recessive; more than 1 gene likely contributes to its etiology	High IgE levels, impaired lymphocyte activation to staphylococcal antigens	Recurrent pneumonia without pneumatoceles sepsis, enzyme, boils, mucocutaneous candidiasis, neurologic symptoms, eosinophilia
MICROBICIDAL ACTIVITY			
Chronic granulomatous disease (CGD)	X-linked and autosomal recessive; failure to express functional gp91 ^{phox} in the phagocyte membrane in p22 ^{phox} (AR) Other AR forms of CGD arise from failure to express protein p47 ^{phox} or p67 ^{phox}	Failure to activate neutrophil respiratory burst, leading to failure to kill catalase-positive microbes	Recurrent pyogenic infections with catalase-positive microorganisms
G6PD deficiency	<5% of normal activity of G6PD	Failure to activate NADPH-dependent oxidase; hemolytic anemia	Infections with catalase-positive microorganisms
Myeloperoxidase deficiency	Autosomal recessive; failure to process modified precursor protein arising from missense mutation	H_2O_2 -dependent antimicrobial activity not potentiated by myeloperoxidase	None
Rac2 deficiency	Autosomal dominant; dominant negative inhibition by mutant protein of Rac2-mediated functions	Failure of membrane receptor–mediated O_2^- generation and chemotaxis	Neutrophilia, recurrent bacterial infections
Deficiencies of glutathione reductase and glutathione synthetase	AR; failure to detoxify H_2O_2	Excessive formation of H_2O_2	Minimal problems with recurrent pyogenic infections

AMP, Adenosine monophosphate; AR, autosomal recessive; C, complement; CD, cluster of differentiation; ELAM, endothelial-leukocyte adhesion molecule; FMF, familial Mediterranean fever; G6PD, glucose-6-phosphate dehydrogenase; GDP, guanosine diphosphate; ICAM, intracellular adhesion molecule; IL-1, interleukin-1; NADPH, nicotinamide adenine dinucleotide phosphate; NK, natural killer.

Unusual frequency or type of infection
Infections
• Recurrent deep tissue infection (e.g., lymphadenitis, pneumonia, osteomyelitis, liver abscess)
• Unusual or resistant infection (S. aureus, Pseudomonas, Klebsiella, Serratia, Candida, Aspergillus, Nocardia)
• Periodontal disease or tooth loss
• Omphalitis
History and physical
• Family history of recurrent infection
• Gingivitis
• Chronic diarrhea
• Infections with absence of neutrophilic infiltration
• ↑ CRP/SED rate
• Splenomegaly or hepatomegaly
• Moderate lymphadenopathy
• Inflammatory anemia
Initial evaluation
• CBC, ESR, r/o lymphopenia
• Quantitative immunoglobulins
• IgE
• Immunoglobulin subsets
• T+B cell quantitation and subsets
• PHA stimulation
• Response to tetanus immunization
• HIV
Neutrophil evaluation
• CBC
• NBT slide test or DHR by FACS
• CD18/CD11b by FACS
• CD15a by FACS
• Bombay blood group
• (Chemotaxis)

FIG. 156.1 **Algorithm for clinical evaluation of patients with recurrent infections. Shown are the evaluations that can be done in a routine clinical laboratory. The complete blood count (CBC) can detect marked leukocytosis in leukocyte adhesion deficiency (LAD) and giant granules of Chédiak-Higashi syndrome may be seen on the smear. Chemotaxis and all other neutrophil functions assays require highly specialized research laboratories. CD, Cluster of differentiation; CRP, C-reactive protein; DHR, dihydrorhodamine; ESR, erythrocyte sedimentation rate; FACS, fluorescence-activated cell sorter; HIV, human immunodeficiency virus; IgE, immunoglobulin E; NBT, nitroblue tetrazolium; PHA, phytohemagglutinin. (Adapted from Dinauer, MC, Coates TD, Disorders of neutrophil function. In Hoffman R, Benz EJ, Silberstein LE, Helsop H, Weitz J, Anastasi J, editors: *Hematology: basic principles and practice,* ed 6, Philadelphia, 2012, Saunders.)**

Chemotaxis , the direct migration of cells into sites of infection, involves a complex series of events (see Chapter 153). Disorders of adhesion or granule abnormalities can have intermediate or profound motility defects, and the propensity to infections is related to a combination of these functional deficits. One family with recessively inherited neutrophil actin dysfunction demonstrated that a pure severe chemotactic defect can result in fatal recurrent infection. Defective in vitro chemotaxis of neutrophils can be detected in children with various clinical conditions. However, unless chemotaxis is essentially absent, it is difficult to establish whether frequent infections arise from a primary chemotactic abnormality or occur as secondary medical complications of the underlying disorder. Dental infection with *Capnocytophaga* is associated with a clear neutrophil motility defect that resolves when the infection is eliminated.

Motility defects present with significant skin and mucosal infections. Tender cutaneous nodular lesions may also be present and characteristically do not contain neutrophils. In fact, presence of a true abscess makes the diagnosis of a significant chemotactic defect less likely.

Laboratory tests of chemotaxis are biologic assays and have high variability except in the most experienced hands. The assays must be done on freshly obtained blood and are affected by many factors related to blood sampling itself. It is best to assay other features of the suspected disorder, such as surface marker expression, to establish a specific diagnosis.

Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency types 1 (LAD-1), 2 (LAD-2), and 3 (LAD-3) are rare autosomal recessive disorders of leukocyte function. LAD-1 affects about 1 per 10 million individuals and is characterized by recurrent bacterial and fungal infections and depressed inflammatory responses despite striking blood neutrophilia (Table 156.3). The neutrophils have significant defects in adhesion, motility, and ability to phagocytose bacteria.

Table 156.3

Leukocyte Adhesion Deficiency Syndromes

LEUKOCYTE ADHESION DEFICIENCY (LAD)	**TYPE 1 (LAD-1)**	**TYPE 2 (LAD-2 or CDG-IIc)**	**TYPE 3 (LAD-3)**	**E-SELECTIN DEFICIENCY**	**Rac2 DEFICIENCY**
OMIM	116920	266265	612840	131210	602049
Inheritance pattern	Autosomal recessive	Autosomal recessive	Autosomal recessive	Unknown	Autosomal dominant
Affected protein(s)	β_2 -Integrin common chain (CD18)	Fucosylated proteins (e.g., sialyl-Lewis^x , CD15s)	Kindlin 3	Endothelial E-selectin expression	Rac2
Neutrophil function affected	Chemotaxis, tight adherence	Rolling, tethering	Chemotaxis, adhesion, superoxide production	Rolling, tethering	Chemotaxis, superoxide production
Delayed umbilical cord separation	Yes (severe phenotype only)	Yes	Yes	Yes	Yes
Leukocytosis/neutrophilia	Yes	Yes	Yes	No (mild neutropenia)	Yes

CDG-IIc, Congenital disorder of glycosylation IIc, OMIM, Online Mendelian Inheritance in Man.

From Leung DYM: *Pediatric allergy principles and practice* , ed 2, Philadelphia, 2010, Saunders, p 139.

Genetics and Pathogenesis

LAD-1 results from mutations of the gene on chromosome 21q22.3 encoding CD18, the 95-kDa β_2 -leukocyte transmembrane integrin subunit. Normal neutrophils express 4 heterodimeric adhesion molecules: LFA-1 (CD11a/CD18), Mac-1 (CD11b/CD18, also known as CR3 or iC3b receptor), p150,95 (CD11c/CD18), and α_1 β_2 (CD11d/CD18). These 4 transmembrane adhesion molecules are composed of unique extracellular α_1 encoded on chromosome 16, and they share a common β_2 subunit (CD18) that links them to the membrane and connects them to intracellular signal transduction machinery. This group of leukocyte integrins is responsible for the tight adhesion of neutrophils to the endothelial cell surface, egress from the circulation, and adhesion to iC3b-coated microorganisms, which promotes phagocytosis and particulate activation of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Some mutations of CD11/CD18 allow a low level of assembly and activity of integrin molecules, resulting in retention of some neutrophil integrin adhesion function and a moderate phenotype.

Because of their inability to adhere firmly to intercellular adhesion molecules 1 (ICAM-1) and 2 (ICAM-2) expressed on inflamed endothelial cells (see Chapter 153), neutrophils cannot transmigrate through the vessel wall and move to the site infection. Furthermore, neutrophils that do arrive at inflammatory sites fail to recognize microorganisms opsonized with complement fragment **iC3b** , an important stable opsonin formed by the cleavage of C3b. Therefore, other neutrophil functions such as degranulation and oxidative metabolism normally triggered by iC3b binding are also greatly compromised in LAD-1 neutrophils, resulting in impaired phagocytic function and high risk for serious and recurrent bacterial infections.

Monocyte function is also impaired, with poor fibrinogen-binding function, an activity that is promoted by the CD11/CD18 complex. Consequently, such cells are unable to participate effectively in wound healing.

Children with **LAD-2** share the clinical features of LAD-1 but have normal CD11/CD18 integrins. Features unique to LAD-2 include neurologic defects, cranial facial dysmorphism, and absence of the erythrocyte ABO blood group antigen (**Bombay** phenotype). LAD-2 (also known as **congenital disorder of glycosylation IIc (CDG-IIc)** derives from mutations in the gene encoding a specific guanosine diphosphate (GDP)-L -fucose transporter of the Golgi apparatus. This abnormality prevents the incorporation of fucose into various cell surface glycoproteins, including the carbohydrate structure sialyl Lewis X that is critical for low-affinity rolling adhesion of neutrophils to vascular endothelium. This is an important initial step necessary for subsequent integrin-mediated activation, spreading, and transendothelial migration. Infections in LAD-2 are milder than that in LAD-1.

LAD-3 is characterized by a **Glanzmann thrombasthenia** –like bleeding disorder, delayed separation of the umbilical cord, and serious skin and soft tissue infections similar to those seen in LAD-1, and failure of leukocytes to undergo β_2 - and β_1 -integrin–mediated adhesion and migration. Mutations in *KINDLIN3* affect integrin activation.

Clinical Manifestations

Patients with the severe clinical form of LAD-1 express <0.3% of the normal amount of the β_2 -integrin molecules, whereas patients with the moderate phenotype may express 2–7% of the normal amount. Children with severe forms of LAD present in infancy with recurrent, indolent bacterial infections of the skin, mouth, respiratory tract, lower intestinal tract, and genital mucosa. Significant neutrophilic leukocytosis, often >25,0000/mm^3 , is a prominent feature. They may have a history of delayed separation of the umbilical cord, usually with associated infection of the cord stump. The presence of significant omphalitis is an important feature that distinguishes these rare patients from the 10% of healthy infants who can have cord separation at age 3 wk or later. Skin infection may progress to large chronic ulcers with polymicrobial infection, including anaerobic organisms (Fig. 156.2). The ulcers heal slowly, need months of antibiotic treatment, and often require plastic surgery grafting. Severe gingivitis can lead to early loss of primary and secondary teeth (Fig. 156.3). Infected areas characteristically have very little neutrophilic infiltration.

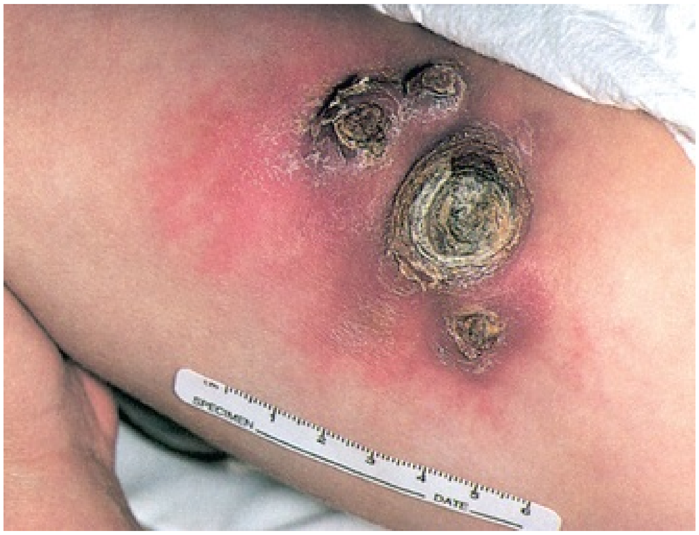

FIG. 156.2 Skin infection of a patient with leukocyte adhesion deficiency type 1. Failure to form pus, inability to demarcate the fibrotic skin debris, and limited inflammation. *Enterococcus gallinarium* was cultured from the wound. (From Rich RR: *Clinical immunology principles and practices* , ed 4, Philadelphia, 2013, Saunders, p 273).

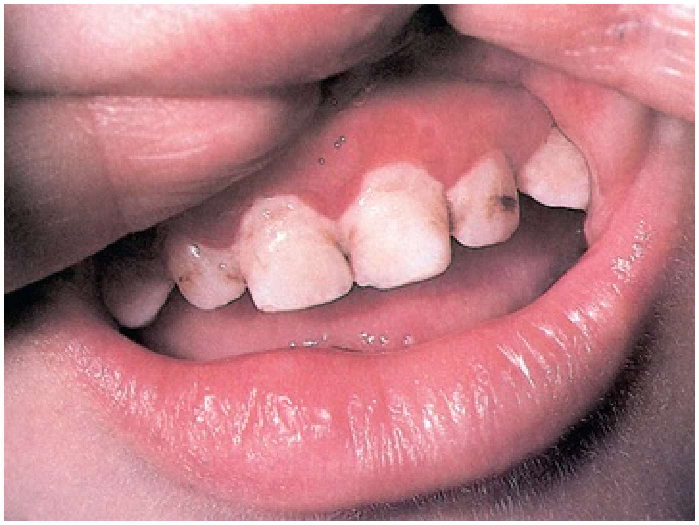

FIG. 156.3 Oral pathology in a patient with leukocyte adhesion deficiency type 1. Gingivitis and severe periodontitis are hallmarks of LAD-1. (From Rich RR: *Clinical immunology principles and practices* , ed 4, Philadelphia, 2013, Saunders, p 273.)

The pathogens infecting patients with LAD-1 are similar to those affecting patients with severe neutropenia (see Chapter 157) and include *Staphylococcus aureus* and enteric gram-negative organisms such as *Escherichia coli*. These patients are also susceptible to opportunistic infection by fungi such as *Candida* and *Aspergillus*. Typical signs of inflammation, such as swelling, erythema, and warmth, may be absent. Pus does not form, and few neutrophils are identified microscopically in biopsy specimens of infected tissues. Despite the paucity of neutrophils within the affected tissue, the circulating neutrophil count during infection typically exceeds 30,000/µL and can surpass 100,000/µL. During intervals between infections, the peripheral blood neutrophil count may chronically exceed 12,000/µL. LAD-1 genotypes with only moderate, rather than absent, amounts of functional integrins at the surface of the neutrophil have significantly reduced severity and frequency of infections compared to children with the severe form, although gingival disease is still a prominent feature.

Laboratory Findings

The diagnosis of LAD-1 is established most readily by flow cytometric measurements of surface CD11b/CD18 in stimulated and unstimulated neutrophils. Neutrophil and monocyte adherence, aggregation, chemotaxis, and iC3b-mediated phagocytosis demonstrate striking abnormalities. However, these assays are not clinically available. Delayed-type hypersensitivity reactions are normal, and most individuals have normal specific antibody synthesis, although some patients have impaired T-lymphocyte–dependent antibody responses. The diagnosis of LAD-2 is established by flow cytometric measurement of sialyl Lewis X (CD15) on neutrophils. It is important to note that the flow cytometric assays are not done the same as the more common lymphocyte subset analysis and require specialized approaches to detect levels of surface expression, especially to detect milder phenotypes.

Treatment

Treatment of LAD-1 depends on the phenotype, as determined by the level of expression of functional CD11/CD18 integrins. Early allogeneic hematopoietic stem cell transplantation (HSCT) is the treatment of choice for severe LAD-1 (and LAD-3). One patient was successfully treated with ustekinumab, an inhibitor of interleukins 12 and 23. Other treatment is largely supportive. Patients can be maintained on prophylactic trimethoprim/sulfamethoxazole (TMP/SMX) and should have close surveillance for early identification of infections and initiation of empirical treatment with broad-spectrum antibiotics. Specific determination of the etiologic agent by culture or biopsy is important because of the prolonged antibiotic treatment required in the absence of neutrophil function.

Some LAD-2 patients have responded to fucose supplementation, which induced a rapid reduction in the circulating leukocyte count and appearance of the sialyl Lewis X molecules, accompanied by marked improvement in leukocyte adhesion.

Prognosis

The severity of infectious complications correlates with the degree of β_2 -integrin deficiency. Patients with severe deficiency may die in infancy, and those surviving infancy have a susceptibility to severe life-threatening systemic infections. Patients with moderate deficiency have infrequent life-threatening infections and relatively long survival.

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by increased susceptibility to infection caused by defective degranulation of neutrophils, a mild bleeding diathesis, partial oculocutaneous albinism, progressive peripheral neuropathy, and a tendency to develop a life-threatening form of **hemophagocytic lymphohistiocytosis** (see Chapter 534.2). CHS is caused by a fundamental defect in granule morphogenesis that results in abnormally large granules in multiple tissues. Pigmentary dilution involving the hair, skin, and ocular fundi results from pathologic aggregation of melanosomes. Neurologic deficits are associated with a failure of decussation of the optic and auditory nerves. Patients exhibit an increased susceptibility to infection that can be explained only in part by defects in neutrophil function. The patients have progressive neutropenia as well as abnormalities in natural killer (NK) function, again related to granule dysfunction.

Genetics and Pathogenesis

LYST (for lysosomal traffic regulator), the gene mutated in CHS, is located at chromosome 1q2-q44. The LYST/CHS protein is thought to regulate vesicle transport by mediating protein-protein interaction and protein-membrane associations. Loss of function may lead to indiscriminate interactions with lysosomal surface proteins, yielding giant granules through uncontrolled fusion of lysosomes with each other.

Almost all cells of patients with CHS show some oversized and dysmorphic lysosomes, storage granules, or related vesicular structures. Melanosomes are oversized, and delivery to the keratinocytes and hair follicles is compromised, resulting in hair shafts devoid of pigment granules. This abnormality in melanosomes leads to the macroscopic impression of hair and skin that is lighter than expected from parental coloration. The same abnormality in melanocytes leads to the partial ocular albinism associated with light sensitivity.

Beginning early in neutrophil development, spontaneous fusion of giant primary granules with each other or with cytoplasmic membrane components results in huge secondary lysosomes with reduced contents of hydrolytic enzymes, including proteinases, elastase, and cathepsin G. This deficiency of proteolytic enzymes may be responsible for the impaired killing of microorganisms by CHS neutrophils.

Clinical Manifestations

Patients with CHS have light skin and silvery hair and frequently complain of solar sensitivity and photophobia that is associated with rotary nystagmus. Other signs and symptoms vary considerably, but frequent infections and neuropathy are common. The infections involve mucous membranes, skin, and respiratory tract. Affected children are susceptible to gram-positive bacteria, gram-negative bacteria, and fungi, with *Staphylococcus aureus* being the most common offending organism. The **neuropathy** may be sensory or motor in type, and ataxia may be a prominent feature. Neuropathy often begins in the teenage years and becomes the most prominent problem.

Patients with CHS have prolonged bleeding times with normal platelet counts, resulting from impaired platelet aggregation associated with a deficiency of the dense granules containing adenosine diphosphate and serotonin.

The most life-threatening complication of CHS is the development of an accelerated phase characterized by pancytopenia, high fever, and lymphohistiocytic infiltration of liver, spleen, and lymph nodes. The onset of the accelerated phase, which can occur at any age, is now recognized to be a genetic form of hemophagocytic lymphohistiocytosis. This occurs in 85% of patients and usually results in death.

Laboratory Findings

The diagnosis of CHS is established by finding large inclusions in all nucleated blood cells. These can be seen on Wright-stained blood films and are accentuated by a peroxidase stain. Because of impaired egress from the bone marrow, cells containing the large inclusions may be missed on peripheral blood smear but readily identified on bone marrow examination. The patients have progressive neutropenia and abnormal platelet, neutrophil, and NK function.

Treatment

High-dose ascorbic acid (200 mg/day for infants; 2,000 mg/day for adults) may improve the clinical status of some children in the stable phase. Although controversy surrounds the efficacy of ascorbic acid, given the safety of the vitamin, it is reasonable to administer ascorbic acid to all patients.

The only curative therapy to prevent the accelerated phase is HSCT. Normal stem cells reconstitute hematopoietic and immunologic function, correct the NK cell deficiency, and prevent conversion to the accelerated phase, but cannot correct or prevent the neuropathy. If the patient is in the accelerated phase with active hemophagocytic lymphohistiocytosis, HSCT often fails to prevent death.

Myeloperoxidase Deficiency

Myeloperoxidase (MPO) deficiency is an autosomal recessive disorder of oxidative metabolism and is one of the most common inherited disorders of phagocytes, occurring at a frequency approaching 1 per 2,000 individuals. MPO is a green heme protein located in the azurophilic lysosomes of neutrophils and monocytes and is the basis for the greenish tinge to pus accumulated at a site of infection.

Clinical Manifestations

MPO deficiency is usually clinically silent. Rarely, patients may have disseminated candidiasis, usually in conjunction with diabetes mellitus. Acquired partial MPO deficiency can develop in acute myelogenous leukemia and in myelodysplastic syndromes.

Laboratory Findings

Deficiency of neutrophil and monocyte MPO can be identified by histochemical analysis. Severe MPO deficiency can cause the dihydrorhodamine (DHR) flow cytometric assay for chronic granulomatous disease (CGD) to be falsely positive. Unlike CGD, eosinophils in severe MPO deficiency will still reduce DHR and yield a normal reaction.

Treatment

There is no specific therapy for MPO deficiency. Aggressive treatment with antifungal agents should be provided for candidal infections. The prognosis is usually excellent.

Chronic Granulomatous Disease

Chronic granulomatous disease is characterized by neutrophils and monocytes capable of normal chemotaxis, ingestion, and degranulation, but unable to kill **catalase-positive microorganisms** because of a defect in the generation of microbicidal oxygen metabolites. CGD is a rare disease, affecting 4-5 per 1 million individuals; it is caused by 4 genes: 1 X-linked and 3 autosomal recessive in inheritance (Table 156.4).

Table 156.4

Classification of Chronic Granulomatous Disease

COMPONENT AFFECTED	INHERITANCE	SUBTYPE[*]	FLAVOCYTOCHROME b SPECTRUM	NBT SCORE (% Positive)	INCIDENCE (% of Cases)
gp91 *phox*	X	$X91^0$	0	0	60
		$X91^-$	Low	80-100 (weak)	5
		$X91^-$	Low	5-10	<1
		$X91^+$	0	0	1
p22 *phox*	A	$A22^0$	0	0	4
		$A22^+$	N	0	<1
p47 *phox*	A	$A47^0$	N	0[†]	25
p67 *phox*	A	$A67^0$	N	0	5
		$A67^+$	N	0	<1
p40 *phox*	A	$A40^-$	N	100	<1

[*] In this nomenclature, the first letter represents the mode of inheritance (X-linked [X] or autosomal recessive [A]), whereas the number indicates the *phox* component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (^{0}), diminished ($^-$), or normal ($^+$), as measured by immunoblot analysis.

[†] Can be weakly positive.

NBT, Nitroblue tetrazolium.

From *Nathan & Oski's hematology and oncology of infancy and childhood,* ed 8, Philadelphia, 2015, Elsevier, p 833.

Genetics and Pathogenesis

Activation of the phagocyte NADPH oxidase requires stimulation of the neutrophils and involves assembly from cytoplasmic and integral membrane subunits (see Fig. 153.3). Oxidase activation initiates with phosphorylation of a cationic cytoplasmic protein, p47 ^{phox} (47-kDa phagocyte oxidase protein). Phosphorylated p47 ^{phox} , together with 2 other cytoplasmic components of the oxidase, p67 ^{phox} and the low-molecular-weight guanosine triphosphatase Rac2, translocates to the membrane, where they combine with the cytoplasmic domains of the transmembrane flavocytochrome b_{558} to form the active oxidase complex. The flavocytochrome is a heterodimer composed of p22 ^{phox} and highly glycosylated gp91 ^{phox} . The gp91 ^{phox} glycoprotein catalyzes electron transport through its NADPH-binding, flavin-binding, and heme-binding domains. Defects in any of these NADPH oxidase components can lead to CGD.

Approximately 65% of patients with CGD are males who inherit their disorder as a result of mutations in *CYBB* , an X-chromosome gene encoding gp91 ^{phox} . Approximately 35% of patients inherit CGD in an autosomal recessive fashion resulting from mutations in the *NCF1* gene on chromosome 7, encoding p47 ^{phox} . Defects in the genes encoding p67 ^{phox} (*NCF2* on chromosome 1) and p22 ^{phox} (*CYBA* on chromosome 16) are inherited in an autosomal recessive manner and account for approximately 5% of cases of CGD.

The CGD phagocytic vacuoles lack microbicidal reactive oxygen species and remain acidic, so bacteria are not killed or digested properly (Fig. 156.4). Hematoxylin-eosin–stained sections from patients’ tissues show multiple granulomas that give CGD its descriptive name.

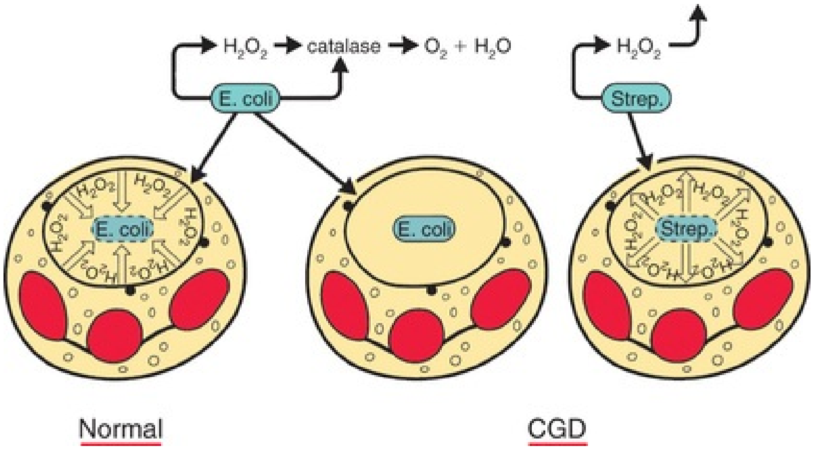

FIG. 156.4 Pathogenesis of chronic granulomatous disease (CGD). The manner in which the metabolic deficiency of the CGD neutrophil predisposes the host to infection is shown schematically. Normal neutrophils stimulate hydrogen peroxide (H_2O_2) in the phagosome containing ingested *Escherichia coli.* Myeloperoxidase is delivered to the phagosome by degranulation, as indicated by the *closed circles.* In this setting, H_2O_2 acts as a substrate for myeloperoxidase to oxidize halide to hypochlorous acid and chloramines that kill the microbes. The quantity of H_2O_2 produced by the normal neutrophil is sufficient to exceed the capacity of catalase, an H_2O_2-catabolizing enzyme of many aerobic microorganisms, including *Staphylococcus aureus,* most gram-negative enteric bacteria, *Candida albicans,* and *Aspergillus.* When organisms such as *E. coli* gain entry into CGD neutrophils, they are not exposed to H_2O_2 because the neutrophils do not produce it, and the H_2O_2 generated by microorganisms themselves is destroyed by their own catalase. When CGD neutrophils ingest streptococci, which lack catalase, the organisms generate enough H_2O_2 to result in a microbicidal effect. As indicated *(middle),* catalase-positive microbes such as *E. coli* can survive within the phagosome of the CGD neutrophil. (Adapted from Boxer LA: Quantitative abnormalities of granulocytes. In Beutler E, Lichtman MA, Coller BS, et al, editors: *Williams hematology,* ed 6, New York, 2001, McGraw-Hill, p 845.)

Clinical Manifestations

Although the clinical presentation is variable, several features suggest the diagnosis of CGD. Any patient with recurrent pneumonia, lymphadenitis, hepatic, subcutaneous, or other abscesses, osteomyelitis at multiple sites, a family history of recurrent infections, or any infection with an unusual catalase-positive organism requires evaluation. Other clinical features include chronic colitis or enteritis, gastric outlet or ureteral obstruction from granulomas, or bloodstream infection caused by *Salmonella* , *Burkholderia cepacia*, or *Candida* .

The onset of clinical signs and symptoms usually occurs in early infancy, although a few patients with very rare CGD subtypes have presented later in life. The attack rate and severity of infections are exceedingly variable; however, the infection incidence decreases in the 2nd decade, coincident with maturation of the lymphocyte and humoral immunity. The most common pathogen is *S. aureus*, but any catalase-positive microorganism may be involved. Other organisms frequently causing infections include *Serratia marcescens, B. cepacia, Aspergillus, Candida albicans, Nocardia,* and *Salmonella.* There may also be increased susceptibility to mycobacteria, including the bacille Calmette-Guérin vaccine. Pneumonia, lymphadenitis, osteomyelitis, and skin infections are the most common illnesses encountered. Bacteremia or fungemia occurs but is much less common than focal infections and usually only occurs when local infections have been inappropriately treated for long periods. Patients may have sequelae of chronic infection, including anemia of chronic disease, poor growth, lymphadenopathy, hepatosplenomegaly, chronic purulent dermatitis, restrictive lung disease, gingivitis, hydronephrosis, esophageal dysmotility, and pyloric outlet narrowing. Perirectal abscesses and recurrent skin infections, including folliculitis, cutaneous granulomas, and discoid lupus erythematosus, also suggest CGD.

Granuloma formation and inflammatory processes are a hallmark of CGD and may be the presenting symptoms that prompt testing for CGD if they cause pyloric outlet obstruction, bladder outlet or ureter obstruction, or rectal fistulas and granulomatous colitis simulating Crohn disease. More than 80% of CGD patients have positive serology for Crohn disease. Persistent fever, especially with splenomegaly and cytopenia warrants an evaluation for secondary macrophage activation syndrome. This has been seen in CGD and may require treatment with corticosteroids and discontinuation of interferon-γ treatment.

Laboratory Findings

The diagnosis is most often made by performing flow cytometry using DHR to measure oxidant production through its increased fluorescence when oxidized by hydrogen peroxide (H_2O_2). The nitroblue tetrazolium dye test is frequently cited in the literature but is now only rarely used clinically. The X-linked carrier state is usually easily diagnosed in the mother by DHR fluorescence through a bimodal response to stimulation. It is important to test the mother as some extremely lyonized carriers with <5% positive cells may have chronic clinical problems as well. Ideally, at least the first patient in a kindred should have DNA analysis to facilitate prenatal diagnosis and for genetic counseling purposes.

A few individuals have been described with apparent CGD caused by severe glucose-6-phosphate dehydrogenase deficiency, leading to insufficient NADPH substrate for the phagocyte oxidase. The erythrocytes of these patients also lack the enzyme, leading to chronic hemolysis.

Treatment

HSCT is the only known cure for CGD, although gene therapy has been transiently successful in a few patients and is the topic of active research. HSCT transplant for all patients with CGD is strongly recommended if a suitable sibling or unrelated donor can be identified. The long-term outcome for survival late into adulthood is not good, even in the hands of experienced CGD physicians.

Patients with CGD should be given daily oral TMP/SMX because it reduces the number of bacterial infections. A placebo-controlled study found that interferon-γ 50 μg/m^2 3 times/wk significantly reduces the number of hospitalizations and serious infections, although the mechanism of action is unclear. Itraconazole (200 mg/day for patients weighing >50 kg and 100 mg/day for patients <50 kg and ≤5 yr old) administered prophylactically reduces the frequency of fungal infections.

Management of infection is dramatically different than in normal children. CGD patients are always at risk for deep-seated, indolent bacterial infections that can become widespread if not treated properly. They also develop the same kinds of infections that occur in normal children, so determination of the appropriate treatment can be difficult. The erythrocyte sedimentation rate (ESR) can be quite helpful. If the child does not have a deep-seated infection, the ESR will be normal or will normalize within several days with standard management. If it does not, however, a search for deep tissues is warranted, as is consideration of empirical antibiotics. Cultures should be obtained, but are usually negative. Because all neutrophil functions in CGD except killing are normal, there is often an exuberant inflammatory reaction to a very small number of organisms. Thus, blood cultures and direct cultures of biopsy samples are usually negative unless there are many organisms. Most abscesses require surgical drainage for therapeutic and diagnostic purposes. Prolonged use of antibiotics is required even for common bacterial infections. A simple pneumonia may require 6-8 wk or more of parenteral antibiotics. Infections should be treated for at least 1 wk past normalization of ESR to prevent recurrence. Severe pneumonias can be cleared completely but may require many months of parenteral antibiotics. Especially because cultures are often not helpful, many support an “antibiotic sensitivity by sedimentation rate response” approach to treatment. The ESRs are often 40-80 mm/hr or more with severe infection and will drop monotonically over a week or so after starting antibacterial drugs. It is important to check the ESR daily or every other day because of moderate variability in this test, and changes in treatment need to be based on trends rather than individual values. If there is a clear downward trend over 3-10 days, continue with antibacterials alone. If this is not the case, parenteral voriconazole should be added to cover *Aspergillus* . Failure of the ESR to drop suggests another antimicrobial approach needs to be tried. This sequential addition of antimicrobials offers some insight into the nature of the infection. If both antibacterials and antifungal are started at the same time, one cannot know what caused a response.

Because of the rarity of this disorder, it is critical to seek counsel from someone with significant direct experience with management of several CGD patients. Granulocyte transfusions have been used, but their benefit is unclear. The ESR should be regularly monitored in well patients and whenever they appear ill. A high ESR itself is usually not enough to trigger treatment. However, in the presence of symptoms, one should search for sources at least by contrast CT of the sinus, chest, and abdomen. If the patient is unstable or has very high fevers, *B. cepacia* should be considered and empirically covered. This organism can cause septic shock quickly, unlike the usual smoldering infections seen in CGD. The patient can be treated with antibiotics until the ESR is normal and radiographic evidence of infection has been cleared, if possible. The overall incidence of infection decreases in the 2nd decade of life as nonneutrophil immunity matures, but increased risk of infection is lifelong.

Corticosteroids may be useful for the treatment of children with antral and urethral obstruction or severe granulomatous colitis. Corticosteroids can also be helpful in pneumonia to shrink granulomas in the lung and promote drainage. Short (4-6 days) pulses of 1-2 mg/kg of prednisone are recommended, with rapid taper to avoid long-term side effects and risk of fungus. Pulses can be repeated if clinical effect has not been achieved.

Genetic Counseling

Identifying a patient's specific genetic subgroup by DNA analysis is useful primarily for genetic counseling and prenatal diagnosis. In X-linked CGD, all possibly affected females should be tested by DHR to exclude carrier state. Diagnosis by DNA is strongly recommended in suspected carriers with normal

DHR who are related to a known proband, because rarely DHR testing is normal in obligate carriers. Counseling is best done by a physician who has direct knowledge of the clinical manifestations of CGD.

Prognosis

The overall mortality rate for CGD is about 2 patient deaths per year per 100 cases, with the highest mortality among young children. The development of effective infection prophylaxis regimens, close surveillance for signs of infections, and aggressive surgical and medical interventions have improved the prognosis.

CHAPTER 157

Leukopenia

Thomas F. Michniacki, Kelly J. Walkovich

Leukopenia refers to an abnormally low number of white blood cells (WBCs) in the circulating blood secondary to a paucity of lymphocytes, granulocytes, or both. Because there are marked developmental changes in normal values for WBC counts during childhood (see Chapter 748), normal ranges must be considered in the context of age. For newborns, the mean WBC count at birth is high, followed by a rapid fall beginning at 12 hr through the 1st wk of life. Thereafter, values are stable until 1 yr of age, after which a slow, steady decline in the WBC count continues throughout childhood until adult values are reached during adolescence. Evaluation of patients with leukopenia begins with a thorough history, physical examination, and at least 1 confirmatory complete blood count with differential. Further evaluation then depends on whether the leukopenia represents a decreased number of neutrophils, lymphocytes, or both cell populations (Table 157.1). Treatment depends on the etiology and clinical manifestations of the leukopenia.

Table 157.1

Diagnostic Approach for Patients With Leukopenia

EVALUATION	ASSOCIATED CLINICAL DIAGNOSES
INITIAL EVALUATION	
• History of acute or chronic leukopenia	
• General medical history including prior serious, recurrent or unusual infections and malignancy	Congenital syndromes (severe congenital neutropenia, cyclic neutropenia, Shwachman-Diamond, Wiskott-Aldrich, Fanconi anemia, dyskeratosis congenita, glycogen storage disease type Ib, disorders of vesicular transport, GATA2 haploinsufficiency, and primary immunodeficiencies)
• Physical examination: stomatitis, gingivitis, dental defects, warts,	

lymphedema, congenital anomalies	
• Spleen size	Hypersplenism
• History of drug exposure	Drug-associated neutropenia
• Complete blood count with differential and reticulocyte counts	Neutropenia, aplastic anemia, autoimmune cytopenias
IF ANC <1,000/µL	
Evaluation of Acute-Onset Neutropenia	
• Repeat blood counts in 3-4 wk	Transient myelosuppression (e.g., viral)
• Serology and cultures for infectious agents	Active or chronic infection with viruses (e.g., EBV, CMV), bacteria, mycobacteria, rickettsia
• Discontinue drug(s) associated with neutropenia	Drug-associated neutropenia
• Test for antineutrophil antibodies	Autoimmune neutropenia
• Measure quantitative immunoglobulins (IgG, IgA, IgM, IgE), lymphocyte subsets	Neutropenia associated with disorders of immune function
IF ANC <500/µL ON 3 SEPARATE TESTS	
• Bone marrow aspiration and biopsy, with cytogenetics	Severe congenital neutropenia, cyclic neutropenia, Shwachman-Diamond syndrome, myelokathexis; chronic benign or idiopathic neutropenia; reticular dysgenesis
• Glucocorticoid stimulation test	Chronic benign or idiopathic neutropenia, some autoimmune neutropenias
• Serial CBCs (3/wk for 6 wk)	Cyclic neutropenia
• Exocrine pancreatic function	Shwachman-Diamond syndrome
• Skeletal radiographs	Shwachman-Diamond syndrome, cartilage-hair hypoplasia, Fanconi anemia
IF ALC <1000/µL	
• Repeat blood counts in 3-4 weeks	Transient leukopenia (e.g., viral)
IF ALC <1000/µL ON 3 SEPARATE TESTS	
• HIV-1 antibody or RNA test	HIV-1 infection, AIDS
• Quantitative immunoglobulins (IgG, IgA, IgM, IgE), vaccine titers, lymphocyte subsets	Congenital or acquired disorders of immune function
IF THERE IS PANCYTOPENIA	
• Bone marrow aspiration and biopsy	Bone marrow replacement by malignancy, fibrosis, granulomata, storage cells; aplastic anemia
• Bone marrow cytogenetics and flow cytometry	Myelodysplasia, leukemia
• Vitamin B_{12} and folate levels	Vitamin deficiencies

ALC, Absolute lymphocyte count; ANC, absolute neutrophil count; CBC, complete blood count; CMV, cytomegalovirus; EBV, Epstein-Barr virus.

Neutropenia

Neutropenia is defined as a decrease in the absolute number of circulating segmented neutrophils and bands in the peripheral blood. The **absolute neutrophil count (ANC)** is determined by multiplying the total WBC count by the percentage of segmented neutrophils plus bands. Normal neutrophil counts must be stratified for age and race. Neutrophils predominate at birth but rapidly decrease in the 1st few days of life. During infancy, neutrophils constitute 20–30% of circulating leukocyte populations. Near-equal numbers of neutrophils and lymphocytes are found in the peripheral circulation at 5 yr of age, and the characteristic 70% predominance of neutrophils that occurs in adulthood is usually attained during puberty. For white children >12 mo old, the lower limit of normal for the ANC is 1,500/µL; for black children >12 mo old, the lower limit of normal is 1,200/µL. The relatively lower limit of normal in blacks likely reflects the prevalence of the Duffy negative (Fy−/−) blood group, which is enriched in populations in the malarial belt of Africa and is associated with ANCs 200-600/µL less than those who are Duffy positive.

Neutropenia may be characterized as **mild** (ANC 1,000-1,500/µL), **moderate** (ANC 500-1,000/µL), or **severe** (ANC <500/µL). ANC <200 is also termed **agranulocytosis** . This stratification aids in predicting the risk of pyogenic infection in patients who have neutropenia resulting from disorders of bone marrow production, because only patients with severe neutropenia have a significantly increased susceptibility to life-threatening infections. Neutropenia associated with monocytopenia, lymphocytopenia, or hypogammaglobulinemia increases the risk for infection compared to isolated neutropenia. *Patients with neutropenia caused by increased destruction (e.g., autoimmune) may tolerate very low ANCs without increased frequency of infection,* because of their often robust ability to generate additional neutrophils from their functioning marrow when needed.

Acute neutropenia evolves over a few days and is often a result of rapid neutrophil use and compromised neutrophil production. **Chronic neutropenia** by definition lasts longer than 3 mo and arises from reduced production, increased destruction, or excessive splenic sequestration of neutrophils. The etiology of neutropenia can be classified as either an acquired disorder or extrinsic insult (Table 157.2) or more rarely an inherited, intrinsic defect (Table 157.3).

Table 157.2

Causes of Neutropenia Extrinsic to Marrow Myeloid Cells

CAUSE	ETIOLOGIC FACTORS/AGENTS	ASSOCIATED FINDINGS
Infection	Viruses, bacteria, protozoa, rickettsia, fungi	Clinical features and laboratory findings of the infectious agent
Drug induced	Phenothiazines, sulfonamides, anticonvulsants, penicillins, aminopyrine	Usually none; occasional hypersensitivity reaction (fever, lymphadenopathy, rash, hepatitis, nephritis, pneumonitis, aplastic anemia) or antineutrophil antibody
Immune neutropenia	Alloimmune, autoimmune	Myeloid hyperplasia with left shift in bone marrow (may appear to be "arrest" at metamyelocyte or band stage)
Reticuloendothelial sequestration	Hypersplenism	Anemia, thrombocytopenia
Bone marrow replacement	Myelofibrosis, malignancy (leukemia, lymphoma, metastatic solid tumor, etc.)	Anemia, thrombocytopenia, marrow fibrosis, malignant cells in bone marrow sites of extramedullary hematopoesis
Cancer chemotherapy or radiation therapy	Suppression of myeloid cell production	Anemia, thrombocytopenia, bone marrow hypoplasia

Table 157.3

Acquired Disorders of Myeloid Cells

CAUSE	ETIOLOGIC FACTORS/AGENTS	ASSOCIATED FINDINGS
Aplastic anemia	Stem cell destruction and depletion	Pancytopenia
Vitamin B_{12} , copper, or folate deficiency	Malnutrition; congenital deficiency of B_{12} absorption, transport, and storage; vitamin avoidance	Megaloblastic anemia, hypersegmented neutrophils
Acute leukemia, chronic myelogenous leukemia	Bone marrow replacement with malignant cells	Pancytopenia, leukocytosis
Myelodysplasia	Dysplastic maturation of stem cells	Bone marrow hypoplasia with megaloblastoid red cell precursors, thrombocytopenia
Prematurity with birthweight <2 kg	Impaired regulation of myeloid proliferation and reduced size of postmitotic pool	Maternal preeclampsia
Chronic idiopathic neutropenia	Impaired myeloid proliferation and/or maturation	None
Paroxysmal nocturnal hemoglobinuria	Acquired stem cell defect secondary to mutation of *PIGA* gene	Pancytopenia, thrombosis (hepatic vein thrombosis)

Clinical Manifestations of Neutropenia

Individuals with neutrophil counts <500/µL are at substantial risk for developing infections, primarily from their endogenous flora as well as from nosocomial organisms. However, some patients with isolated chronic neutropenia may not experience many serious infections, probably because the remainder of the immune system remains intact or because neutrophil delivery to tissues is preserved, as in autoimmune neutropenias. In contrast, children whose neutropenia is secondary to acquired disorders of production, as occurs with cytotoxic therapy, immunosuppressive drugs, or radiation therapy, are likely to develop serious bacterial infections because many arms of the immune system are markedly compromised and the ability of the marrow to robustly generate new phagocytes is impaired. Neutropenia associated with additional monocytopenia or lymphocytopenia is more highly associated with serious infection than neutropenia alone. The integrity of skin and mucous membranes, the vascular supply to tissues, and nutritional status also influence the risk of infection.

The most common clinical presentation of profound neutropenia includes fever, aphthous stomatitis, and gingivitis. Infections frequently associated with neutropenia include cellulitis, furunculosis, perirectal inflammation, colitis, sinusitis, warts, and otitis media, as well as more serious infections such as pneumonia, deep tissue abscess, and sepsis. The most common pathogens causing infections in neutropenic patients are *Staphylococcus aureus* and gram-negative bacteria. Isolated neutropenia does not heighten a patient's susceptibility to parasitic or viral infections or to bacterial meningitis but does increase the risk of fungal pathogens causing disease. The usual signs and symptoms of local infection and inflammation (e.g., exudate, fluctuance, regional lymphadenopathy) may be diminished in the absence of neutrophils because of the inability to form pus, but patients with agranulocytosis still experience fever and feel pain at sites of inflammation.

Laboratory Findings

Isolated absolute neutropenia has a limited number of causes (see Tables 157.2 to 157.5). The duration and severity of the neutropenia greatly influence the extent of laboratory evaluation. Patients with chronic neutropenia since infancy and a history of recurrent fevers and chronic gingivitis should have WBC counts and differential counts determined 3 times/wk for 6-8 wk to evaluate for periodicity suggestive of **cyclic neutropenia** . Bone marrow aspiration and biopsy should be performed on select patients to assess cellularity and myeloid maturation. Additional marrow studies, such as cytogenetic analysis and special stains for detecting leukemia and other malignant disorders, should be obtained for patients with suspected intrinsic defects in the myeloid progenitors and for patients with suspected malignancy. Selection of further laboratory tests is determined by the duration and severity of the neutropenia and the associated findings on physical examination (see Table 157.1).

Table 157.4

Infections Associated With Neutropenia

Viral	Cytomegalovirus, dengue, Epstein-Barr virus, hepatitis viruses, HIV, influenza, measles, parvovirus B19, rubella, varicella, HHV-6
Bacterial	*Brucella*, paratyphoid, pertussis, tuberculosis (disseminated), tularemia, Shigella, typhoid; any form of sepsis
Fungal	Histoplasmosis (disseminated)
Protozoan	Malaria, leishmaniasis (kala-azar)
Rickettsial	*Anaplasma* (formerly *Ehrlichia*) *phagocytophilum*, psittacosis, Rocky Mountain spotted fever, typhus, rickettsialpox

Table 157.5

Forms of Drug-Induced Neutropenia

	IMMUNOLOGIC	TOXIC	HYPERSENSITIVITY
Paradigm drugs	Aminopyrine, propylthiouracil, penicillins	Phenothiazines, clozapine	Phenytoin, phenobarbital
Time to onset	Days to weeks	Weeks to months	Weeks to months
Clinical appearance	Acute, often explosive symptoms	Often asymptomatic or insidious onset	May be associated with fever, rash, nephritis, pneumonitis, or aplastic anemia
Rechallenge	Prompt recurrence with small test dose	Latent period; high doses required	Latent period; high doses required
Laboratory findings	Antineutrophil antibody may be positive; bone marrow myeloid hyperplasia	Bone marrow myeloid hypoplasia	Bone marrow myeloid hypoplasia

Acquired Neutropenia

Infection-Related Neutropenia

Transient neutropenia often accompanies or follows **viral infections** and is the most frequent cause of neutropenia in childhood (Table 157.4). Viruses causing acute neutropenia include influenzas A and B, adenovirus, respiratory syncytial virus, enteroviruses, human herpesvirus 6, measles, rubella, and varicella. Parvovirus B19 and hepatitis A or B may also cause neutropenia, but are more often associated with pure red cell aplasia or multiple cytopenias, respectively. Viral-associated acute neutropenia often occurs during the 1st 24-48 hr of illness and usually persists for 3-8 days, which generally corresponds to the period of viremia. The neutropenia is related to virus-induced redistribution of neutrophils from the circulating to the marginating pool. In addition, neutrophil sequestration may occur after virus-induced tissue damage or splenomegaly.

Significant neutropenia also may be associated with severe bacterial, protozoal, rickettsial, or fungal infections (see Table 157.4). **Bacterial sepsis** is a particularly serious cause of neutropenia, especially among younger infants and children. Premature neonates are especially prone to exhausting their marrow reserve and rapidly succumbing to bacterial sepsis.

Chronic neutropenia often accompanies infection with Epstein-Barr virus, cytomegalovirus, or HIV and certain immunodeficiencies such as X-linked agammaglobulinemia, hyper IgM syndrome and HIV. The neutropenia associated with AIDS probably arises from a combination of viral bone marrow suppression, antibody-mediated destruction of neutrophils, and effects of antiretroviral or other drugs.

Drug-Induced Neutropenia

Drugs constitute a common cause of neutropenia (Table 157.5). The incidence of drug-induced neutropenia increases dramatically with age; only 10% of cases occur among children and young adults. The majority of cases occur among adults >65 yr, likely reflecting the more frequent use of multiple medications in that age-group. Almost any drug can cause neutropenia. The most common offending drug classes are antimicrobial agents, antithyroid drugs, antipsychotics, antipyretics, and antirheumatics. Drug-induced neutropenia has several underlying mechanisms—immune-mediated, toxic, idiosyncratic, hypersensitivity, idiopathic—that are distinct from the severe neutropenia that predictably occurs after administration of antineoplastic drugs or radiotherapy.

Drug-induced neutropenia from immune mechanisms usually develops abruptly, is accompanied by fever, and lasts for about 1 wk after the discontinuation of the drug. The process likely arises from effects of drugs such as propylthiouracil or penicillin that act as haptens to stimulate antibody formation, or drugs such as quinine that induce immune complex formation.

Other drugs, including the antipsychotic drugs such as the phenothiazines, can cause neutropenia when given in toxic amounts, but some individuals, such as those with preexisting neutropenia, may be susceptible to levels at the high end of the usual therapeutic range. Late-onset neutropenia can occur after rituximab therapy. Idiosyncratic reactions, for example to chloramphenicol, are unpredictable with regard to dose or duration of use. Hypersensitivity reactions are rare and may involve arene oxide metabolites of aromatic anticonvulsants. Fever, rash, lymphadenopathy, hepatitis, nephritis, pneumonitis, and aplastic anemia are often associated with hypersensitivity-induced neutropenia. Acute hypersensitivity reactions such as those caused by phenytoin or phenobarbital may last for only a few days if the offending drug is discontinued. Chronic hypersensitivity may last for months to years.

Once neutropenia occurs, the most effective therapeutic measure is withdrawal of nonessential drugs, particularly drugs most commonly associated with neutropenia. Usually the neutropenia will resolve soon after withdrawal of the offending drug. If the neutropenia fails to improve with drug withdrawal and the patient is symptomatic with infection or stomatitis, subcutaneous administration of recombinant human granulocyte colony-stimulating factor (filgrastim, 5 µg/kg/day) should be considered. Drug-induced neutropenia may be asymptomatic and noted only as an incidental finding or because of regular monitoring of WBC counts during drug therapy. For patients who are asymptomatic, continuation of the suspected offending drug depends on the relative risks of neutropenia vs discontinuation of a possibly essential drug. If the drug is continued, blood counts should be monitored for possible progression to agranulocytosis.

Neutropenia usually and predictably follows the use of anticancer drugs or radiation therapy, especially radiation directed at the pelvis or vertebrae, secondary to cytotoxic effects on rapidly replicating myeloid precursors. A decline in the WBC count typically occurs 7-10 days after administration of the anticancer drug and may persist for 1-2 wk. The neutropenia accompanying malignancy or following cancer chemotherapy is frequently associated with compromised cellular immunity and barrier compromise secondary to central venous lines and mucositis, thereby predisposing patients to a much greater risk of infection (see Chapter 205) than found in disorders associated with isolated neutropenia. Patients with chemotherapy/radiation-related neutropenia and fever must be treated aggressively with broad-spectrum antibiotics.

Nutrition-Related Neutropenia

Poor nutrition can contribute to neutropenia. Ineffective myelopoiesis may result in neutropenia caused by acquired dietary copper, vitamin B_{12} , or folic acid deficiency. In addition, megaloblastic pancytopenia also can result from extended use of antibiotics such as trimethoprim/sulfamethoxazole that inhibit folic acid metabolism and from the use of phenytoin, which may impair folate absorption in the small intestine, or from surgical resection of the small intestine. Neutropenia also occurs with starvation and marasmus in infants, with anorexia nervosa, and occasionally among patients receiving prolonged parenteral nutrition without vitamin supplementation.

Immune-Mediated Neutropenia

Immune-mediated neutropenia is usually associated with the presence of circulating antineutrophil antibodies, which may mediate neutrophil destruction by complement-mediated lysis or splenic phagocytosis of opsonized neutrophils, or by accelerated apoptosis of mature neutrophils or myeloid precursors.

Alloimmune neonatal neutropenia occurs after transplacental transfer of maternal alloantibodies directed against antigens on the infant's neutrophils, analogous to Rh-hemolytic disease. Prenatal sensitization induces maternal IgG antibodies to neutrophil antigens on fetal cells. The neutropenia is often severe and infants may present within the 1st 2 wk of life with skin or umbilical infections, fever, and pneumonia caused by the usual microbes that cause neonatal disease. By 7 wk of age, the neutrophil count usually returns to normal, reflecting the decay of maternal antibodies in the infant's circulation. Treatment consists of supportive care and appropriate antibiotics for clinical infections, plus granulocyte colony-stimulating factor (G-CSF) for severe infections without neutrophil recovery.

Mothers with autoimmune disease may give birth to infants who develop transient neutropenia, known as **neonatal passive autoimmune neutropenia** . The duration of the neutropenia depends on the time required for the infant to clear the maternally transferred circulating IgG antibody. It persists in most cases for a few weeks to a few months. Neonates almost always remain asymptomatic.

Autoimmune neutropenia (AIN) of infancy is a benign condition with an annual incidence of approximately 1 per 100,000 among children between infancy and 10 yr of age. Patients usually have severe neutropenia on presentation, with ANC <500/µL, but the total WBC count is generally within normal limits. Monocytosis or eosinophilia may occur but does not impact the low rate of infection. The median age of presentation is 8-11 mo, with a range of 2-54 mo. The diagnosis is often evident when a blood count incidentally reveals neutropenia in a child with a minor infection or when a routine complete blood count is obtained at the 12 mo well-child visit. Occasionally, children may present with more severe infections, including abscesses, pneumonia, or sepsis. The diagnosis may be supported by the presence of antineutrophil antibodies in serum; however, the test has frequent false-negative and false-positive results, so the absence of detectable antineutrophil antibodies does not exclude the diagnosis, and a positive result does not exclude other conditions. Therefore the diagnosis is best made clinically based on a benign course and, if obtained, a normal or hyperplastic myeloid maturation in the bone marrow. There is considerable overlap between AIN of infancy and “chronic benign neutropenia.”

Treatment is not generally necessary because the disease is only rarely associated with severe infection and usually remits spontaneously. Low-dose G-CSF may be useful for severe infections, to promote wound healing following surgery, or to avert emergency room visits or hospitalizations for febrile illnesses. Longitudinal studies of infants with AIN demonstrate median duration of disease ranging from 7-30 mo. Affected children generally have no evidence or risk of other autoimmune diseases.

AIN in older children can occur as an isolated process, as a manifestation of other autoimmune diseases, or as a secondary complication of infection, drugs, or malignancy. In primary AIN, low circulating neutrophil counts are the only hematologic finding, and associated diseases or other factors that cause neutropenia are absent. Secondary AIN associated with immune dysregulation or other factors is more often identified in older children and is less likely to remit spontaneously. AIN is distinguished from other forms of neutropenia by the demonstration of antineutrophil antibodies (with caveats previously discussed) and myeloid hyperplasia on bone marrow examination. The most common antineutrophil antibody targets are human neutrophil antigens 1a, 1b, and 2.

Treatment of AIN relies on management of any underlying disorders. In addition, judicious use of appropriate antibiotics for bacterial infections and regular dental hygiene are generally beneficial, as is family and primary care provider education. Infections tend to be less frequent in AIN than with the corresponding degree of neutropenia from other causes, probably because tissue delivery of neutrophils is greater than that in conditions resulting from impaired production. Prophylactic antibiotics may be helpful for the management of recurrent minor infections. For patients with serious or recurrent infections, G-CSF is generally effective at raising the ANC and preventing infection. Very low doses (<1-2 μg/kg/day) are usually effective, and administration of standard doses can lead to severe bone pain from marrow expansion.

Neutropenia Secondary to Bone Marrow Replacement

Various acquired bone marrow disorders lead to neutropenia, usually accompanied by anemia and thrombocytopenia. Hematologic malignancies, including leukemia, lymphoma, and metastatic solid tumors, suppress myelopoiesis by infiltrating the bone marrow with tumor cells. Neutropenia may also accompany aplastic anemia, myelodysplastic disorders, or preleukemic syndromes, which are characterized by multiple cytopenias and often macrocytosis. Treatment requires management of the underlying disease.

Neutropenia Secondary to Reticuloendothelial Sequestration

Splenic enlargement resulting from intrinsic splenic disease (storage disease), portal hypertension, or systemic causes of splenic hyperplasia (inflammation or neoplasia) can lead to neutropenia. Most often the neutropenia is mild to moderate and is accompanied by corresponding degrees of thrombocytopenia and anemia. The reduced neutrophil survival corresponds to the size of the spleen, and the extent of the neutropenia is inversely proportional to bone marrow compensatory mechanisms. Usually the neutropenia can be corrected by successfully treating the underlying disease. In select cases, splenectomy may be necessary to restore the neutrophil count to normal, but results in increased risk of infections by encapsulated bacterial organisms. Patients undergoing splenectomy should receive appropriate preoperative immunizations and may benefit from antibiotic prophylaxis after splenectomy to help mitigate the risk of sepsis. Splenectomy should be avoided in patients with common variable immunodeficiency (CVID), autoimmune lymphoproliferative disease, and other immunodeficiency syndromes because of the higher risk of sepsis.

Inherited Neutropenia

Intrinsic disorders of proliferation or maturation of myeloid precursor cells are rare. Table 157.6 presents a classification based on genetics and molecular mechanisms; select disorders are discussed next.

Table 157.6

Intrinsic Disorders of Myeloid Precursor Cells

SYNDROME	INHERITANCE *(GENE)*	CLINICAL FEATURES (INCLUDING STATIC NEUTROPENIA UNLESS OTHERWISE NOTED)
PRIMARY DISORDERS OF MYELOPOIESIS		
Cyclic neutropenia	AD *(ELANE)*	Periodic oscillation (21-day cycles) in ANC
Severe congenital neutropenia	AD (primarily *ELANE*, also *GFI* and others)	Risk of MDS/AML
	AR *(G6PC3, HAX1)* (*HAX1* = Kostmann syndrome)	*G6PC3:* cardiac and urogenital anomalies, venous angioectasias; *HAX1:* neurologic abnormalities, risk of MDS/AML
	XL *(WAS)*	Neutropenic variant of Wiskott-Aldrich syndrome
DISORDERS OF MOLECULAR PROCESSING		
Shwachman-Diamond syndrome	Ribosomal defect: AR *(SBDS, DNAJC21, EFL1, SRP54)*	Pancreatic insufficiency, metaphyseal dysostosis, bone marrow failure, MDS/AML
Dyskeratosis congenita	Telomerase defects: XL *(DKC1)*, AD *(TERC)*, AR *(TERT)*	Nail dystrophy, leukoplakia, abnormal and carious teeth, lacey reticulated hyperpigmentation of the skin, bone marrow failure
DISORDERS OF VESICULAR TRAFFICKING		
Chédiak-Higashi syndrome	AR *(LYST)*	Partial albinism, giant granules in myeloid cells, platelet storage pool defect, impaired NK cell function, HLH
Griscelli syndrome, type II	AR *(RAB27a)*	Partial albinism, impaired NK cell function, neurologic impairment, HLH
Cohen syndrome	AR *(COH1)*	Partial albinism, pigmentary retinopathy, developmental delay, facial dysmorphism
Hermansky-Pudlak syndrome, type II	AR *(AP3B1)*	Cyclic neutropenia, partial albinism, HLH
p14 deficiency	Probable AR *(MAPBPIP)*	Partial albinism, decreased B and T cells
VPS45 defects	AR *(VPS45)*	Neutrophil dysfunction, bone marrow fibrosis, nephromegaly
DISORDERS OF METABOLISM		
Glycogen storage disease, type 1b	AR *(G6PT1)*	Hepatic enlargement, growth retardation, impaired neutrophil motility
Methylmalonic/propionic acidemias	AR Mutase or cobalamin transporters/propionyl coenzyme A carboxylase	Ketoacidosis, metabolic stroke, depressed consciousness
Barth syndrome	XL *(TAZ1)*	Episodic neutropenia, dilated cardiomyopathy, methylglutaconic aciduria
Pearson syndrome	Mitochondrial (DNA deletions)	Episodic neutropenia, pancytopenia; defects in exocrine pancreas, liver, and kidneys
NEUTROPENIA IN DISORDERS OF IMMUNE FUNCTION		
Common variable immunodeficiency	Familial, sporadic *(TNFRSF13B)*	Hypogammaglobulinemia, other immune system defects
IgA deficiency	Unknown (Unknown or *TNFRSF13B*)	Decreased IgA

Severe combined immunodeficiency	AR, XL (multiple loci)	Absent humoral and cellular immune function
Hyper-IgM syndrome	XL *(HIGM1)*	Absent IgG, elevated IgM, autoimmune cytopenias
WHIM syndrome	AD *(CXCR4)*	Warts, hypogammaglobulinemia, infections, myelokathexis
Cartilage-hair hypoplasia	AR *(RMRP)*	Lymphopenia, short-limbed dwarfism, metaphyseal chondrodysplasia, fine sparse hair
Schimke immunoosseous dysplasia	Probable AR *(SMARCAL1)*	Lymphopenia, pancytopenia, spondyloepiphyseal dysplasia, growth retardation, renal failure
X-linked agammaglobulinemia	Bruton tyrosine kinase (Btk)	Agammaglobulinemia, neutropenia in ~25%

AD, Autosomal dominant; AML, acute myelogenous leukemia; ANC, absolute neutrophil count; AR, autosomal recessive; HLH, hemophagocytic lymphohistiocytosis; MDS, myelodysplastic syndrome; XL, X-linked.

Primary Disorders of Granulocytopoiesis

Cyclic neutropenia is an autosomal dominant congenital granulopoietic disorder occurring with an estimated incidence of 0.5-1 cases per 1 million population. The disorder is characterized by regular, periodic oscillations, with the ANC ranging from normal to <200/µL, mirrored by reciprocal cycling of monocytes. Cyclic neutropenia is sometimes termed *cyclic hematopoiesis* because of the secondary cycling of other blood cells, such as platelets and reticulocytes. The mean oscillatory period of the cycle is 21 days (±4 days). During the neutropenic nadir, many patients develop malaise, fever, oral and genital ulcers, gingivitis, periodontitis, or pharyngitis, and occasionally lymph node enlargement. More serious infections occasionally occur, including pneumonia, mastoiditis, and intestinal perforation with peritonitis leading to life-threatening clostridial sepsis. Before the availability of G-CSF, approximately 10% of patients developed fatal clostridial or gram-negative infections. Cyclic neutropenia arises from a regulatory abnormality involving early hematopoietic precursor cells and is almost invariably associated with mutations in the neutrophil elastase gene, *ELANE* , that lead to accelerated apoptosis as a result of abnormal protein folding. Many patients experience abatement of symptoms with age. The cycles tend to become less noticeable in older patients, and the hematologic picture often begins to resemble that of chronic idiopathic neutropenia.

Cyclic neutropenia is diagnosed by obtaining blood counts 3 times/wk for 6-8 wk. The requirement for repeated blood counts is necessary because some of the elastase mutations overlap with those in patients who have **severe congenital neutropenia** . Demonstrating oscillation or a lack thereof in the blood counts helps to identify the patients' risk for progression to **myelodysplastic syndrome (MDS)/acute myelogenous leukemia (AML)** , a risk that is only associated with severe congenital neutropenia. The diagnosis can be confirmed with genetic studies demonstrating a mutation in *ELANE* . Affected patients with neutrophil nadirs <200/µL are treated with G-CSF, and their cycle of profound neutropenia changes from a 21-day period with at least 3-5 days of profound neutropenia to 9-11 days with 1 day of less profound neutropenia. The dose needed to maintain nadirs >500/µL is usually 2-4 µg/kg/day administered daily or every other day.

Severe congenital neutropenia (SCN) is a rare, genetically heterogeneous, congenital granulopoietic disorder with an estimated incidence of 1-2 cases per 1 million population. The disorder is characterized by an arrest in myeloid maturation at the promyelocyte stage in the bone marrow, resulting in ANCs consistently <200/µL and may occur sporadically, with autosomal dominant or recessive inheritance. The **dominant** form is caused most often by mutations in *ELANE* , which accounts for 60–80% of SCN cases, whereas **recessive** forms arise from mutations in *HAX1* (the form also known as **Kostmann disease**) or *G6PC3* (encoding a myeloid-specific isoform of glucose-6-phosphatase). *HAX1* mutations may be associated with neurologic deficits, and *G6PC3* with heart defects, urogenital abnormalities, and venous angiectasia. In addition to severe neutropenia, peripheral blood counts generally show monocytosis and many also exhibit eosinophilia; chronic inflammation may lead to secondary anemia and thrombocytosis. Patients who have SCN experience frequent episodes of fever, skin infections (including omphalitis), oral ulcers, gingivitis, pneumonia, and perirectal abscesses, typically appearing in the 1st few mo of life. Infections often disseminate to the blood, meninges, and peritoneum and are usually caused by *S. aureus* , *Escherichia coli,* and *Pseudomonas* species. Without filgrastim therapy, most patients die of infectious complications within the first 1-2 yr of life despite prophylactic antibiotics.

More than 95% of SCN patients respond to filgrastim treatment with an increase in the ANC and a decrease in infections. Doses required to achieve an ANC >1000/uL vary greatly. A starting dose of filgrastim at 5 µg/kg/day is recommended; the dose should be gradually increased, if necessary, as high as 100 µg/kg/day to attain an ANC of 1,000-2,000/µL. The 5% of patients who do not respond to filgrastim or who require high doses (>8 µg/kg/day) should be considered for hematopoietic stem cell transplantation (HSCT). Besides infections, patients with SCN are at risk for developing MDS associated with monosomy 7 and AML. For this reason, regular monitoring with blood counts and yearly bone marrow surveillance, including karyotyping and fluorescence in situ hybridization, should be performed on all SCN patients. Although clonal cytogenetic abnormalities may spontaneously remit, their appearance should be considered a strong indication for HSCT, which is much more likely to be successful before progression to MDS/AML.

Disorders of Molecular Processing

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disorder classically characterized by neutropenia, pancreatic insufficiency, and short stature with skeletal abnormalities. SDS is most commonly caused by proapoptotic mutations of the *SBDS* gene, which encodes a protein that plays a role in ribosome biogenesis and RNA processing. The initial symptoms are usually steatorrhea and failure to thrive because of malabsorption, which usually develops by 4 mo of age, although the gastrointestinal symptoms may be subtle in some patients and go unrecognized. Patients have also been reported to have respiratory problems with frequent otitis media, pneumonia, and eczema. Virtually all patients with SDS have neutropenia, with the ANC periodically <1000/µL. Some children have defects in chemotaxis or in the number or function of B, T, and natural killer (NK) cells that may contribute to the increased susceptibility to pyogenic infection. The diagnosis of SDS is based on clinical phenotype; approximately 90% of patients have mutations identified in *SBDS* with additional mutations now recently discovered in *DNAJC21*, *EFL1*, and *SRP54* . SDS may progress to bone marrow hypoplasia or MDS/AML; cytogenetic abnormalities, particularly isochromosome i(7q) and del(20q), often precede conversion to MDS, so bone marrow monitoring is warranted. Treatment includes pancreatic enzyme replacement, plus G-CSF in patients with severe neutropenia.

Dyskeratosis congenita , a disorder of telomerase activity, most often presents as bone marrow failure rather than isolated neutropenia. The classic phenotype also includes nail dystrophy, leukoplakia, malformed teeth, and reticulated hyperpigmentation of the skin, although many patients, particularly young ones, do not exhibit these clinical features.

Vesicular Trafficking Disorders

This group of rare **primary immunodeficiency syndromes** (see Table 157.6) derives from autosomal recessive defects in the biogenesis or trafficking of lysosomes and related endosomal organelles. As a result, the syndromes share phenotypic characteristics, including defects in melanosomes contributing to partial albinism, abnormal platelet function, and immunologic defects involving not only neutrophil number, but also the function of neutrophils, B lymphocytes, NK cells, and cytotoxic T lymphocytes. The syndromes share a high risk of hemophagocytic lymphohistiocytosis (HLH) as a result of defects in T and NK cells.

Chédiak-Higashi syndrome , best known for the characteristic giant cytoplasmic granules in neutrophils, monocytes, and lymphocytes, is a disorder of subcellular vesicular dysfunction caused by mutations in the *LYST* gene, with resultant giant granules in all granule-bearing cells. Patients have increased susceptibility to infections, mild bleeding diathesis, progressive peripheral neuropathy, and predisposition to life-threatening HLH. The only curative treatment is HSCT, but transplant does not treat all aspects of the disorder.

Griscelli syndrome type II also features neutropenia, partial albinism, and a high risk of HLH, but peripheral blood granulocytes do not show giant granules. Patients often have hypogammaglobulinemia. The disorder is caused by mutations in *RAB27a* , which encodes a small guanosine triphosphatase that regulates granule secretory pathways. The only curative treatment is HSCT.

Disorders of Metabolism

Recurrent infections with neutropenia are a distinctive feature of **glycogen storage disease (GSD) type Ib** . As in classic **von Gierke disease** (GSDIa), glycogen storage in GSDIb causes massive hepatomegaly and severe growth retardation. Mutations in glucose-6-phosphate transporter 1, *G6PT1* , inhibit glucose transport in GSDIb, resulting in both defective neutrophil motility and increased apoptosis associated with neutropenia and recurrent bacterial infections. Treatment with G-CSF can correct the neutropenia but does not correct the underlying functional neutrophil defects.

Neutropenia in Disorders of Immune Dysfunction

Congenital immunologic disorders that have severe neutropenia as a clinical feature include X-linked agammaglobulinemia (XLA), CVID, the severe combined immunodeficiencies, autoimmune lymphoproliferative syndrome, hyperimmunoglobulin M syndrome, WHIM (warts, hypogammaglobulinemia, infections, myelokathexis) syndrome, GATA2 haploinsufficiency, and a number of even rarer immunodeficiency disorders (see Table 157.6).

Unclassified Neutropenic Disorders

Chronic benign neutropenia of childhood represents a common group of disorders characterized by mild to moderate neutropenia that does not lead to an increased risk of pyogenic infections. Spontaneous remissions are often reported, although these may represent misdiagnosis of AIN of infancy, in which remissions often occur during childhood. Chronic benign neutropenia may be sporadic or inherited in either dominant or recessive form. Because of the relatively low risk of serious infection, patients usually do not require any therapy.

Idiopathic chronic neutropenia is characterized by the onset of neutropenia after 2 yr of age, with no identifiable etiology. Patients with an ANC persistently <500/µL may have recurrent pyogenic infections involving the skin, mucous membranes, lungs, and lymph nodes. Bone marrow examination reveals variable patterns of myeloid formation with arrest generally occurring between the myelocyte and band forms. The diagnosis overlaps with chronic benign and AINs.

Treatment

The management of acquired transient neutropenia associated with malignancies, myelosuppressive chemotherapy, or immunosuppressive chemotherapy differs from that of congenital or chronic forms of neutropenia. In the former situation, infections sometimes are heralded only by fever, and sepsis is a major cause of death. Early recognition and treatment of infections may be lifesaving (see Chapter 205). Therapy of severe chronic neutropenia is dictated by the clinical manifestations. Patients with benign neutropenia and no evidence of repeated bacterial infections or chronic gingivitis require no specific therapy. Superficial infections in children with mild to moderate neutropenia may be treated with appropriate oral antibiotics. In patients who have invasive or life-threatening infections, broad-spectrum intravenous antibiotics should be started promptly.

Subcutaneously administered G-CSF can provide effective treatment of severe chronic neutropenia, including SCN, cyclic neutropenia, and chronic symptomatic idiopathic neutropenias. Treatment leads to dramatic increases in neutrophil counts, resulting in marked attenuation of infection and inflammation. Doses range from 2-5 µg/kg/day for cyclic, idiopathic, and autoimmune neutropenias, to 5-100 µg/kg/day for SCN. The long-term effects of G-CSF therapy include a propensity for the development of moderate splenomegaly, thrombocytopenia, and rarely vasculitis; only patients with SCN are at risk for MDS/AML.

Patients with SCN or SDS who develop MDS or AML respond only to HSCT; chemotherapy is ineffective. HSCT is also the treatment of choice for aplastic anemia or familial HLH.

Lymphopenia

The definition of **lymphopenia** , as with neutropenia, is age dependent and can have acquired or inherited causes. **The absolute lymphocyte count (ALC)** is determined by multiplying the total WBC count by the percentage of total lymphocytes. For children <12 mo old, lymphopenia is defined as an ALC <3,000 cells/µL. For older children and adults, an ALC <1,000 cells/µL is considered lymphopenia. In isolation, mild to moderate lymphopenia is generally a benign condition often detected only in the evaluation of other illnesses. However, severe lymphopenia can result in serious, life-threatening illness. Lymphocyte subpopulations can be measured by flow cytometry, which uses the pattern of lymphocyte antigen expression to quantitate and classify T, B, and NK cells.

Acquired Lymphopenia

Acute lymphopenia is most often a result of infection and/or is iatrogenic from lymphocyte-toxic medications and treatments (Table 157.7). Microbial causes include viruses (e.g., respiratory syncytial virus, cytomegalovirus, influenza, measles, hepatitis), bacterial infections (e.g., tuberculosis, typhoid fever, histoplasmosis, brucellosis), and malaria. The mechanisms behind infection-associated lymphopenia are not fully elucidated but probably include lymphocyte redistribution and accelerated apoptosis. Corticosteroids are a common cause of medication-induced lymphopenia, as are lymphocyte-specific immunosuppressive agents (e.g., antilymphocyte globulin, alemtuzumab, rituximab), chemotherapy drugs, and radiation. In most cases, infectious and iatrogenic causes of acute lymphopenia are reversible, although full lymphocyte recovery from chemotherapy and lymphocyte-specific immunosuppressive agents may take several months to years. Prolonged lymphopenia (Table 157.7) may be caused by recurrent infection; persistent infections, mostly notably HIV; malnutrition; mechanical loss of lymphocytes through protein-losing enteropathy or thoracic duct leaks; or systemic diseases such as lupus erythematosus, rheumatoid arthritis, sarcoidosis, renal failure, lymphoma, and aplastic anemia.

Table 157.7

Causes of Lymphocytopenia

ACQUIRED	
Infectious diseases	AIDS, hepatitis, influenza, sepsis, tuberculosis, typhoid
Iatrogenic	Corticosteroids, cytotoxic chemotherapy, high-dose PUVA, immunosuppressive therapy, radiation, thoracic duct drainage
Systemic diseases	Hodgkin disease, lupus erythematosus, myasthenia gravis, protein-losing enteropathy, renal failure, sarcoidosis
Other	Aplastic anemia, dietary deficiencies, thermal injury
INHERITED	
Aplasia of lymphopoietic stem cells	Cartilage-hair hypoplasia, ataxia-telangiectasia, SCID, thymoma, Wiskott-Aldrich syndrome

PUVA, Psoralen and ultraviolet A irradiation; SCID, severe combined immunodeficiency.

Inherited Lymphopenia

Primary immunodeficiencies and bone marrow failure syndromes are the main cause of inherited lymphopenia in children (see Table 157.7). Primary immunodeficiency may result in a severe quantitative defect, as in XLA and severe combined immunodeficiency (SCID), or a qualitative or progressive defect, as in Wiskott-Aldrich syndrome and CVID. XLA is characterized by a near-absence of mature B cells because of a mutation in *BTK* that results in a dysfunctional tyrosine kinase. SCIDs are a genetically heterogeneous group of disorders characterized by abnormalities of thymopoiesis and T-cell maturation. Newborn screening for severe T-cell deficiency, by analysis of T-cell receptor excision circles from dried blood spot Guthrie cards, aids in the rapid identification and treatment of infants with SCID and other T-cell disorders. Quantitative defects in lymphocytes can also be appreciated in select forms of inherited bone marrow failure such as reticular dysgenesis, SCN secondary to *GFI1* mutation, and dyskeratosis congenita.

CHAPTER 158

Leukocytosis

Thomas F. Michniacki, Kelly J. Walkovich

Leukocytosis is an elevation in the total leukocyte or white blood cell (WBC) count that is 2 SD above the mean for age (see Chapter 748). It is most often caused by elevated numbers of neutrophils (i.e., neutrophilia), although marked increases in monocytes, eosinophils, basophils, and lymphocytes can be seen. Before extensive evaluation, it is important to assess for spurious elevations in the WBC count caused by platelet clumping (secondary to insufficient sample anticoagulation or the presence of EDTA-dependent agglutinins), high numbers of circulating nucleated red blood cells (RBCs), and the presence of cryoglobulins by review of the peripheral smear.

Malignancy, namely leukemia and lymphoma, is a primary concern for patients with leukocytosis. For discussion of WBC elevation caused by immature leukocytes in acute and chronic leukemias, see Chapter 522 . Nonmalignant WBC counts exceeding 50,000/µL have historically been termed a **leukemoid reaction.** Unlike leukemia, leukemoid reactions show relatively small proportions of immature myeloid cells, consisting largely of band forms, occasional metamyelocytes, and progressively rarer myelocytes, promyelocytes, and blasts. Leukemoid reactions are most often neutrophilic and are frequently associated with severe bacterial infections, including shigellosis, salmonellosis, and meningococcemia; physiologic stressors; and certain medications.

The presence of a **left shift** , defined as having >5% immature neutrophils in the peripheral blood, is consistent with marrow stress. Higher degrees of left shift with more immature neutrophil precursors are indicative of serious bacterial infections and may be a dire sign of depletion of the bone marrow reserve pool of neutrophils. Marked left shift may occasionally be encountered with trauma, burns, surgery, acute hemolysis, or hemorrhage.

Neutrophilia

Neutrophilia is an increase in the total number of blood neutrophils that is 2 SD above the mean count for age (see Chapter 748). Elevated absolute neutrophil counts represent disturbances of the normal equilibrium involving bone marrow neutrophil production, migration out of the marrow compartments into the circulation, and neutrophil destruction. Neutrophilia may arise either alone or in combination with enhanced mobilization into the **circulating pool** from either the bone marrow storage compartment or the peripheral blood **marginating pool** , by impaired neutrophil egress into tissues, or by expansion of the circulating neutrophil pool secondary to increased granulocytopoiesis. Myelocytes are not released to the blood except under extreme circumstances.

Acute Acquired Neutrophilia

Neutrophilia is usually an acquired, secondary finding associated with inflammation, infection, injury, or an acute physical or emotional stressor (Table 158.1). Bacterial infections, trauma (especially with hemorrhage), and surgery are among the most common causes encountered in clinical practice. Neutrophilia may also be associated with heat stroke, burns, diabetic ketoacidosis, pregnancy, or cigarette use.

Table 158.1

Causes of Neutrophilia

TYPE	CAUSE	EXAMPLE
Acute acquired	Bacterial infections	
	Surgery	
	Acute stress	Burns, diabetic ketoacidosis, heat stroke, postneutropenia rebound, exercise
	Drugs	Corticosteroids, epinephrine, hematopoietic growth factors, lithium
Chronic acquired	Chronic inflammation	Inflammatory bowel disease, rheumatoid arthritis, vasculitis, cigarette exposure
	Persistent infection	Tuberculosis
	Persistent stress	Chronic blood loss, hypoxia, sickle cell and other chronic hemolytic anemias
	Drugs	Corticosteroids, lithium; rarely ranitidine, quinidine
	Other	Postsplenectomy, tumors, Hodgkin disease, pregnancy, Sweet syndrome
Lifelong	Congenital asplenia	
	Hereditary disorders	Familial cold urticaria, hereditary neutrophilia, leukocyte adhesion deficiencies, periodic fever syndromes

Drugs commonly associated with neutrophilia include epinephrine, corticosteroids, and recombinant growth factors such as recombinant human granulocyte colony-stimulating factor (G-CSF) and recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF). Epinephrine causes release into the circulation of a sequestered pool of neutrophils that normally marginate along the vascular endothelium. Corticosteroids accelerate the release of neutrophils and bands from a large storage pool within the bone marrow and impair the migration of neutrophils from the circulation into tissues. G-CSF and GM-CSF cause acute and chronic neutrophilia by mobilizing cells from the marrow reserves and stimulating neutrophil production.

Acute neutrophilia in response to inflammation and infections occurs because of release of neutrophils from the marrow storage pool. The postmitotic marrow neutrophil pools are approximately 10 times the size of the blood neutrophil pool, and about half of these cells are bands and segmented neutrophils. Exposure of blood to foreign substances such as hemodialysis membrane activates the complement system and causes transient neutropenia, followed by neutrophilia secondary to release of bone marrow neutrophils. Reactive neutrophils often have toxic granulation and Döhle bodies present.

Chronic Acquired Neutrophilia

Chronic acquired neutrophilia is usually associated with continued stimulation of neutrophil production resulting from persistent inflammatory reactions or chronic infections (e.g., tuberculosis), vasculitis, postsplenectomy states, Hodgkin disease, chronic myelogenous leukemia, chronic blood loss, sickle cell disease, some chronic hemolytic anemias, and prolonged administration of corticosteroids (see Table 158.1). Chronic neutrophilia can arise after expansion of cell production secondary to stimulation of cell divisions within the mitotic precursor pool, which consists of promyelocytes and myelocytes. Subsequently, the size of the postmitotic pool increases. These changes lead to an increase in the marrow reserve pool, which can be readily mobilized for release of neutrophils into the circulation. The neutrophil production rate can increase greatly in response to exogenously administered hematopoietic growth factors, such as G-CSF, with a maximum response taking at least 1 wk to develop.

Lifelong Neutrophilia

Congenital or acquired asplenia is associated with lifelong neutrophilia. Some patients with trisomy-21 also have neutrophilia. Uncommon genetic disorders that present with neutrophilia include leukocyte function disorders such as leukocyte adhesion deficiency and Rac2 deficiency (see Chapter 156) and systemic disorders such as familial cold urticaria, periodic fever syndromes, and familial myeloproliferative disease (see Table 158.1). Rare patients with an autosomal dominant hereditary neutrophilia have been reported.

Evaluation of persistent neutrophilia requires a careful history, physical examination, and laboratory studies to search for infectious, inflammatory, and neoplastic conditions. The leukocyte alkaline phosphatase score of circulating neutrophils can differentiate chronic myelogenous leukemia, in which the level is uniformly almost zero, from reactive or secondary neutrophilia, which features normal to elevated levels.

Additional Forms of Leukocytosis

Monocytosis

The average absolute blood monocyte count varies with age, which must be considered in the assessment of monocytosis. Given the role of monocytes in antigen presentation and cytokine secretion and as effectors of ingestion of invading organisms, it is not surprising that many clinical disorders give rise to monocytosis (Table 158.2). Typically, monocytosis occurs in patients recovering from myelosuppressive chemotherapy and is a harbinger of the return of the neutrophil count to normal. Monocytosis is occasionally a sign of an acute bacterial, viral, protozoal, or rickettsial infection and may also occur in some forms of chronic neutropenia and postsplenectomy states. Chronic inflammatory conditions can stimulate sustained monocytosis, as can preleukemia, chronic myelogenous leukemia, and lymphomas.

Table 158.2

Causes of Monocytosis

CAUSE	EXAMPLE
Infections	
Bacterial infections	Brucellosis, subacute bacterial endocarditis, syphilis, tuberculosis, typhoid
Nonbacterial	Fungal infections, kala-azar, malaria, Rocky Mountain spotted fever, typhus

infections	
Hematologic disorders	Congenital and acquired neutropenias, hemolytic anemias
Malignant disorders	Acute myelogenous leukemia, chronic myelogenous leukemia, juvenile myelomonocytic leukemia, Hodgkin disease, non-Hodgkin lymphomas, preleukemia
Chronic inflammatory diseases	Inflammatory bowel disease, polyarteritis nodosa, rheumatoid arthritis, sarcoidosis, systemic lupus erythematosus
Miscellaneous	Cirrhosis, drug reaction, postsplenectomy, recovery from bone marrow suppression

Eosinophilia

Eosinophilia is defined as an absolute eosinophil count >1500 cells/μL. The majority of eosinophilic conditions are reactive, including infections (especially parasitic diseases), connective tissue disorders, allergic and hyperinflammatory diseases, pulmonary disorders, and dermatologic conditions. Hypereosinophilic syndrome and systemic mastocytosis are additional important causes of an elevated eosinophil count. However, persistent eosinophilia can also herald a malignancy such as leukemia, lymphoma, or carcinoma.

Basophilia

Basophilia is defined as an absolute basophil count >120 cells/μL. Basophilia is a nonspecific sign of a wide variety of disorders and is usually of limited diagnostic importance. Basophilia is most often present in hypersensitivity reactions and frequently accompanies the leukocytosis of chronic myeloid leukemia.

Lymphocytosis

The most common cause of lymphocytosis is an acute viral illness, as part of the normal T-cell response to the infection. In infectious mononucleosis, the B cells are infected with the Epstein-Barr virus, and the T cells react to the viral antigens present in the B cells, resulting in **atypical lymphocytes** with characteristic large, vacuolated morphology. Other viral infections classically associated with lymphocytosis are cytomegalovirus and viral hepatitis. Chronic bacterial infections such as tuberculosis and brucellosis may lead to a sustained lymphocytosis. Pertussis is accompanied by marked lymphocytosis in approximately 25% of infants infected before 6 mo of age. Thyrotoxicosis and Addison disease are endocrine disorders associated with lymphocytosis.

Persistent or pronounced lymphocytosis suggests acute lymphocytic leukemia.

SECTION 4

The Complement System

OUTLINE

Chapter 159 Complement Components and Pathways
Chapter 160 Disorders of the Complement System

CHAPTER 159

Complement Components and Pathways

Richard B. Johnston Jr.

Complement is an exquisitely balanced, highly influential system that is fundamental to the clinical expression of host defense and inflammation. The complement system also has the capacity to perform functions beyond host defense, such as promoting phagocytic removal of dying cells, molecular debris, and weak or superfluous synapses during brain formation. Complement components and receptors function within individual cells and can stabilize intracellular homeostasis. However, complement activation can also cause harm and has been implicated in many illnesses.

The complement system, an essential component of innate and adaptive immunity, is broadly conceptualized as (1) the classical, lectin, and alternative **pathways** , which interact and depend on each other for their full activity; (2) the **membrane attack complex** (C5b6789), formed from activity of any pathway; (3) cell membrane **receptors** that bind complement components or fragments to mediate complement activity; and (4) a large array of serum and membrane **regulatory proteins** (Table 159.1 and Fig. 159.1). The circulating components and regulators together comprise approximately 15% of the globulin fraction and 4% of the total proteins in serum. The normal concentrations of serum complement components vary by age (see Chapter 748); newborn infants have mild to moderate deficiencies of all components.

Table 159.1

Constituents of the Complement System

Serum Components That Are the Core of the Complement System

Classical pathway: C1q, C1r, C1s, C4, C2, C3
Alternative pathway: factor B, factor D
Lectin pathway: Mannose-binding lectin (MBL), ficolins 1/2/3, MBL-associated serine proteases (MASPs) 1/2/3
Membrane attack complex: C5, C6, C7, C8, C9
Regulatory protein, enhancing: properdin
Regulatory proteins, downregulating: C1 inhibitor (C1 INH), C4-binding protein (C4-bp), factor H, factor I, vitronectin, clusterin, carboxypeptidase N (anaphylatoxin inactivator)

Membrane Regulatory Proteins

CR1 (CD35), membrane cofactor protein (MCP; CD46), decay-accelerating factor (DAF, CD55), CD59 (membrane inhibitor of reactive lysis)

Membrane Receptors

CR1 (CD35), CR2 (CD21), CR3 (CD11b/CD18), CR4 (CD11c/CD18), C3a receptor, C5a receptor, C1q receptors, complement receptor of the immunoglobulin superfamily (CRIg)

FIG. 159.1 Activation of the complement cascade. The classical pathway is activated primarily by antibody, whereas the mannose-binding lectin and alternative pathways are activated directly by pathogens. In each case, the activation arm leads to cleavage of C3. (From Leung DYM, editor: *Pediatric allergy principles and practice* , ed 2, Philadelphia, 2010, Saunders, p 121.)

After C1423, complement nomenclature is logical and consists of only a few rules. Fragments of components resulting from cleavage by other components acting as enzymes are assigned lowercase letters (a, b, c, d, e); with the exception of C2 fragments, the smaller piece that is released into surrounding fluids is assigned the lowercase letter a, and the major part of the molecule, bound to other components or to some part of the immune complex, is assigned letter b, such as C3a and C3b. Components of the alternative pathway, B and D, have been assigned uppercase letters, as have the control proteins I and H, which downregulate both pathways. **C3** , and especially its major fragment **C3b** , is a component of both classical and alternative pathways.

Complement is a system of interacting proteins. The biologic functions of the system depend on the interactions of individual components, which occur in sequential, cascade fashion. Activation of each component, except the 1st, depends on activation of the prior component or components in the sequence. Interaction occurs along the 3 pathways (Fig. 159.2): the **classical pathway** , in the order antigen–antibody–C142356789; the **lectin** (carbohydrate-binding) **pathway** , in the order microbial carbohydrate–lectin (mannose-binding lectin

[MBL] or ficolin)–MBL-associated serine protease–C42356789; and the **alternative pathway,** in the order activator–C3bBD–C356789. Antibody accelerates the rate of activation of the alternative pathway, but activation can occur on appropriate surfaces in the absence of antibody. The classical and the alternative pathways interact with each other through the ability of both to activate C3.

FIG. 159.2 Sequence of activation of the components of the classical and lectin pathways of complement and interaction with the alternative pathway. MBL, Mannose-binding lectin; MASP, MBL-associated serine protease. Activation of C3 is the essential target. Functional activities generated during activation are enclosed in *boxes.* The multiple sites at which inhibitory regulator proteins *(not shown)* act are indicated by *asterisks,* emphasizing the delicate balance between action and control in this system that is essential for host defense yet capable of profound damage to host tissues. Ab, Antibody (immunoglobulin G or M class); Ag, antigen (bacterium, virus, tumor or tissue cell); B, D, I, P, factors B, D, I, and properdin; C-CRP, carbohydrate–carbohydrate-reactive protein; C4-bp, C4-binding protein; MBL, mannose-binding lectin; MASP, MBL-associated serine protease.

Activation of the early-acting components of complement (C1423) results in the generation of a series of active enzymes, C1, C42, and C423, on the surface of the immune complex or underlying cell. These enzymes cleave and activate the next component in the sequence. In contrast, the interaction among C5b, C6, C7, C8, and C9 is nonenzymatic and depends on changes in molecular configuration.

Classical and Lectin Pathways

The classical pathway sequence begins with fixation of C1, by way of C1q, to the Fc, non–antigen-binding part of the antibody molecule after antigen-antibody interaction. The C1 tricomplex changes configuration, and the C1s subcomponent becomes an active enzyme, “C1 esterase.” Certain bacteria, RNA viruses, and the lipid A component of bacterial endotoxin can activate C1q directly and trigger the full complement cascade.

As part of the **innate immune response** , broadly reactive “natural” antibodies and C-reactive protein, which reacts with carbohydrate from microorganisms and with dying cells, can substitute for specific antibody in the fixation of C1q and initiate reaction of the entire sequence. Endogenous agents, including uric acid crystals, amyloid deposits, DNA, and components of damaged cells such as apoptotic blebs and mitochondrial membranes, can activate C1q directly. In this case, however, the ligand-C1q complex interacts strongly with the inhibitors C4-binding protein and factor H, allowing some C3-mediated opsonization and phagocytosis but limiting the full inflammatory response typically triggered by microbes. C1q synthesized in the brain and retina fixes to superfluous synapses, which then can be cleared through C1q receptors on microglia, clearing the way for fresh synapses to populate the developing nervous system.

There are 4 recognition molecules in the lectin pathway: **mannose-binding lectin (MBL)** and **ficolins** 1, 2, and 3. MBL is the prototype of the collectin family of carbohydrate-binding proteins (**lectins**) that are believed to play an important part in innate, nonspecific immunity; its structure is homologous to that of C1q. These lectins, in association with **MBL-associated serine proteases** 1, 2, and 3 (**MASPs** 1, 2, 3), can bind to mannose, lipoteichoic acid, and other carbohydrates on the surface of bacteria, fungi, parasites, and viruses. There, MASPs then function like C1s to cleave C4 and C2 and activate the complement cascade. The peptide C4a has weak “anaphylatoxin” activity and reacts with mast cells to release the chemical mediators of immediate hypersensitivity, including histamine. C3a and C5a, released later in the sequence, are potent anaphylatoxins, and C5a is also an important chemotactic factor. Fixation of C4b to the complex permits it to adhere to neutrophils, macrophages, B cells, dendritic cells, and erythrocytes. MASP-2 can activate clotting by generating thrombin from prothrombin, which could prevent microbial spread.

Cleavage of C3 and generation of C3b is the next step in the sequence. The serum concentration of C3 is the highest of any component, and its activation is the most crucial step in terms of biologic activity. Cleavage of C3 can be achieved through the **C3 convertase** of the classical pathway, C142, or of the alternative pathway, C3bBb. Once C3b is fixed to a complex or dead or dying host cell, it can bind to cells with receptors for C3b (complement receptor 1 [**CR1**]), including B lymphocytes, erythrocytes, and phagocytic cells (neutrophils, monocytes, and macrophages). Efficient **phagocytosis** of most microorganisms, especially by neutrophils, requires binding of C3 to the microbe. The severe pyogenic infections that frequently occur in C3-deficient patients illustrate this point. The biologic activity of C3b is controlled by cleavage by **factor I** to iC3b, which promotes phagocytosis on binding to the **iC3b receptor (CR3)** on phagocytes. Further degradation of iC3b by factor I and proteases yields C3dg, then C3d; C3d binds to CR2 on B lymphocytes and thereby serves as a co-stimulator of antigen-induced B-cell activation.

Alternative Pathway

The alternative pathway can be activated by C3b generated through classical pathway activity or proteases from neutrophils or the clotting system. It can also be activated by a form of C3 created by low-grade, spontaneous reaction of native C3 with a molecule of water, a “tickover” that occurs constantly in plasma. Once formed, C3b or the hydrolyzed C3 can bind to any nearby cell or to factor B. **Factor B** attached to C3b in the plasma or on a surface can be cleaved to Bb by the circulating protease **factor D** . The complex C3bBb becomes an efficient C3 convertase, which generates more C3b through an amplification loop. **Properdin** can bind to C3bBb, increasing stability of the enzyme and protecting it from inactivation by **factors I and H** , which modulate the loop and the pathway.

Certain “activating surfaces” promote alternative pathway activation if C3b is fixed to them, including bacterial teichoic acid and endotoxin, virally infected cells, antigen–immunoglobulin A complexes, and cardiopulmonary bypass and renal dialysis membranes. These surfaces act by protecting the C3bBb enzyme from the control otherwise exercised by factors I and H. Rabbit red blood cell membrane is such a surface, which serves as the basis for an assay of serum alternative pathway activity. Conversely, sialic acid on the surface of microorganisms or cells prevents formation of an effective alternative pathway C3 convertase by promoting activity of factors I and H. In any event, significant activation of C3 can occur through the alternative pathway, and the resultant biologic activities are qualitatively the same as those achieved through activation by C142 (see Fig. 159.2).

Membrane Attack Complex

The sequence leading to cytolysis begins with the attachment of C5b to the C5-activating enzyme from the classical pathway, C4b2a3b, or from the alternative pathway, C3bBb3b. C6 is bound to C5b without being cleaved, stabilizing the activated C5b fragment. The C5b6 complex then dissociates from C423 and reacts with C7. C5b67 complexes must attach promptly to the membrane of the parent or a bystander cell, or they lose their activity. Next, C8 binds, and the C5b678 complex then promotes the addition of multiple C9 molecules. The C9 polymer of at least 3-6 molecules forms a transmembrane channel, and lysis ensues.

Control Mechanisms

Without control mechanisms acting at multiple points, there would be no effective complement system, and unbridled consumption of components would generate severe, potentially lethal damage to the host. At the 1st step, **C1 inhibitor (C1 INH)** inhibits C1r and C1s enzymatic activity, and thus the cleavage of C4 and C2. C1 INH also inhibits MASP-2, factors XIa and XIIa of the clotting system, and kallikrein of the contact system. Activated C2 has a short half-life, and this relative instability limits the effective life of C42 and C423. The alternative pathway enzyme that activates C3, C3bBb, also has a short half-life, although it can be prolonged by the binding of properdin (P) to the enzyme complex. P can also bind directly to microbes and promote assembly of the alternative pathway C3 convertase.

Serum contains the enzyme carboxypeptidase N, which cleaves the N-terminus arginine from C4a, C3a, and C5a, thereby limiting their biologic activity. Factor I inactivates C4b and C3b; factor H accelerates inactivation of C3b by factor I; and an analogous factor, C4-binding protein (**C4-bp**), accelerates C4b cleavage by factor I, thus limiting assembly of the C3 convertase. Three protein constituents of cell membranes—**CR1** , membrane cofactor protein (**MCP**), and decay-accelerating factor (**DAF**)—promote the disruption of C3 and C5 convertases assembled on those membranes. Another cell membrane–associated protein, **CD59** , can bind C8 or both C8 and C9 and thereby interfere with insertion of the membrane attack complex (C5b6789). The serum proteins **vitronectin** and **clusterin** can inhibit attachment of the C5b67 complex to cell membranes, bind C8 or C9 in a full membrane attack complex, or otherwise interfere with the formation or insertion of this complex. Vitronectin also promotes macrophage uptake of dying neutrophils. The genes for the regulatory proteins factor H, C4-bp, MCP, DAF, CR1, and CR2 are clustered on chromosome 1.

Participation in Host Defense

Neutralization of virus by antibody can be enhanced with C1 and C4 and further enhanced by the additional fixation of C3b through the classical or alternative pathway. Complement may therefore be particularly important in the early phases of a viral infection when antibody is limited. Antibody and the full complement sequence can also eliminate infectivity of at least some viruses by the production of typical complement “holes,” as seen by electron microscopy. Fixation of C1q can opsonize (promote phagocytosis) through binding to the phagocyte C1q receptor.

C4a, C3a, and C5a can bind to mast cells and thereby trigger release of histamine and other mediators, leading to vasodilation and the swelling and redness of inflammation. C5a can enhance macrophage phagocytosis of C3b-opsonized particles and induce macrophages to release the cytokines tumor necrosis factor and interleukin-1. C5a is a major chemotactic factor for neutrophils, monocytes, and eosinophils, which can efficiently phagocytize microorganisms opsonized with C3b or cleaved C3b (iC3b). Further inactivation of cell-bound C3b by cleavage to C3d and C3dg removes its opsonizing activity, but it can still bind to B cells. Fixation of C3b to a target cell can enhance its lysis by natural killer cells or macrophages.

Insoluble immune complexes can be solubilized if they bind C3b, apparently because C3b disrupts the orderly antigen-antibody lattice. Binding C3b to a complex also allows it to adhere to C3 receptors (CR1) on red blood cells, which then transport the complexes to hepatic and splenic macrophages for removal.

This phenomenon may at least partially explain the immune complex disease found in patients who lack C1, C4, C2, or C3.

The complement system serves to link the innate and adaptive immune systems. C4b or C3b coupled to immune complexes promotes their binding to antigen-presenting macrophages, dendritic cells, and B cells. Coupling of antigen to C3d allows binding to CR2 on B cells, which greatly reduces the amount of antigen needed to trigger an antibody response.

Neutralization of endotoxin in vitro and protection from its lethal effects in experimental animals require C1 INH and later-acting components of complement, at least through C6. Finally, activation of the entire complement sequence can result in lysis of virus-infected cells, tumor cells, and most types of microorganisms. Bactericidal activity of complement has not appeared to be important to host defense, except for the occurrence of *Neisseria* infections in patients lacking later-acting components of complement (see Chapter 160).

CHAPTER 160

Disorders of the Complement System

160.1

Evaluation of the Complement System

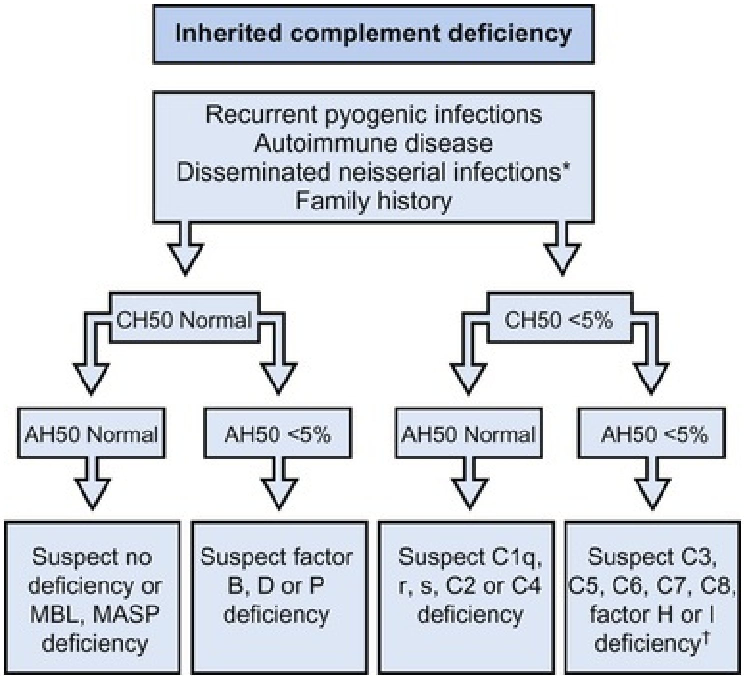
Richard B. Johnston Jr.

Keywords

hereditary angioedema
total hemolytic complement activity
CH_{50}
alternative pathway activity
AP_{50}

Testing for **total hemolytic complement activity (CH_{50})** effectively screens for most of the common diseases of the complement system. A normal result in this assay depends on the ability of all 11 components of the classical pathway and membrane attack complex to interact and lyse antibody-coated sheep erythrocytes. The dilution of serum that lyses 50% of the cells determines the end-point. In **congenital deficiencies** of C1 through C8, the CH_{50} value is 0 or close to 0; in C9 deficiency the value is approximately half-normal. Values in the acquired deficiencies vary with the type and severity of the underlying disorder.

This assay does not detect deficiency of mannose-binding lectin (MBL), factor D or B of the alternative pathway, or properdin (Fig. 160.1). Deficiency of factor I or H permits persistence of the classical and alternative pathway convertase and thus consumption of C3, with reduction in the CH_{50} value. When clotted blood or serum sits at room temperature or warms, CH_{50} activity begins to decline, leading to values that are falsely low but not zero. It is important to separate the serum and freeze it at −70°C (−94°F) by no more than 1 hr after blood draw.



Inherited complement deficiency
Recurrent pyogenic infections
Autoimmune disease
Disseminated neisserial infections*

AH50 Normal
AH50 <5%
Suspect no deficiency or MBL, MASP deficiency
Suspect factor B, D or P deficiency
Suspect C1q, r, s, C2 or C4 deficiency
Suspect C3, C5, C6, C7, C8, factor H or I deficiency†

FIG. 160.1 **Flow chart for the evaluation of inherited complement deficiencies using hemolytic screening assays for the classical (CH50) and alternative pathways (AH50). For each assay, the entire activation pathway, including the membrane attack complex, is required for lysis. MASP, MBL-associated serine protease; MBL, mannose-binding lectin. *Gonococcal and meningococcal. † C9 deficiency may have up to 30% normal CH50 with low AH50. (Adapted from Rich RR, Fleisher TA, Shearer WT, et al, editors: *Clinical immunology: principles and practice* , ed 4, Philadelphia, 2012, Saunders, p 262.)**

In **hereditary angioedema** , depression of C4 and C2 during an attack significantly reduces the CH_{50} . Typically, C4 is low and C3 normal or slightly decreased. Concentrations of C1 inhibitor protein will be normal in 15% of cases; but C1 acts as an esterase, and the diagnosis can be established by showing increased capacity of the patient's sera to hydrolyze synthetic esters.

A decrease in serum concentration of both C4 and C3 suggests activation of the *classical pathway* by immune complexes. Decreased C3 and normal C4 levels suggest activation of the *alternative pathway.* This difference is particularly useful in distinguishing nephritis secondary to immune complex deposition from that caused by **NeF** (nephritic factor). In the latter condition and in deficiency of factor I or H, factor B is consumed and C3 serum concentration is low. Alternative pathway activity can be measured with a relatively simple and reproducible hemolytic assay that depends on the capacity of rabbit erythrocytes to serve as both an activating (permissive) surface and a target of alternative pathway activity. This assay, **AP_{50}** , detects deficiency of properdin, factor D, and factor B. Immunochemical methods can be used to quantify individual components and split products of all 3 pathways, guided by results of the screening hemolytic assays.

A defect of complement function should be considered in any patient with recurrent angioedema, autoimmune disease (especially SLE), chronic nephritis, hemolytic-uremic syndrome, or partial lipodystrophy, or with recurrent pyogenic infections, disseminated meningococcal or gonococcal infection, or a 2nd episode of bacteremia at any age. A previously well adolescent or young adult with meningococcal meningitis caused by an uncommon serotype (not A, B, or C) should undergo screening for a late-component or alternative pathway deficiency with CH_{50} and AP_{50} assays.

160.2

Genetic Deficiencies of Complement Components

Richard B. Johnston Jr.

Keywords

complement component deficiencies
C1q deficiency
C3 deficiency
MBL deficiency
complement deficiency and meningitis

Congenital deficiencies of all 11 components of the classical–membrane attack pathway and of factors D and B and properdin of the alternative pathway are described in Table 160.1 . All components of the classical and alternative pathways except properdin and factor B are inherited as autosomal recessive co-dominant traits. Each parent transmits a gene that codes for synthesis of half the serum level of the component. Deficiency results from inheritance of 1 null gene from each parent; the hemizygous parents typically have low normal CH_{50} levels and no consequences of the partial deficiency. Properdin deficiency is transmitted as an X-linked trait. Factor B is an autosomal recessive non–co-dominant trait.

Table 160.1

Complement Defects

DISEASE	GENETIC DEFECT/PRESUMED PATHOGENESIS	INHERITANCE	FUNCTIONAL DEFECT	ASSOCIATED FEATURES
C1q deficiency	Mutation in *C1QA* , *C1QB* , *C1QC:* classical complement pathway	AR	Absent CH_{50} hemolytic activity; defective activation of the classical pathway,	SLE, infections with encapsulated organisms

	components		diminished clearance of apoptotic cells	
C1r deficiency	Mutation in *C1R:* classical complement pathway component	AR	Absent CH$_{50}$ hemolytic activity; defective activation of the classical pathway	SLE, infections with encapsulated organisms
C1s deficiency	Mutation in *C1S:* classical complement pathway component	AR	Absent CH$_{50}$ hemolytic activity; defective activation of the classical pathway	SLE, infections with encapsulated organisms
C4 deficiency	Mutation in *C4A* , *C4B:* classical complement pathway components	AR	Absent CH$_{50}$ hemolytic activity; defective activation of the classical pathway, defective humoral immune response to carbohydrate antigens in some patients	SLE, infections with encapsulated organisms
C2 deficiency	Mutation in *C2:* classical complement partway component	AR	Absent CH$_{50}$ hemolytic activity; defective activation of the classical pathway	SLE, infections with encapsulated organisms, atherosclerosis
C3 deficiency	Mutation in *C3:* central complement component	AR, gain-of-function AD	Absent CH$_{50}$ and AH$_{50}$ hemolytic activity; defective opsonization, defective humoral immune response	Infections; glomerulonephritis, aHUS with gain-of-function mutations
C5 deficiency	Mutation in *C5:* terminal complement component	AR	Absent CH$_{50}$ and AH$_{50}$ hemolytic activity; defective bactericidal activity	Neisserial infections
C6 deficiency	Mutation in *C6:* terminal complement component	AR	Absent CH$_{50}$ and AH$_{50}$ hemolytic activity; defective bactericidal activity	Neisserial infections
C7 deficiency	Mutation in *C7:* terminal complement component	AR	Absent CH$_{50}$ and AH$_{50}$ hemolytic activity; defective bactericidal activity	Neisserial infections
C8 α-γ deficiency	Mutation in *C8A, C8G:* terminal complement components	AR	Absent CH$_{50}$ and AH$_{50}$ hemolytic activity; defective bactericidal activity	Neisserial infections
C8b deficiency	Mutation in *C8B:* terminal complement component	AR	Absent CH$_{50}$ and AH$_{50}$ hemolytic activity. defective bactericidal activity	Neisserial infections
C9 deficiency	Mutation in *C9:* terminal complement component	AR	Reduced CH$_{50}$ and AH$_{50}$ hemolytic activity; deficient bactericidal activity	Mild susceptibility to neisserial infections
C1 inhibitor deficiency	Mutation in *C1NH:* regulation of kinins and complement activation	AD	Spontaneous activation of the complement pathway with consumption of C4/C2; spontaneous activation of the contact system with generation of bradykinin from high-molecular-weight kininogen	Hereditary angioedema
Factor B	Mutation in *CFB:* activation of the alternative pathway	AD	Gain-of-function mutation with increased spontaneous AH$_{50}$	aHUS
Factor D deficiency	Mutation in *CFD:* regulation of the alternative complement pathway	AR	Absent AH$_{50}$ hemolytic activity	Neisserial infections

Properdin deficiency	Mutation in *CFP:* regulation of the alternative complement pathway	XL	Absent AH_{50} hemolytic activity	Neisserial infections
Factor I deficiency	Mutation in *CFI:* regulation of the alternative complement pathway	AR	Spontaneous activation of the alternative complement pathway with consumption of C3	Infections, neisserial infections, aHUS, preeclampsia, membranoproliferative glomerulonephritis
Factor H deficiency	Mutation in *CFH:* regulation of the alternative complement pathway	AR	Spontaneous activation of the alternative complement pathway with consumption of C3	Infections, neisserial infections, aHUS, preeclampsia, membranoproliferative glomerulonephritis
MASP-1 deficiency	Mutation in *MASP1:* cleaves C2 and activates MASP-2	AR	Deficient activation of the lectin activation pathway, cell migration	Infections, 3MC syndrome

AD, Autosomal dominant; aHUS, atypical hemolytic-uremic syndrome; AR, autosomal recessive; SLE, systemic lupus erythematosus; XL, X-linked; 3MC, previously Carnevale, Mingarelli, Malpuech, and Michels syndromes.

From Kliegman RM, Lye PS, Bordini BJ, et al, editors: *Nelson pediatric symptom-based diagnosis,* Philadelphia, 2018, Elsevier, Table 41.11, p 765.

Most patients with primary **C1q deficiency** have systemic lupus erythematosus (SLE); some have an SLE-like syndrome without typical SLE serology, a chronic rash with underlying vasculitis, or membranoproliferative glomerulonephritis (MPGN). Some C1q-deficient children have serious infections, including septicemia and meningitis. Individuals with **C1r, C1s, combined C1r/C1s, C4, C2,** or **C3 deficiency** also have a high incidence of autoimmune syndromes (see Table 160.1), especially SLE or an SLE-like syndrome, without an elevated antinuclear antibody level.

C4 is encoded by 2 genes, *C4A* and *C4B* . **C4 deficiency** represents absence of both gene products. Complete deficiency of only C4A, present in approximately 1% of the population, also predisposes to SLE, although C4 levels are only partially reduced. Patients with only C4B deficiency may be predisposed to infection. A few patients with **C5, C6, C7,** or **C8 deficiency** have SLE, but recurrent meningococcal infections are much more likely to be the major problem.

There are at least 2 possible reasons for the concurrence of complement component deficiencies, especially C1, C4, C2, or C3 deficiency, and autoimmune–immune complex diseases. First, deposition of C3 on autoimmune complexes facilitates their removal from the circulation through binding to complement receptor 1 (CR1) on erythrocytes and transport to the spleen and liver. Second, the early components, particularly C1q and C3, expedite the clearance of necrotic and apoptotic cells, which are sources of autoantigens.

Individuals with **C2 deficiency** carry the risk of life-threatening septicemic illnesses, usually caused by pneumococci. However, most have not had problems with other increased susceptibility to infection, presumably because of the protective function of the alternative pathway, particularly if enhanced by pneumococcal and *Haemophilus influenzae* immunization. The genes for C2, factor B, and C4 are situated close to each other on chromosome 6, and a partial depression of factor B levels can occur in conjunction with C2 deficiency. Persons with a deficiency of both proteins may be at particular risk. One percent of European Caucasians carry 1 null gene for C2.

Because C3 can be activated by C142 or by the alternative pathway, a defect in the function of either pathway can be compensated for, at least to some extent. Without C3, however, opsonization of bacteria is inefficient, and the chemotactic fragment from C5 (C5a) is not generated. Some organisms must be well opsonized in order to be cleared, and genetic **C3 deficiency** has been associated with recurrent, severe pyogenic infections caused by pneumococci, *H. influenzae* , and meningococci.

More than half the individuals reported to have congenital **C5, C6, C7,** or **C8 deficiency** have had meningococcal meningitis or extragenital gonococcal infection. **C9 deficiency** is most often reported in individuals of Japanese or Korean descent. C9-deficient individuals retain about one-third normal CH_{50} titers; some have had *Neisseria* disease. In studies of patients ≥10 yr old with systemic meningococcal disease, 3–15% have had a genetic deficiency of C5, C6, C7, C8, C9, or properdin. Among patients with infections caused by the uncommon *Neisseria meningitidis* serogroups (X, Y, Z, W135, 29E, or nongroupable; but not A, B, or C), 33–45% have an underlying complement deficiency. It is not clear why patients with a deficiency of one of the late-acting components have a particular predisposition to *Neisseria* infections. It may be that serum bacteriolysis is uniquely important in defense against this organism. Many persons with such a deficiency have no significant illness.

A few individuals have been identified with **deficiency of factor D or Factor B** of the alternative pathway, all with recurrent infections, most often neisserial or pneumococcal. Hemolytic complement activity and C3 levels in their serum were normal, but alternative pathway activity was markedly deficient or absent.

Mutations in the structural gene encoding MBL or polymorphisms in the promoter region of the gene result in pronounced interindividual variation in the level of circulating MBL. More than 90% of individuals with **MBL deficiency** do not express a predisposition to infection. Those with a very low level of MBL have a predisposition to recurrent respiratory infections in infancy and to serious pyogenic and fungal infections if there is another underlying defect of host defense. MBL-associated serine protease (**MASP)-2 deficiency** has been reported with SLE-like symptoms and recurrent pneumococcal pneumonia. Homozygous **ficolin-3 deficiency** has been associated with repeated pneumonia since early childhood, cerebral abscesses, and bronchiectasis.

160.3

Deficiencies of Plasma, Membrane, or Serosal Complement Control Proteins

---

Richard B. Johnston Jr.

Keywords

atypical hemolytic-uremic syndrome
properdin deficiency
hereditary angioedema
paroxysmal nocturnal hemoglobinuria
factor I deficiency

Congenital deficiencies of 5 plasma complement control proteins have been described (see Table 160.1). **Factor I deficiency** was reported originally as a deficiency of C3 resulting from hypercatabolism. The 1st patient described had suffered a series of severe pyogenic infections similar to those associated with agammaglobulinemia or congenital deficiency of C3. Factor I is an essential regulator of both pathways. Its deficiency permits prolonged existence of C3b as a part of the C3 convertase of the alternative pathway, C3bBb. This results in constant activation of the alternative pathway and cleavage of more C3 to C3b, in circular fashion. Intravenous infusion of plasma or purified factor I induced a prompt rise in serum C3 concentration in the patient and a return to normal of C3-dependent functions in vitro, such as opsonization.

The effects of **factor H deficiency** are similar to those of factor I deficiency because factor H also assists in dismantling the alternative pathway C3 convertase. A trigger event such as infection initiates uninhibited continuous activation of the alternative pathway, which consumes C3, factor B, total hemolytic activity, and alternative pathway activity. Patients have sustained systemic infections due to pyogenic bacteria, particularly *Neisseria meningitidis*. Many have had glomerulonephritis or **atypical hemolytic-uremic syndrome** (aHUS) (see Chapter 538.5). Mutations in genes encoding membrane cofactor protein (MCP, CD46), factors I or B, C3, or the endothelial antiinflammatory protein thrombomodulin, or autoantibodies to factors H or B, are also associated with aHUS. The majority of patients with factor H deficiency and aHUS, typically <2 yr old, develop end-stage renal disease, and many die.

The few patients thus far reported as having **C4-binding protein deficiency** have approximately 25% of the normal levels of the protein and no typical disease presentation, although one patient had angioedema and Behçet disease.

Persons with **properdin deficiency** have a striking predisposition to *N. meningitidis* meningitis. All reported patients have been male. The predisposition to infection in these patients demonstrates clearly the need for the alternative pathway in defense against bacterial infection. Serum hemolytic complement activity is normal in these patients, and if the patient has specific antibacterial antibody from immunization or prior exposure, the need for the alternative pathway and properdin is greatly reduced. Several patients have had dermal vasculitis or discoid lupus.

Hereditary angioedema occurs in persons unable to synthesize normal levels of functional C1 inhibitor (C1 INH). In 85% of affected families, the patient has markedly reduced concentrations of inhibitor, averaging 30% of normal; the other 15% have normal or elevated concentrations of an immunologically cross-reacting but nonfunctional protein. Both forms of the disease are transmitted as autosomal dominant traits. C1 INH suppresses the complement proteases C1rs and MASP-2 and the activated proteases of the contact and fibrinolysis systems. In the absence of full C1 INH function, activation of any of these proteases tips the balance toward the protease. This activation leads to uncontrolled C1 and kallikrein activity with breakdown of C4 and C2 and release of bradykinin, which interacts with vascular endothelial cells to cause vasodilation, producing localized, nonpitting edema. The biochemical triggers that induce attacks of angioedema in these patients are not well understood.

Swelling of the affected part progresses rapidly, without urticaria, itching, discoloration, or redness and often without severe pain. Swelling of the intestinal wall, however, can lead to intense abdominal cramping, sometimes with vomiting or diarrhea. Concomitant subcutaneous edema is often absent, and patients have undergone abdominal surgery or psychiatric examination before the true diagnosis was established. Laryngeal edema can be fatal. Attacks last 2-3 days and then gradually abate. They may occur at sites of trauma, especially dental, after vigorous exercise, or with menses, fever, or emotional stress. Attacks begin in the 1st 5 yr of life in almost half of patients, but are usually not severe until late childhood or adolescence. **Acquired C1 INH deficiency** can occur in association with B-cell cancer or autoantibody to C1 INH. SLE and glomerulonephritis have been reported in patients with the congenital disease (for treatment see Chapter 160.5).

Three of the membrane complement control proteins—CR1, MCP (CD46), and decay-accelerating factor (DAF)—prevent the formation of the full C3-cleaving enzyme, C3bBb, which is triggered by C3b deposition. CD59 (membrane inhibitor of reactive lysis) prevents the full development of the membrane attack complex that creates the "hole." **Paroxysmal nocturnal hemoglobinuria** (PNH) is a hemolytic anemia that occurs when DAF and CD59 are not expressed on the erythrocyte surface. The condition is acquired as a somatic mutation in a hematopoietic stem cell of the *PIGA* gene on the X chromosome. The product of this gene is required for normal synthesis of a glycosyl-phosphatidylinositol molecule that anchors about 20 proteins to cell membranes, including DAF and CD59. One patient with **genetic isolated CD59 deficiency** had a mild PNH-like disease despite normal expression of membrane DAF. In contrast, **genetic isolated DAF deficiency** has not resulted in hemolytic anemia (for treatment see Chapter 160.5).

160.4

Secondary Disorders of Complement

Richard B. Johnston Jr.

Keywords

immune complex disease
systemic lupus erythematosus
SLE
nephritic factor

Partial deficiency of C1q has occurred in patients with severe combined immunodeficiency disease or hypogammaglobulinemia, apparently secondary to the deficiency of IgG, which normally binds reversibly to C1q and prevents its rapid catabolism.

Chronic membranoproliferative glomerulonephritis can be caused by nephritic factor (NeF), an IgG autoantibody to the C3-cleaving enzyme of the classical pathway (C4b2a) or alternative pathway (C3bBb). NeF protects the enzyme from inactivation and promotes consumption of C3 and decreased concentration of serum C3. Pyogenic infections, including meningitis, may occur if the serum C3 level drops to <10% of normal. This disorder has been found in children and adults with dense-deposit disease or partial lipodystrophy. Adipocytes are the main source of factor D and synthesize C3 and factor B; exposure to NeF induces their lysis. The IgG NeF that inhibits the classical pathway C3 convertase has been described in acute postinfectious nephritis and in SLE. The consumption of C3 that characterizes poststreptococcal nephritis and SLE could be caused by this factor, by immune complex activation, or by both.

Newborn infants have mild to moderate reductions in all plasma components of the complement system. Opsonization and generation of chemotactic activity in serum from full-term newborns can be markedly deficient through either the classical or the alternative pathway. Complement activity is even lower in preterm infants. Patients with severe chronic cirrhosis of the liver, hepatic failure, malnutrition, or anorexia nervosa can have significant deficiency of complement components and functional activity. Synthesis of components is depressed in these conditions, and serum from some patients with malnutrition also contains immune complexes that could accelerate depletion.

Patients with **sickle cell disease** have normal activity of the classical pathway, but some have defective function of the alternative pathway in opsonization of pneumococci, in bacteriolysis and opsonization of *Salmonella,* and in lysis of rabbit erythrocytes. Deoxygenation of erythrocytes from patients with sickle cell disease alters their membranes to increase exposure of phospholipids that can activate the alternative pathway and consume its components. This activation is accentuated during painful crisis. Children with **nephrotic syndrome** may have decreased serum levels of factors B and D and subnormal serum opsonizing activity.

Immune complexes initiated by microorganisms or their by-products can induce complement consumption. Activation occurs primarily through fixation of C1 and initiation of the classical pathway. Formation of immune complexes and consumption of complement have been demonstrated in lepromatous leprosy, bacterial endocarditis, infected ventriculojugular shunts, malaria, infectious mononucleosis, dengue hemorrhagic fever, and acute hepatitis B. Nephritis or arthritis can develop as a result of deposition of immune complexes and activation of complement in these infections. In SLE, immune complexes activate C142, and C3 is deposited at sites of tissue damage, including kidneys and skin; depressed synthesis of C3 is also noted. The syndrome of recurrent urticaria, angioedema, eosinophilia, and hypocomplementemia secondary to activation of the classical pathway may be caused by autoantibody to C1q and circulating immune complexes. Circulating immune complexes and decreased C3 have been reported in some patients with dermatitis herpetiformis, celiac disease, primary biliary cirrhosis, and Reye syndrome.

Circulating bacterial products in **sepsis** or tissue factors released after severe **trauma** can initiate activation of the classical and alternative pathways, leading to increased serum levels of C3a, C5a, and C5b-9 and systemic inflammatory response syndrome (SIRS) and multi-organ failure. C5a and its receptors, particularly on neutrophils, appear to be central to the pathogenesis of SIRS. Intravenous injection of iodinated roentgenographic contrast medium can trigger a rapid and significant activation of the alternative pathway, which may explain the occasional reactions that occur in patients undergoing this procedure.

Burns can induce massive activation of the complement system, especially the alternative pathway, within a few hours after injury. Resulting generation of C3a and C5a stimulates neutrophils and induces their sequestration in the lungs, leading to shock lung. Cardiopulmonary bypass, extracorporeal membrane oxygenation, plasma exchange, or hemodialysis using **cellophane membranes** may be associated with a similar syndrome as a result of activation of plasma complement, with release of C3a and C5a. In patients with **erythropoietic protoporphyria** or **porphyria cutanea tarda** , exposure of the skin to light of certain wavelengths activates complement, generating chemotactic activity. This chemotactic activity leads to lysis of capillary endothelial cells, mast cell degranulation, and the appearance of neutrophils in the dermis.

Some tumor cells can avoid complement-mediated lysis by overexpressing DAF, MCP, CD59, CR1, or factor H, or by secreting proteases that cleave tumor-bound C3b. Microorganisms have evolved similar evasive mechanisms; for example, HIV-1 particles budding from infected cells acquire the membrane proteins DAF and CD59, and staphylococci can produce multiple complement inhibitors.

Treatment of Complement Disorders

Richard B. Johnston Jr.

Keywords

C1-esterase inhibitor
immunization
complement deficiency

No specific therapy is available at present for genetic deficiencies of the components of the classical, alternative, and lectin complement pathways. Much can be done, however, to protect patients with any of these disorders from serious complications; and specific treatment is available for 3 disorders caused by control-protein deficiencies: hereditary angioedema, aHUS, and PNH.

Management of **hereditary angioedema** starts with avoidance of precipitating factors, usually trauma. Infusion of C1 INH concentrate (nanofiltered **C1-esterase inhibitor**) was approved by the U.S. Food and Drug Administration (FDA) for use in children in 2016. An inhibitor of kallikrein (**ecallantide**) that blocks bradykinin production and an antagonist of the bradykinin receptor (**icatibant**) are approved in the United States for use in adolescents and adults for long-term prophylaxis, preparation for surgery or dental procedures, or treatment of acute attacks. The synthetic androgen **oxandrolone** increases the level of functional C1 INH several-fold and is approved for cautious use in children. Antihistamines, epinephrine, and corticosteroids have no effect.

Lanadelumab, a selective inhibitor of kallikein, has potential as a prophylactic agent. **Eculizumab** , a humanized monoclonal antibody to C5, prevents generation of the membrane-attack complex C5b9 and is an effective treatment for **PNH** and **aHUS** .

Effective supportive management is available for other primary diseases of the complement system, and identification of a specific defect in the complement system can have an important impact on management. Concern for the associated complications, such as autoimmune disease and infection, should encourage vigorous diagnostic efforts and earlier institution of therapy. Individuals with SLE and a complement defect generally respond as well to therapy as do those without complement deficiency. With the onset of unexplained fever, cultures should be obtained and antibiotic therapy instituted more quickly and with less stringent indications than in a normal child.

The parent or patient should be given letters describing any predisposition to systemic bacterial infection or autoimmune disease associated with the patient's deficiency, along with the recommended initial approach to management, for possible use by school, camp, or emergency department physicians. The patient and close household contacts should be immunized against *H. influenzae, Streptococcus pneumoniae,* and *N. meningitidis.* High titers of specific antibody might opsonize effectively without the full complement system, and immunization of household members could reduce the risk of exposing patients to these particularly threatening pathogens. *Repeat immunization of patients is advisable since complement deficiency can be associated with a blunted or shorter-lived antibody response than normal.*

Heparin , which inhibits both classical and alternative pathways, has been used to prevent “postpump syndrome.”

CHAPTER 161

Principles and Clinical Indications of Hematopoietic Stem Cell Transplantation

Rachel A. Phelan, David Margolis

Allogeneic (from a donor) or **autologous** (from the same individual) hematopoietic stem cells have been used to cure both malignant and nonmalignant disorders. **Autologous** transplantation is employed as a rescue strategy after delivering otherwise lethal doses of chemotherapy with or without radiotherapy in children with hematologic malignancies such as relapsed lymphoma or selected solid tumors (e.g., neuroblastoma, brain tumors). **Allogeneic** transplantation is used to treat children with genetic diseases of blood cells, such as hemoglobinopathies, primary immunodeficiency diseases, various inherited metabolic diseases, and bone marrow failure. Allogeneic transplant is also used as treatment for hematologic malignancies, such as leukemia and myelodysplastic syndromes. Bone marrow had represented the only source of hematopoietic progenitors employed. Growth factor (granulocyte colony-stimulating factor)–mobilized peripheral blood hematopoietic stem cells and umbilical cord blood hematopoietic progenitors have now also been regularly used in clinical practice to perform hematopoietic stem cell transplantation (**HSCT**).

An HLA-matched sibling was once the only type of donor employed. Currently, matched unrelated volunteers, full-haplotype mismatched family members, and unrelated cord blood donors have been largely employed to transplant patients lacking an HLA-identical relative.

Protocols for allogeneic HSCT consist of 2 parts: the preparative regimen and transplantation itself. During the **preparative conditioning regimen** , chemotherapy, at times associated with irradiation, is administered to destroy the patient's hematopoietic system and to suppress the immune system, especially T cells, so that graft rejection is prevented. In patients with malignancies, the preparative regimen also serves to significantly reduce the tumor burden. The patient then receives an intravenous infusion of hematopoietic cells from the donor. Less aggressive conditioning regimens, known as **reduced-intensity conditioning regimens** , are also used in pediatric patients. These regimens are mainly immunosuppressive and aim at inducing a state of reduced immune competence of the recipient to avoid the rejection of donor cells.

The immunology of HSCT is distinct from that of other types of transplant because, in addition to stem cells, the graft contains mature blood cells of donor origin, including T cells, B cells, natural killer cells, and dendritic cells. These cells repopulate the recipient's lymphohematopoietic system and give rise to a new immune system, which helps eliminate residual leukemia cells that survive the conditioning regimen. This effect is known as the **graft-versus-leukemia (GVL) effect.**

The donor immune system exerts its T-cell–mediated GVL effect through alloreactions directed against histocompatibility antigens displayed on recipient leukemia cells. Because some of these histocompatibility antigens are also displayed on tissues, however, unwanted T-cell–mediated alloreactions may ensue. Specifically, donor alloreactive cytotoxic $CD8^+$ effector T cells may attack recipient tissues, particularly the skin, gastrointestinal (GI) tract, and liver, causing acute **graft-versus-host disease (GVHD)** , a condition of varying severity that in some cases can be life threatening or even fatal (see Chapter 163).

The success of allogeneic HSCT is undermined by diversity between donors and recipients in major and minor histocompatibility antigens. The **human leukocyte antigens (HLA)** , including HLA-A, HLA-B, and HLA-C major histocompatibility complex (MHC) class I molecules, present peptides to $CD8^+$ T cells, whereas the HLA-DR, HLA-DQ, and HLA-DP MHC class II molecules present peptides to $CD4^+$ T cells. There are 100s of variant forms of each class I and class II molecule, and even small differences can elicit alloreactive T-cell responses that mediate graft rejection and/or GVHD. Disparities for HLA-A, -B, -C, or -DRB1 alleles in the donor-recipient pair are independent risk factors for both acute and chronic GVHD. There is also increasing evidence that HLA-DQ and HLA-DP may play a role, prompting some transplant centers to also explore matching at these alleles.

Minor histocompatibility antigens derive from differences between the HLA-matched recipient and donor in peptides that are presented by the same HLA allotype. These antigens result from polymorphisms of non-HLA proteins, differences in the level of expression of proteins, or genetic differences between males and females. An example of the latter is represented by the H-Y antigens encoded by the Y chromosome, which can stimulate GVHD when a female donor is employed to transplant an HLA-identical male recipient. Thus, from this evidence, it is clear that GVHD may occur even when the donor and recipient are HLA identical.

The preferred donor for any patient undergoing HSCT is an HLA-identical sibling. Because polymorphic HLA genes are closely linked and usually constitute a single genetic locus**, any pair of siblings has a 25% chance of being HLA identical** . Thus, also in view of the limited family size in the developed countries, <25–30% of patients in need of an allograft can receive their transplant from an HLA-identical sibling. This percentage is even lower in patients with inherited disorders since affected siblings will not be considered donor candidates.

HSCT From an HLA-Identical Sibling Donor

Allogeneic HSCT from an HLA-compatible sibling is the treatment of choice for children with hematologic malignancies and various congenital or acquired diseases (Table 161.1). Best results are achieved in patients with congenital or acquired nonmalignant disorders because the risk of disease recurrence is low and the cumulative transplantation-related mortality is lower than in children receiving transplants for hematologic malignancies.

Table 161.1

Indications for Allogeneic Hematopoietic Stem Cell Transplantation for Pediatric Diseases

Malignancy

- Acute lymphoblastic leukemia (ALL)
    - First complete remission for patients at very high risk of relapse
    - T-cell immunophenotype and poor response to corticosteroid

    - therapy
    - Not in remission at the end of the induction phase
    - Marked hypodiploidy (<43 chromosomes)
    - Minimal residual disease at the end of consolidation therapy
- High-risk infant ALL
    - Second complete remission
    - Third or later complete remission
- Acute myeloid leukemia in 1st complete remission or in advanced-disease phase
- Philadelphia chromosome–positive chronic myeloid leukemia
- Myelodysplastic syndromes
- Hodgkin and non-Hodgkin lymphomas
- Selected solid tumors
    - Metastatic neuroblastoma
    - Rhabdomyosarcoma refractory to conventional treatment
    - Very-high-risk Ewing sarcoma

Anemias

- Severe acquired aplastic anemia
- Fanconi anemia
- Paroxysmal nocturnal hemoglobinemia
- Congenital dyskeratosis
- Diamond-Blackfan anemia
- Thalassemia major
- Sickle cell disease
- Shwachman-Diamond syndrome

Immunologic Disorders

- Variants of severe combined immunodeficiency
- Hyper-IgM syndrome
- Leukocyte adhesion deficiency
- Omenn syndrome
- Zap-70 kinase deficiency
- Cartilage-hair hypoplasia

PNP deficiency
CD40 ligand deficiency
MHC class II deficiency
Wiskott-Aldrich syndrome
Chédiak-Higashi syndrome
Kostmann syndrome (infantile malignant agranulocytosis)
Chronic granulomatous disease
Autoimmune lymphoproliferative syndrome
X-linked lymphoproliferative disease (Duncan syndrome)
IPEX syndrome
Interleukin-10 receptor deficiency
Hemophagocytic lymphohistiocytosis
Interferon-γ receptor deficiency
Griscelli disease
Granule deficiency

Other Disorders

- Selected severe variants of platelet function disorders (e.g., Glanzmann thromboasthenia, congenital amegakaryocytic thrombocytopenia)
- Selected types of mucopolysaccharidosis (e.g., Hurler disease) or other liposomal/peroxisomal disorders (e.g., Krabbe disease, adrenoleukodystrophy)
- Infantile malignant osteopetrosis
- Life-threatening cytopenia unresponsive to conventional treatments

IPEX, Immune dysregulation, polyendocrinopathy, enteropathy, X-linked; MHC, major histocompatibility complex; PNP, purine nucleoside phosphorylase.

Acute Lymphoblastic Leukemia

Allogeneic HSCT is used for pediatric patients with acute lymphoblastic leukemia (**ALL**), either in the 1st complete remission when a child is considered to be at high risk of leukemia recurrence (e.g., those carrying poor-risk cytogenetic characteristics or with high levels of minimal residual disease), or in

2nd or further complete remission after previous marrow relapse. ALL is the most common indication for HSCT in childhood. Several patient-, donor-, disease-, and transplant-related variables may influence the outcome of patients with ALL given an allogeneic HSCT. The long-term probabilities of **event-free survival (EFS)** for patients with ALL transplanted in the 1st or 2nd complete remission is 60–70% and 40–60%, respectively. Inferior results are obtained in patients receiving transplants in more advanced disease phases. The use of **total body irradiation (TBI)** during the preparative regimen offers an advantage in terms of better EFS compared to a regimen consisting of cytotoxic drugs alone (Fig. 161.1), but it can induce more long-term side effects. This has prompted more investigation into TBI-sparing alternatives. Less intensive GVHD prophylaxis is also associated with a better outcome. Bone marrow is generally still the preferred source of stem cells to be employed for transplantation, although this differs among transplant centers.

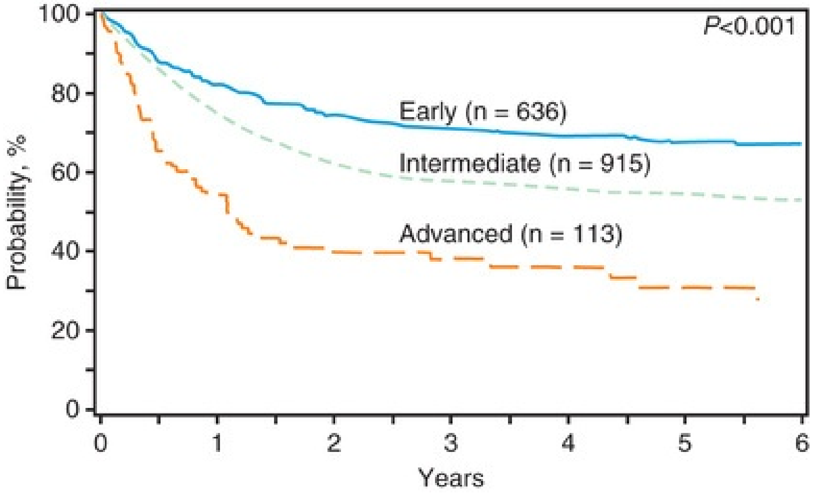

FIG. 161.1 Survival after HLA-matched sibling donor hematopoietic stem cell transplantation for acute lymphoblastic leukemia (ALL), age <18 yr, 2004–2014. *Early,* first complete remission (CR1); *Intermediate,* second or greater complete remission (CR2+); *Advanced,* active disease. (From D'Souza A, Zhu X: Current uses and outcomes of hematopoietic cell transplantation (HCT), CIBMTR Summary Slides, 2016. http://www.cibmtr.org .)

Although the main benefit for allogeneic HSCT recipients with leukemia derives from the GVL effect displayed by immunocompetent cells, disease recurrence remains the main cause of treatment failure. The risk of failing to eradicate leukemia is influenced by many variables, including disease phase, molecular lesions of tumor cells, and disparity for major or minor histocompatibility antigens in the donor/recipient pairs. To overcome the hurdle of tumor elusion caused by HLA loss on malignant cells, the use of non-HLA–restricted **chimeric antigen receptors (CARs)** has been proposed. This therapeutic strategy is based on genetic reprogramming of T cells through artificial immune receptors that reproducibly and efficiently redirect the antigen specificity of polyclonal T lymphocytes toward target antigens expressed by leukemic cells. When expressed by T cells, CARs mediate antigen recognition and tumor cytolysis in an MHC-unrestricted fashion and can target any molecule (protein, carbohydrate, or glycolipid) expressed on the surface of tumor cells, thus bypassing one of the major tumor escape mechanisms based on the downregulation of MHC molecules. CARs are composed of an extracellular specific antigen-binding moiety, obtained from the variable regions of a monoclonal antibody, linked together to form a single-chain antibody (scFv), and of an intracellular signaling component derived from the ζ chain of the T-cell–receptor (TCR)–CD3 complex. The addition to the *CAR* gene construct of co-stimulation signals and cytokines promoting T-cell expansion and survival improves the antitumor efficiency of the engineered T cells and their survival in the tumor milieu. Gamma retrovirus and lentiviruses are usually used to transduce CARs into T lymphocytes to be employed in the clinical setting. These vectors have been shown to efficiently infect T lymphocytes, integrate into the host genome, and produce robust expression of the gene in human T cells and their progeny.

Acute Myeloid Leukemia

Allogeneic HSCT from an HLA-identical sibling is largely employed as postremission treatment of pediatric patients with acute myeloid leukemia (**AML**). Children with AML in 1st complete remission who are given allogeneic HSCT as consolidation therapy have a better probability of EFS than those treated with either chemotherapy alone or autologous transplantation. Results obtained in patients given HSCT from an HLA-identical sibling after either a TBI-containing or a chemotherapy-based preparative regimen are similar, the probability of EFS being in the order of 70%. Therefore, for AML, conditioning regiments generally omit the use of TBI because of associated long-term side effects. Children with acute promyelocytic leukemia in molecular remission at the end of treatment with chemotherapy and all-*trans* -retinoic acid, or with

AML and translocation t(8;21); inversion of chromosome 16 (inv16), translocation t(16;16), or normal cytogenetics and presence of *NPM1* or *CEPB* α mutation are no longer considered eligible for allogeneic HSCT in 1st complete remission in view of their improved prognosis with alternative treatments. Studies suggest restricting the use of HSCT to those patients with poor molecular lesions, such as FLT3-internal tandem duplication or mixed-lineage leukemia abnormalities, or with high levels of minimal residual disease at the end of induction therapy. Approximately 40–60% of pediatric patients with AML in the 2nd complete remission can be rescued by HSCT.

Chronic Myelogenous Leukemia

For many years, allogeneic HSCT has been considered the only proven curative treatment for children with Philadelphia-positive (Ph+) chronic myelogenous leukemia. Leukemia-free survival of chronic myelogenous leukemia patients after an allograft is 45–80%. The phase of disease (chronic phase, accelerated phase, blast crisis), recipient age, type of donor employed (related or unrelated), and time between diagnosis and HSCT are the main factors influencing the outcome. The best results are obtained in children transplanted during the chronic phase from an HLA-identical sibling within 1 yr from diagnosis. Unlike other forms of pediatric leukemia, infusion of donor leukocytes can reinduce a state of complete remission in a large proportion of patients experiencing leukemia relapse.

Treatment with the specific BCR-ABL tyrosine protein kinase inhibitors (imatinib mesylate, dasatinib, nilotinib), targeting the enzymatic activity of the BCR-ABL fusion protein, has modified the natural history of the disease and thus the indications for transplantation. The indication for HSCT in this population is thus evolving and is generally reserved for patients with a poor response to tyrosine kinase inhibitors or those who do not tolerate their side effects.

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (**JMML**) is a rare hematopoietic malignancy of early childhood, representing 2–3% of all pediatric leukemias. JMML is characterized by hepatosplenomegaly and organ infiltration, with excessive proliferation of cells of monocytic and granulocytic lineages. Hypersensitivity to granulocyte-macrophage colony-stimulating factor (GM-CSF) and pathologic activation of the RAS-RAF-MAP (mitogen-activated protein) kinase signaling pathway play an important role in the pathophysiology. JMML usually runs an aggressive clinical course, with a median duration of survival for untreated children of <12 mo from diagnosis. Rare patients with *CBL1* or *N-RAS* mutations can survive for years without an allograft.

HSCT is able to cure approximately 50–60% of patients with JMML. Patients who receive a transplant from an unrelated donor have comparable outcome to those given HSCT from an HLA-compatible related donor. Cord blood transplantation represents a suitable alternative option. Leukemia recurrence is the main cause of treatment failure in children with JMML after HSCT, with the relapse rate as high as 40–50%. Because children with JMML frequently have massive spleen enlargement, splenectomy has been performed before transplantation. However, spleen size at the time of HSCT and splenectomy before HSCT do not appear to affect the posttransplantation outcome. Unlike in CML, donor leukocyte infusion is not useful to rescue patients experiencing disease recurrence; a 2nd allograft can induce sustained remission in approximately one third of children with JMML relapsing after a 1st HSCT.

Myelodysplastic Syndromes Other Than Juvenile Myelomonocytic Leukemia

Myelodysplastic syndromes are a heterogeneous group of clonal disorders characterized by ineffective hematopoiesis leading to peripheral blood cytopenia and a propensity to evolve toward AML. HSCT is the treatment of choice for children with **refractory anemia with excess of blasts (RAEB)** and for those with RAEB in transformation (RAEB-t). The probability of survival without evidence of disease for these children is 65–70%. It is still unclear whether patients with myelodysplastic syndromes and a blast percentage >20% benefit from pretransplantation chemotherapy. HSCT from an HLA-identical sibling is also the preferred treatment for all children with refractory cytopenia. Transplantation from an alternative donor is also employed in children with refractory cytopenia associated with monosomy 7, complex karyotype, life-threatening infections, profound neutropenia, or transfusion dependency. For children with refractory cytopenia, the probability of EFS after HSCT may be as high as 80%, disease recurrence being rarely observed. This observation has provided the rationale for testing reduced-intensity regimens in these patients.

Non-Hodgkin Lymphoma and Hodgkin Disease

Childhood non-Hodgkin lymphoma (NHL) and Hodgkin disease (HD) are very responsive to conventional chemoradiotherapy, but some patients have refractory disease or are at high risk for relapse. HSCT can cure a proportion of patients with relapsed NHL and HD and should be offered early after relapse, while the disease is still sensitive to therapy. If an HLA-matched donor is available, allogeneic transplantation can be offered to patients with NHL to take advantage of the GVL effect. Patients with sensitive disease and limited tumor burden have favorable outcomes, with EFS rates of 50–60%. Studies also suggest that patients with relapsed or refractory HD do well after autologous HSCT, with EFS of 50–60%. HD patients may also benefit from a GVL effect when given an allograft.

Acquired Aplastic Anemia

Because the probability of long-term survival for a matched-*sibling* bone marrow transplant (BMT) is reproducibly >80% for children and young adults, BMT is the treatment of choice for children and young adults with acquired severe aplastic anemia. Historically, the treatment of choice for children and young adults without an HLA-matched sibling has been intensive immunosuppression. Because the outcomes of matched *unrelated donor* transplant for children with acquired aplastic anemia have improved to probability of survival rates >75%, the use of unrelated donor HSCT upfront *without* prior immunosuppressive therapy is being considered more frequently; 2-year overall survival can be as high as 96% in upfront, matched unrelated donor recipients.

For patients who do not have a matched-sibling donor or well-matched unrelated donor, historically the transplant options were very disappointing. Fortunately, there is hope in current studies looking at haploidentical transplant for this disease. Although numbers are small, the use of posttransplant cyclophosphamide has shown significant improvement over prior experiences.

There is hope that all children and young adults who need a transplant for severe aplastic anemia will have the opportunity to do well with a BMT.

Inherited Bone Marrow Failure Syndromes

Fanconi anemia and dyskeratosis congenita are genetic disorders associated with a high risk of developing pancytopenia. **Fanconi anemia** (FA) is an autosomal recessive disease characterized by spontaneous chromosomal fragility, which is increased after exposure of peripheral blood lymphocytes to DNA cross-linking agents, including clastogenic compounds such as diepoxybutane, mitomycin C, and melphalan. Patients with FA, besides being at risk for pancytopenia, show a high propensity to develop clonal disorders of hematopoiesis, such as myelodysplastic syndromes and AML. HSCT can rescue aplastic anemia and prevent the occurrence of clonal hematopoietic disorders. In view of their defects in DNA repair mechanisms, which are responsible for the chromosomal fragility, FA patients have an exquisite sensitivity to alkylating agents and radiation therapy. Thus, they must be prepared for the allograft with reduced doses of cyclophosphamide and only judicious use of radiation. Many FA patients were once successfully transplanted after receiving low-dose cyclophosphamide and thoracoabdominal irradiation. However, the use of this regimen is associated with an increased incidence of posttransplantation head and neck cancers. Low-dose cyclophosphamide combined with fludarabine has been very well tolerated in patients with FA who have a matched-related donor. The addition of low-dose TBI and antithymocyte globulin (ATG) for those with an unrelated donor has shown similar success. Currently, the 5-yr overall survival is >90% in patients with FA who receive HSCT before the transformation to hematologic malignancy. Because of their underlying disorder, however, patients with FA must be monitored closely in the years after transplant to assess for late effects, including secondary malignancies and endocrinopathies.

Allogeneic HSCT remains the only potentially curative approach for severe bone marrow failure associated with **dyskeratosis congenita** , a rare congenital syndrome characterized also by atrophy and reticular pigmentation of the skin, nail dystrophy, and leukoplakia of mucous membranes. Results of allograft in these patients have been relatively poor, with 10-yr survival of 20–30%, because of both early and late complications, reflecting increased sensitivity of endothelial cells to radiotherapy and alkylating agents.

Thalassemia

Conventional treatment (i.e., regular blood transfusion and iron-chelation therapy) has dramatically improved both the survival and the quality of life of patients with thalassemia, changing a previously fatal disease with early death to a chronic, slowly progressive disease compatible with prolonged survival. However, HSCT remains the only curative treatment for patients with thalassemia. In these patients the risk of dying from transplant-related complications depends primarily on patient age, iron overload, and concomitant hepatic viral infections. Adults, especially when affected by chronic active hepatitis, have a poorer outcome than children. Among children, 3 classes of risk have been identified on the basis of 3 parameters: regularity of previous iron chelation, liver enlargement, and presence of portal fibrosis. In pediatric patients without liver disease who have received regular iron chelation (class 1 patients), the probability of survival with transfusion independence is >90%, whereas for patients with low compliance with iron chelation and signs of severe liver damage (class 3 patients), the probability of survival has been 60%.

With improvements in supportive care and conditioning regimens, even patients with more advanced liver disease have had excellent outcomes (Fig. 161.2). The most effective pharmacologic combinations (e.g., including cyclosporine and methotrexate) should be employed to prevent GVHD. The outcome of patients transplanted from an unrelated donor has been reported similar to that of HLA-identical sibling recipients. The increased use of umbilical cord blood and haploidentical donors in this population is being explored to expand the number of patients eligible for HSCT. Also, advancements in gene therapy are being made in thalassemia in early trials, which may eventually change the approach to this disease.

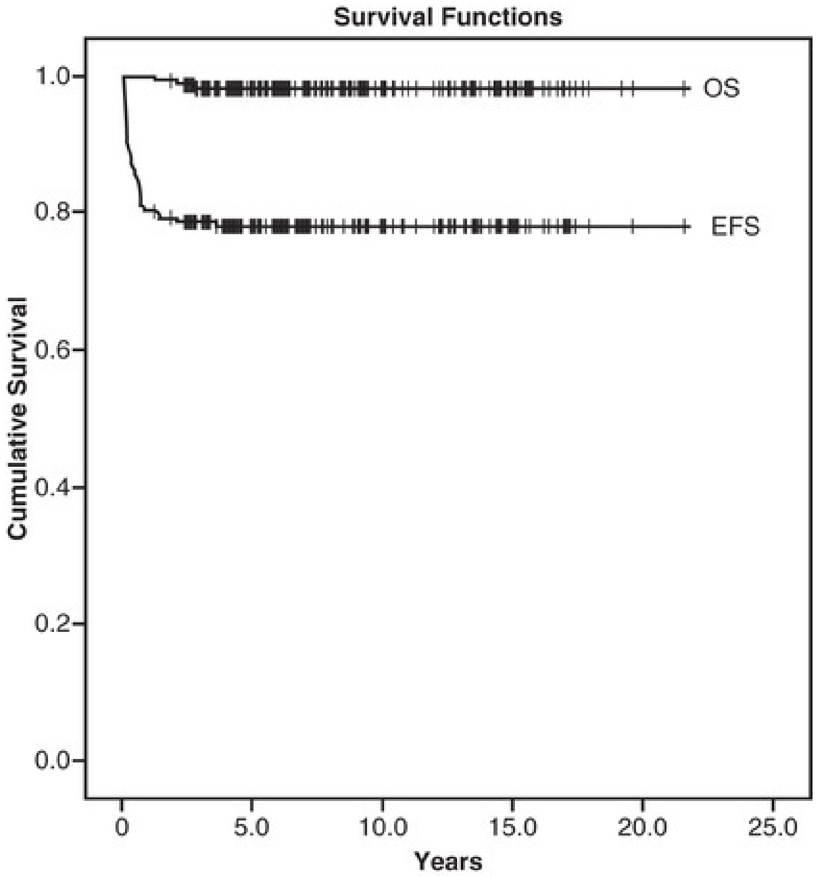

FIG. 161.2 Overall survival (OS) and event-free (graft failure) survival (EFS) after hematopoietic stem cell transplantation in children ≥1 yr from transplant for β-thalassemia major. (From Chaudhury S, Ayas M, Rosen C, et al: A multicenter retrospective analysis stressing the importance of long-term follow-up after hematopoietic cell transplantation for β-thalassemia, *Biol Blood Marrow Transplant* 23(10):1695–1700, 2017.)

Sickle Cell Disease

Disease severity varies greatly among patients with sickle cell disease, with 5–20% of the overall population suffering significant morbidity from vasoocclusive crises and pulmonary, renal, or neurologic damage. Hydroxyurea, an agent favoring the synthesis of fetal hemoglobin, reduces the frequency and severity of vasoocclusive crises and improves the quality of life for patients with sickle cell disease; however allogeneic HSCT is the only curative treatment for this disease at this time. Although HSCT can cure homozygous hemoglobin S, hemoglobin Sβ0, or hemoglobin SC disease, selecting appropriate candidates for transplantation is difficult. Patients with sickle cell disease may survive for decades, but some patients have a poor quality of life, with repeated hospitalizations for painful vasoocclusive crises and central nervous system (CNS) infarcts. The main indications for performing HSCT in patients with sickle cell disease are history of strokes, MRI of CNS lesions associated with impaired neuropsychologic function, failure to respond to hydroxyurea as shown by recurrent acute chest syndrome, and/or recurrent vasoocclusive crises, severe anemia, or osteonecrosis. The results of HSCT are best when performed in children with an HLA-identical sibling, with a probability of cure of 80–90%. However, the use of alternative donor transplants in this population, including matched unrelated donors and haploidentical donors, is being investigated through a number of clinical trials and may increase the number of patients eligible to undergo potentially curative HSCT. Reduced-intensity and reduced-toxicity regimens are also being explored to further decrease transplant-related morbidity and mortality, although graft failure remains an important issue in this patient population.

Immunodeficiency Disorders

HSCT is the treatment of choice for children affected by severe combined immunodeficiency (SCID), as well as for other inherited immunodeficiencies, including Wiskott-Aldrich syndrome, leukocyte adhesion deficiency (LAD), and chronic granulomatous disease (see Table 161.1). With an HLA-identical sibling, the probability of survival approaches 100%, with less favorable results for patients transplanted from an HLA–partially matched relative. Some children with SCID, mainly those without residual natural killer activity or maternal T-cell engraftment, may be transplanted without receiving any preparative regimen, the donor lymphoid cells usually being the only elements that engraft. Sustained donor engraftment is more difficult to achieve in children with Omenn syndrome, **hemophagocytic lymphohistiocytosis** , or LAD. Life-threatening opportunistic fungal and viral infections occurring before the allograft adversely affect the patient's outcome after HSCT. Because of this, patients with the most severe immunodeficiencies must be transplanted as early as possible to prevent infectious complications.

Inherited Metabolic Diseases

Inherited metabolic diseases are a broad group of diseases that result from the accumulation of substrate within tissues caused by dysfunction of the lysosome or peroxisome. The use of HSCT has been established for a variety of inherited metabolic diseases, including mucopolysaccharidosis type 1 (Hurler syndrome) and adrenoleukodystrophy (ALD). Although some of these diseases are treatable with exogenous enzyme replacement therapy, the clinical manifestations of disease tend to progress over time, especially disease in the CNS, where enzyme is unable to be reliably delivered. It is thought that undergoing HSCT results in the engraftment of microglial cells that are able to provide new enzyme to the areas where enzyme replacement therapy, if available, cannot have a substantial impact. Multiple studies have shown significantly improved outcomes for patients who are diagnosed with their underlying conditions relatively early and are able to undergo HSCT expeditiously, before significant damage from accumulated substrate that may be irreversible.

CHAPTER 162

Hematopoietic Stem Cell Transplantation From Alternative Sources and Donors

Rachel A. Phelan, David Margolis

Two thirds of patients who need allogeneic hematopoietic stem cell transplantation (HSCT) do not have an available HLA-identical sibling. Alternative sources of hematopoietic stem cells (HSCs) are being increasingly used and include **matched unrelated donors, unrelated umbilical cord blood** , and **HLA-haploidentical relatives** . Each of these 3 options has advantages and limitations, but rather than being considered competing alternatives, they should be regarded as complementary strategies to be chosen after a careful evaluation of the relative risks and benefits in the patient's best interest. The choice of the donor will depend on various factors related to urgency of transplantation, patient-, disease-, transplant-related factors, center experience, and physician preference.

Unrelated Donor Transplants

One of the most widely used strategies for children who need an allograft and do not have an available HLA-identical sibling is to identify an unrelated HLA-matched donor in a registry (Fig. 162.1). Worldwide international registries include almost 27 million HLA-typed volunteer donors. HLA-A, -B, -C class I loci, and the DRB1 class II locus are the HLA loci most influencing outcome after HSCT from an unrelated volunteer. Other class II loci (namely, DQB1 and DP1 loci), as well as KIR haplotypes, are also being increasingly considered when choosing a donor, although their impact on outcome is less well studied.

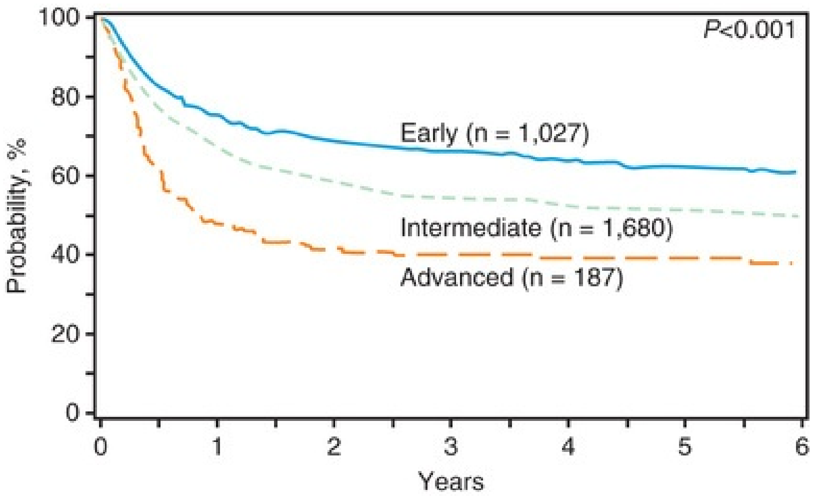

FIG. 162.1 Survival after unrelated donor HCT for acute lymphoblastic leukemia (ALL), age <18 yr, 2004–2014. *Early,* first complete remission (CR1); *Intermediate,* second or greater complete remission (CR2+); *Advanced,* active disease. (From D'Souza A, Zhu X: Current uses and outcomes of hematopoietic cell transplantation (HCT), CIBMTR Summary Slides, 2016. http://www.cibmtr.org .)

Although in the past serologic (low-resolution) typing was used for HLA-A and HLA-B loci, currently the unrelated donors are selected using high-resolution (allelic) molecular typing of loci HLA-A, -B, -C, and -DRB1. Less stringent HLA typing is required for cord blood units, where only HLA-A, -B, and -DRB1 are used. The chance of finding an HLA-matched unrelated donor depends on the frequency of the HLA phenotype, which is closely linked to the ethnic origin of the registry donors. Data from the National Marrow Donor Program (NMDP) donor registry and banked cord blood units estimated that essentially every patient in need of a transplant would be able to find a donor in a timely fashion, despite the recipient's race/ethnic group, donor availability, and cell dose. However, many of those patients may not have access to an “ideal” graft, defined as HLA matching of 8/8 for bone marrow and 6/6 for cord blood. It is also estimated that an additional 5.5 million donors will be added to the registry by 2017, making it even more likely for a potential, and more ideal, donor to be identified.

Initially, HLA polymorphism and the intrinsic limitations of conventional (i.e., serologic) HLA-typing techniques unfavorably affected the accuracy of matching, thus increasing rejection rates and the incidence of acute and chronic graft-versus-host disease (GVHD). The advent of both high-resolution molecular HLA classes I and II loci typing coupled with progress in the prophylaxis and treatment of GVHD has resulted in a reduction of transplantation-related mortality and improvement in outcome. Indeed, outcomes from a fully matched unrelated volunteer donor are now similar to those of HSCT from an HLA-identical sibling. The outcomes of haploidentical transplantation are similarly reaching that of matched unrelated donors as well as matched sibling donors.

Although a single locus disparity in patients with leukemia may be seen as beneficial by a reduction in the relapse rate caused by the graft-versus-leukemia (GVL) effect, in patients with nonmalignant disorders in whom GVL is not beneficial, optimal results are obtained only when a donor matched at the allelic level with the recipient is selected. In general, a single HLA disparity in the donor-recipient pair, irrespective of whether antigenic or allelic in nature, predicts a greater risk of nonleukemia mortality; multiple allelic disparities at different HLA loci have an additive detrimental effect and are associated with an even worse outcome. To reduce the risk of acute GVHD, **ex vivo T-cell depletion of the graft** has been employed, with variable efficacy. Studies are looking at selectively depleting donor α/β T cells, which are the T cells that drive GVHD, while preserving the T cells and natural killer (NK) cells, which may be responsible for GVL and protection from infection.

Although the majority of patients who have required a matched unrelated donor transplant have received a bone marrow or peripheral stem cell graft, for patients who urgently need a transplant, the time required to identify a suitable donor from a potential panel, establish eligibility, and harvest the cells may lead to relapse and failure to transplant. For this subset of patients who urgently need a transplant, attention has focused on unrelated cord blood and HLA-haploidentical, mismatched family donors.

Umbilical Cord Blood Transplants

Umbilical cord blood transplantation (UCBT) is a viable option for children who need allogeneic HSCT. UCBT offers the advantages of absence of risks to donors, reduced risk of transmitting infections, and for transplants from unrelated donors, immediate availability of cryopreserved cells, with the median time from start of search to transplantation only 3-4 wk. Compared with bone marrow transplantation (BMT), the advantages of UCBT are also represented by lower incidence of chronic GVHD and the possibility of using donors showing HLA disparities with the recipient. Despite these advantages, the large experience gained over the last 2 decades has demonstrated that UCBT patients may be exposed to an increased risk of early fatal complications, mainly because of a lower engraftment rate of donor hematopoiesis, delayed kinetics of neutrophil recovery, and lack of adoptive transfer of pathogen-specific memory T cells. Transfer of donor-derived, memory T cells significantly contributes to early immunologic reconstitution of children after unmanipulated allogeneic bone marrow or peripheral blood stem cell transplantation.

Concerning the issues of engraftment and hematopoietic recovery, it has been demonstrated that an inverse correlation exists between the number of nucleated cord blood cells infused per kilogram recipient body weight and the risk of dying for transplantation-related causes. In particular, engraftment is a major concern when the nucleated cells are $<2.5 \times 10^7$ /kg of recipient body weight. Since a cord blood unit usually contains between 1×10^9 and 1.8×10^9 cells, it is not surprising that UCBT has been less frequently employed for adolescents or adults with body weight >40 kg. Indeed, it can be estimated that only 30% of the UCB units available in the bank inventory could suffice for a 75 kg patient, according to the recommended threshold cell dose. Efforts have focused on approaches capable of increasing the number of UCB cells to be transplanted. Selection of the richest cord blood units, infusion of 2 units in the same recipient (i.e., double UCBT), and transplantation of ex vivo expanded progenitors have been explored to improve the results of UCBT, opening new scenarios for a wider application of the procedure. The results of these studies have been mixed, with one large study demonstrating no survival advantage for children and adolescents that receive double UCBT.

The long-term results of UCB transplants are similar to those after transplantation from other sources of HSCs for pediatric hematologic malignancies. In patients with hematologic malignancies, recipients of UCBT may be transplanted from donors with greater HLA disparities, receive 1-log fewer nucleated cells, have delayed neutrophil and platelet recovery, and show reduced incidence of GVHD compared with children given BMT from unrelated donors. In one study, there were similar rates of acute GVHD, but significantly less chronic GVHD in patients who received UCBT. Nevertheless, both the relapse rate and the overall survival probability did not differ in unrelated UCBT or BMT pediatric recipients. Thus, in the absence of an HLA-identical family donor, unrelated UCBT can be considered a suitable option for children with malignant and nonmalignant disorders. Results of UCBT have been of particular interest in children with certain nonmalignant disorders to proceed to transplant quickly and prevent further progression of disease. An additional benefit is the potential for lower rates of GVHD, which serves no benefit in a patient receiving a transplant for a nonmalignant disorder.

Haploidentical Transplants

HSCT from an HLA-haploidentical (**haplo-HSCT**) donor offers an immediate source of HSCs to almost all patients who fail to find a matched donor, whether related or unrelated, or a suitable cord blood unit. Indeed, almost all children have at least 1 haploidentical–3 loci mismatched family member who is promptly available as donor. The few patients who reject the haploidentical transplant also have the advantage of another immediately available donor within the family. Moreover, this may represent an approach that would be attractive in the global health setting, where more sophisticated donor registries and cell-processing techniques are unavailable.

Efficient T-cell depletion of the graft has been demonstrated to prevent acute and chronic GVHD even when using haploidentical parental bone marrow differing at the 3 major HLA loci. This can be done ex vivo or in vivo with the use of chemotherapeutic agents before and after cell infusion. The use of **posttransplant cyclophosphamide** is one such in vivo technique now being widely incorporated into haploidentical transplant regimens. The benefits of T-cell depletion were first demonstrated in transplantation of children with severe combined immunodeficiency (SCID). More than 300 transplants in SCID patients using haploidentical donors have been performed worldwide, with a high rate of long-term partial or complete immune reconstitution.

The elimination of mature T cells from the graft, necessary for preventing GVHD in a context of great immune genetic disparity, results in recipients being unable to benefit from the adoptive transfer of donor memory T lymphocytes that, through their peripheral expansion, are the main factor responsible for protection from infections in the 1st few mo after transplantation. A state of profound immunodeficiency lasts for at least 4-6 mo after transplantation in haplo-HSCT recipients. Sophisticated strategies of adoptive infusions of T-cell lines or clones specific for the most common and life-threatening pathogens (Epstein-Barr virus [EBV], human cytomegalovirus, *Aspergillus* , adenovirus) have been successfully tested in a few pilot trials, to protect the recipients in the early posttransplant period.

Selective approaches of graft manipulation in haploidentical and unrelated donor transplant have also been developed. In particular, promising results have been obtained through a negative depletion of T lymphocytes carrying the α/β chains of the T-cell receptor, which are believed to be the mediators of GVHD. B lymphocytes are also depleted to prevent EBV-related lymphoproliferative disease. Through this approach the patient can benefit from the adoptive transfer of committed hematopoietic progenitors, mature NK cells and γ/δ+ T cells, which can confer a protection against life-threatening infections as well as provide a GVL effect.

The outcomes of haplo-HSCT have been more extensively reported in adults than in children. The reported probability of survival at 3-4 yr after a haplo-HSCT in children with acute leukemia ranged from 18–48%. Survival was influenced by many factors, most importantly the state of remission at transplantation, with poorer outcomes in children with myeloid leukemias than in those with lymphoid leukemia. In haplotype-mismatched parent-to-child HSCT, patients with acute leukemia grafted from the mother had reduced relapse rates compared with recipients of paternal grafts, translating into better event-free survival.

For many years the absence of the T-cell–mediated GVL effect has been considered as rendering the recipients of a T-cell–depleted allograft more susceptible to leukemia relapse. However, it has been demonstrated that a GVL effect displayed by donor NK cells can compensate for this lack of T-specific alloreactivity when an HLA-disparate NK-alloreactive relative is employed as a donor.

Donor Versus Recipient NK-Cell Alloreactivity

Natural killer cells are the first lymphocytes derived from the donor to recover after allogeneic HCT. Donor vs recipient NK-cell alloreactivity derives from a mismatch between donor NK clones, carrying specific inhibitory receptors for self–major histocompatibility complex (MHC) class I molecules, and MHC class I ligands on recipient cells. NK cells are primed to kill by several activating receptors, which play an important role in the NK cell–mediated GVL effect. Human NK cells discriminate allelic forms of MHC molecules via **killer cell immunoglobulin-like receptors (KIRs),** which are clonally distributed with each cell in the repertoire bearing at least 1 receptor that is specific for self-MHC class I molecules. Because NK cells co-express inhibitory receptors for self-MHC class I molecules, autologous cells are not killed. When faced with mismatched allogeneic targets, NK cells sense the missing expression of self–class I alleles and mediate alloreactions. In mismatched transplants, there are many donor recipient pairs in which the donor NK inhibitory cells do not recognize the recipient's class I alleles as self. Consequently, the donor NK cells are not blocked and are activated to lyse the recipient's lymphohematopoietic cells.

Haplo-HSCT trials demonstrate that MHC class I mismatches, which generate an alloreactive NK-cell response in the graft-vs-host direction, eradicate leukemia cells, improve engraftment, and protect from T-cell–mediated GVHD. The potential for donor vs recipient NK-cell alloreactivity, which can be predicted by standard HLA typing, is increasingly being examined when selecting the donor of choice. Although the importance of KIR haplotype in transplants other than haploidentical transplantation has still not been fully elucidated in the pediatric population, its role in preventing GVHD as well as relapse has been shown to be increasingly beneficial in the adult population.

Autologous Hematopoietic Stem Cell Transplantation

Autologous transplantation , using the patient's own stored marrow, is associated with a low risk of life-threatening transplant-related complications, although the main cause of failure is disease recurrence. Bone marrow was once the only source of stem cells employed in patients given an autograft. In the past few years, the vast majority of patients treated with autologous HSCT receive hematopoietic progenitors mobilized in peripheral blood by either cytokines alone (mainly granulocyte colony-stimulating factor) or by cytokines plus cytotoxic agents. A CXCR4 antagonist (plerixafor) can be extremely effective in mobilizing hematopoietic progenitors in the periphery. Compared with bone marrow, the use of peripheral blood progenitors is associated with a faster hematopoietic recovery and a comparable outcome. A major concern in patients with malignancies given autologous HSCT is represented by the risk of reinfusing malignant cells with the graft; tumor progenitors contained in the graft can contribute to recurrence of the original malignant disease. This observation has provided the rationale for **tumor purging** using elaborate strategies aimed at reducing or eliminating tumor contamination of the graft.

Autologous HSCT is employed primarily for selected children with relapsed lymphomas and select solid tumors (Table 162.1).

Table 162.1

Indications for Autologous Hematopoietic Stem Cell Transplantation for Pediatric Diseases

- Relapsed Hodgkin or non-Hodgkin lymphoma
- Stage IV or relapsed neuroblastoma
- High-risk, relapsed, or resistant brain tumors
- Stage IV Ewing sarcoma
- Life-threatening autoimmune diseases resistant to conventional treatments

Patients with sensitive lymphomas and minimal tumor burden have favorable outcomes after autologous HSCT, with disease-free survival rates of 50–60%, whereas high-risk patients with bulky tumor or poorly responsive disease have a poor outcome, with survival rates of 10–20%.

Autologous HSCT in patients with high-risk neuroblastoma is associated with a better outcome than conventional chemotherapy. A Children's Oncology Group (COG) study demonstrated further survival advantage by performing 2 sequential, or **tandem** , transplants that use different chemotherapeutic agents. Because of these improved outcomes, tandem autologous transplants are now considered the standard recommended treatment. In these patients, posttransplantation infusion of a monoclonal antibody directed against a molecule (GD2) expressed on the surface of neuroblastoma cells confers a protection against the risk of tumor recurrence.

For children with brain tumors at high risk of relapse, or resistant to conventional chemotherapy and irradiation, the dose-limiting toxicity for intensifying therapy is myelosuppression, thus providing a role for stem cell rescue. Several studies provide encouraging results for patients with different histologic types of brain tumors treated with autologous HSCT.

CHAPTER 163

Graft-Versus-Host Disease, Rejection, and Venoocclusive Disease

Rachel A. Phelan, David Margolis

A major cause of mortality and morbidity after allogeneic hematopoietic stem cell transplantation (HSCT) is **graft-versus-host disease (GVHD)** , which is caused by engraftment of immunocompetent donor T lymphocytes in an immunologically compromised host who shows histocompatibility differences with the donor. These differences between the donor and the host may result in donor T-cell activation against either recipient major histocompatibility complex (MHC) antigens or minor histocompatibility antigens. GVHD is usually subdivided in 2 forms: **acute GVHD** , which occurs within 3 mo after transplantation, and **chronic GVHD** , which, although related, is a different disease, occurring later and displaying some clinical and pathologic features that resemble those observed in selected autoimmune disorders (e.g., systemic sclerosis, Sjögren syndrome).

Acute Graft-Versus-Host Disease

Acute GVHD is caused by the alloreactive, donor-derived T cells contained in the graft, which attack nonshared recipient's antigens on target tissues. A 3-step process generates the clinical syndrome. First, conditioning-induced tissue damage activates recipient antigen-presenting cells, which present recipient alloantigens to the donor T cells transferred with the graft and secrete **cytokines** , such as interleukin (IL)-12, favoring the polarization of T-cell response in the type 1 direction. Second, in response to recipient antigens, donor T cells become activated, proliferate, expand, and generate cytokines such as tumor necrosis factor (TNF)-α, IL-2, and interferon (IFN)-γ. In the 3rd step of the process, these cytokines cause tissue damage and promote differentiation of cytotoxic CD8$^+$ T cells, which, together with macrophages, kill recipient cells and further disrupt tissues.

Acute GVHD usually develops 2-8 wk after transplantation. The primary manifestations depend on the sites of involvement and may include an erythematous maculopapular rash (Figs. 163.1 and 163.2), persistent anorexia, vomiting and/or diarrhea, and liver disease with increased serum levels of bilirubin, alanine transaminase (ALT), aspartate transaminase (AST), and alkaline phosphatase (ALP). Diagnosis may benefit from skin, liver, or gastrointestinal (GI) biopsy for confirmation. Endothelial damage and lymphocytic infiltrates are seen in all affected organs. The epidermis and hair follicles of the skin are damaged, the hepatic small bile ducts show segmental disruption, and there is destruction of the crypts and mucosal ulceration of the GI tract. Grade I acute GVHD (skin rash alone) has a favorable prognosis and often requires no treatment, or topical treatment alone. Grade II GVHD is a moderately severe multiorgan disease requiring immunosuppressive therapy. Grade III GVHD is a severe multiorgan disease, and grade IV GVHD is a life-threatening, often fatal condition (Table 163.1).

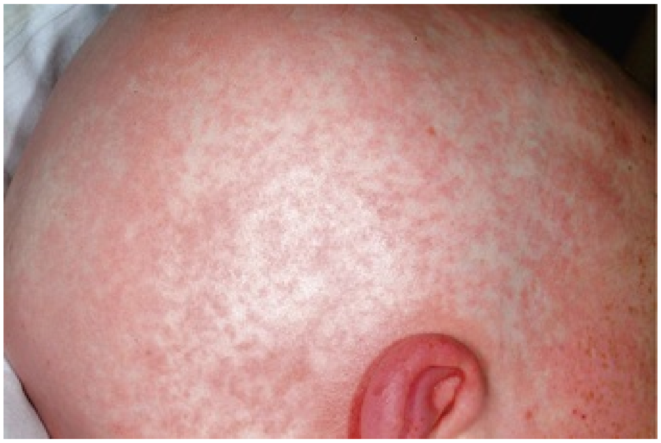

FIG. 163.1 **Acute graft-versus-host disease. Involvement of the scalp, ears, palms, and soles is common. (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology,* ed 5, Philadelphia, 2016, Elsevier, p 577.)**

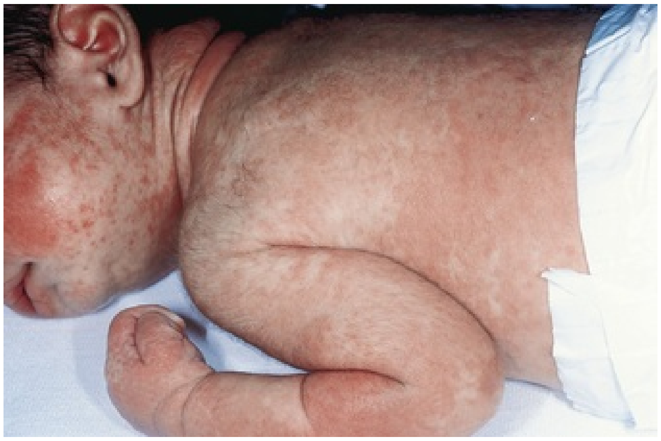

FIG. 163.2 Acute graft-versus-host disease. Almost confluent eruption of erythematous macules and papules in an immunodeficient neonate treated with extracorporeal membrane oxygenation (ECMO) and transfusion of nonirradiated blood. (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology,* ed 5, Philadelphia, 2016, Elsevier, p 577.)

Table 163.1

Clinical Staging and Grading* of Graft-Versus-Host Disease (GVHD)

STAGE	SKIN (ACTIVE ERYTHEMA ONLY)	LIVER (BILIRUBIN)	UPPER GI	LOWER GI (STOOL OUTPUT/DAY)
0	No active (erythematous) GVHD rash	<2 mg/dL	No or intermittent nausea, vomiting, or anorexia	Adult: <500 mL/day or <3 episodes/day Child: <10 mL/kg/day or <4 episodes/day
1	Maculopapular rash <25% BSA	2-3 mg/dL	Persistent nausea, vomiting or anorexia	Adult: 500-999 mL/day or 3-4 episodes/day Child: 10-19.9 mL/kg/day or 4-6 episodes/day
2	Maculopapular rash 25-50% BSA	3.1-6 mg/dL		Adult: 1000-1500 mL/day or 5-7 episodes/day Child: 20-30 mL/kg/day or 7-10 episodes/day
3	Maculopapular rash >50% BSA	6.1-15 mg/dL		Adult: >1500 mL/day or >7 episodes/day Child: >30 mL/kg/day or >10 episodes/day
4	Generalized erythroderma (>50% BSA) plus bullous formation and desquamation >5% BSA	>15 mg/dL		Severe abdominal pain with or without ileus or grossly bloody stool (regardless of stool volume)

* Overall clinical grade (based on most severe target organ involvement):

Grade 0: no stage 1-4 of any organ.

Grade I: stage 1-2 skin without liver, upper GI, or lower GI involvement.

Grade II: stage 3 rash and/or stage 1 liver and/or stage 1 upper GI and/or stage 1 lower GI.

Grade III: stage 2-3 liver and/or stage 2-3 lower GI, with stage 0-3 skin and/or stage 0-1 upper GI.

Grade IV: stage 4 skin, liver, or lower GI involvement, with stage 0-1 upper GI.

GI, Gastrointestinal; BSA, body surface area.

From Harris AC, Young R, Devine S, et al: International, multicenter standardization of acute graft-versus-host disease clinical data collection: a report from the Mount Sinai Acute GVHD International Consortium, Biol Blood Marrow Transplant 22:4–10, 2016.

The standard **pharmacologic prophylaxis** of GVHD after an unmanipulated allograft relies mainly on posttransplant administration of immunosuppressive drugs, such as cyclosporine or tacrolimus or combinations of either with methotrexate or prednisone, anti–T-cell antibodies, mycophenolate mofetil (MMF), and other immunosuppressive agents. Infusion of cyclophosphamide on days +3 and +5 after transplantation has been proposed as a strategy to deplete alloreactive donor T lymphocytes that become activated after exposure to recipient antigens. This approach has been successful in patients undergoing haploidentical transplantation. Pretransplantation infusion of either antithymocyte globulin (ATG) or monoclonal antibodies (mAbs) such as alemtuzumab is largely used to modulate alloreactivity of donor T cells, in particular in patients given the allograft from either an unrelated donor or a partially matched relative. An alternative approach, which has been widely used in clinical practice, is the removal of T lymphocytes from the graft (**T-cell depletion**). Other approaches, through clinical trials, are being used to selectively remove the α/β T cells, which are thought to be responsible for the development of GVHD, while preserving the γ/δ T cells in order to sustain GVL and the ability to fight infection. Any form of GVHD prophylaxis in itself may impair posttransplantation immunologic reconstitution, increasing the risk of infection-related deaths. Traditional T-cell depletion of the graft is also associated with an increased risk of leukemia recurrence in patients transplanted from an HLA-identical sibling or an unrelated volunteer.

Despite prophylaxis, significant acute GVHD develops in approximately 30% of recipients of HSCT from matched siblings and in as many as 60% of HSCT recipients from unrelated donors. These numbers are estimates, and the actual risk of acute GVHD is highly variable depending on several factors. Risk for development of GVHD is increased by diagnosis of malignant disease, older donor and recipient age, and in patients given an unmanipulated allograft, GVHD prophylaxis including only 1 drug. The most important risk factor for acute GVHD is the presence of disparities for HLA molecules in the donor-recipient pair.

Acute GVHD is usually initially treated with glucocorticoids; approximately 40–50% of patients show a complete response to corticosteroids. The risk of transplantation-related mortality is much higher in patients who do not respond to corticosteroids than in those showing a complete response. Promising results in children with steroid-resistant acute GVHD have been obtained using **mesenchymal stromal cells** , which are able to blunt the inflammatory response associated with acute GVHD. MMF, pentostatin, or mAbs targeting molecules expressed on T cells or cytokines released during the inflammatory cascade (including infliximab and etanercept targeting TNF, and tocilizumab targeting IL-6), which underlies the pathophysiology of GVHD, have been used in patients with steroid-resistant acute GVHD. There are no clear data showing the superiority of one of these approaches over the others. **Extracorporeal photopheresis** is another second-line treatment for GVHD and is most efficacious for skin GVHD. A patient's peripheral blood is exposed to a photosensitive compound and then exposed to ultraviolet light. The cells are then reinfused into the patient. It is thought that this process results in an increase in apoptosis of lymphocytes responsible for GVHD as well as the upregulation of antiinflammatory cytokines and regulatory T cells.

Chronic Graft-Versus-Host Disease

Chronic GVHD develops or persists >3 mo after transplantation and is the most frequent late complication of allogeneic HSCT with an incidence of approximately 25% in pediatric patients. Chronic GVHD is the major cause of nonrelapse mortality and morbidity in long-term HSCT survivors. Acute GVHD is recognized as the most important factor predicting the development of the chronic form of the disease. The use of matched unrelated volunteers as donors and use of peripheral blood as the stem cell source have increased the incidence and severity of chronic GVHD. Other factors that predict occurrence of chronic GVHD include older donor and recipient ages, female donor for male recipient, diagnosis of malignancy, and use of total body irradiation (TBI) as part of the preparative regimen.

Chronic GVHD is a disorder of immune regulation characterized by autoantibody production, increased collagen deposition and fibrosis, and clinical symptoms similar to those seen in patients with autoimmune diseases (Table 163.2). The predominant cytokines involved in the pathophysiology of chronic GVHD are usually type II cytokines such as IL-4, IL-5, and IL-13. IL-4 and IL-5 contribute to eosinophilia, B-cell hyperactivity with elevated IgM, IgG, and IgE titers. Associated monoclonal gammopathies indicate clonal dysregulation. Chronic GVHD is dependent on the development and persistence of donor T cells that are not tolerant to the recipient. Maturation of transplanted stem cells within a damaged thymus could lead to errors in negative selection and production of cells that have not been tolerized to recipient antigens and are therefore autoreactive or, more accurately, **recipient reactive** . This ongoing immune reactivity results in clinical features resembling a systemic autoimmune disease with lichenoid and sclerodermatous skin lesions, malar rash, sicca syndrome, arthritis, joint contractures, bronchiolitis obliterans, and bile duct degeneration with cholestasis.

Table 163.2

Clinical Findings in Chronic Graft-Versus-Host Disease

ORGAN SYSTEM	SYMPTOMS AND SIGNS
Systemic	Immunodeficiency and recurrent infections
Skin	Lichen planus, scleroderma, hyperpigmentation or hypopigmentation, erythema, freckling, ichthyosis, ulcerations Flexion contractures Vaginal scars Onycholysis Nail loss
Hair	Alopecia; scarring or nonscarring
Mouth	Sicca syndrome, lichen planus, depapillation of tongue with variegations, scalloping of lateral margins, xerostomia, mucocele
Joints	Diffuse myositis/tendonitis, arthritis, contractures
Eyes	Decreased tearing, injected sclerae, scarring conjunctivitis, keratopathy
Liver	Increased enzymes, cholestasis, hepatomegaly, cirrhosis
Gastrointestinal	Failure to thrive, malabsorption, chronic diarrhea Esophageal strictures

Lung	Cough, dyspnea, wheezing Bronchiolitis obliterans, chronic rales, pneumothorax, fibrosis
Hematology	Thrombocytopenia, eosinophilia, Howell-Jolly bodies (splenic dysfunction)

Patients with chronic GVHD involving only the skin and liver have a favorable course (Figs. 163.3 and 163.4). Extensive multiorgan disease may be associated with a very poor quality of life, recurrent infections associated with prolonged immunosuppressive regimens to control GVHD, and a high mortality rate. Morbidity and mortality are highest in patients with a **progressive onset** of chronic GVHD that directly follows acute GVHD, intermediate in those with a **quiescent onset** after resolution of acute GVHD, and lowest in patients with **de novo onset** in the absence of acute GVHD. Chronic GVHD can be classified as mild, moderate, or severe depending on extent of involvement. Single-agent prednisone is standard treatment at present, although other agents, including extracorporeal photopheresis, MMF, anti-CD20 mAb, and pentostatin, have been employed with variable success. Treatment with imatinib mesylate, which inhibits the synthesis of collagen, has been effective in some patients with chronic GVHD and sclerotic features. As a consequence of prolonged immunosuppression, patients with chronic GVHD are particularly susceptible to infections and should receive appropriate antibiotic prophylaxis, including trimethoprim/sulfamethoxazole (TMP/SMX). Chronic GVHD resolves in most pediatric patients but may require 1-3 yr of immunosuppressive therapy before the drugs can be withdrawn without the disease recurring. Chronic GVHD promotes the development of secondary neoplasms, in particular in patients with Fanconi anemia, and has a significant impact on quality of life.

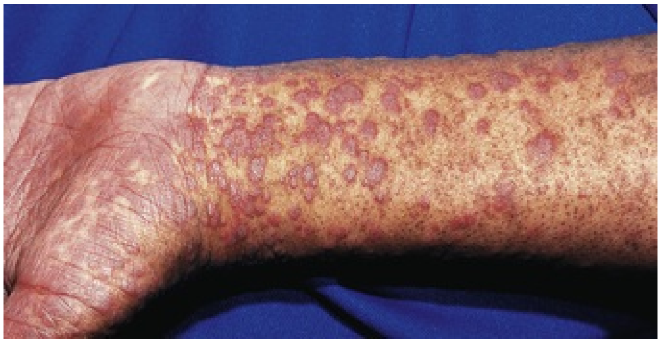

FIG. 163.3 **Chronic graft-versus-host disease (GVHD), lichenoid. After bone marrow transplantation, this boy had acute GVHD and subsequently developed cutaneous scaling papules and plaques typical of lichen planus. (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology,* ed 5, Philadelphia, 2016, Elsevier, p 577.)**

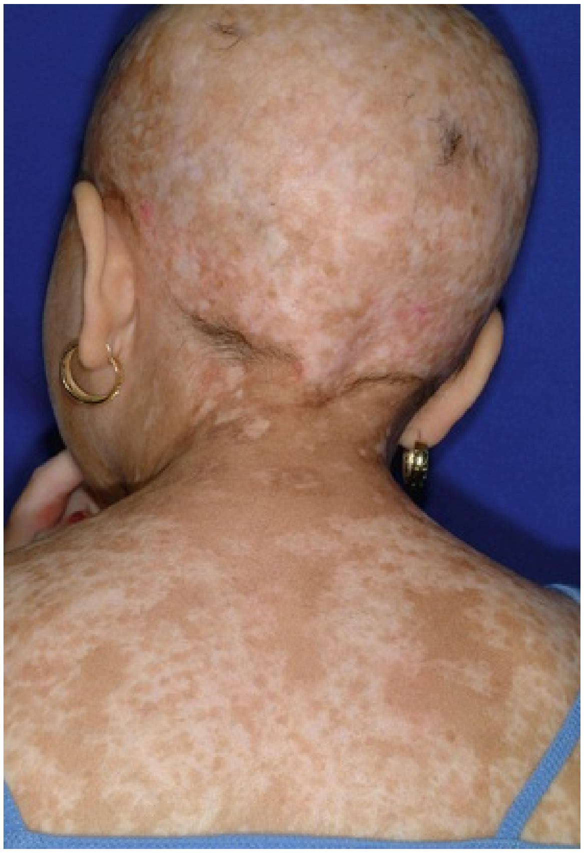

FIG. 163.4 Chronic graft-versus-host disease. Note the extensive alopecia of the scalp with dyschromia and numerous sclerodermatous plaques of the scalp and back. (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology,* ed 5, Philadelphia, 2016, Elsevier, p 579.)

Graft Failure

Graft failure is a serious complication exposing patients to a high risk of fatal infection. **Primary graft failure** is defined as failure to achieve a neutrophil count of 0.5×10^9 /L after transplantation. **Secondary graft failure** is loss of peripheral blood counts following initial transient engraftment of donor cells. Causes of graft failure after autologous and allogeneic transplantation include transplantation of an inadequate stem cell dose (more frequently observed in children given cord blood transplantation) and viral infections such as with cytomegalovirus or human herpesvirus type 6, which are often associated with activation of recipient macrophages. Graft failure after allogeneic transplantation, however, is mainly caused by immunologically mediated rejection of the graft by residual recipient-type T cells that survive the conditioning regimen.

Diagnosis of graft failure resulting from immunologic mechanisms is based on examination of peripheral blood and marrow aspirate and biopsy, along with molecular analysis of chimerism status. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic rejection. The risk of immune-mediated graft rejection is higher in patients given HLA-disparate, T-cell–depleted grafts, reduced-intensity conditioning regimens, and transplantation of low numbers of stem cells, and in recipients who are sensitized toward HLA antigens or, less frequently, minor histocompatibility antigens. Allosensitization develops as a consequence of preceding blood product transfusions and is observed particularly in recipients with aplastic anemia, sickle cell disease, and thalassemia. In HSCT for nonmalignant diseases, such as mucopolysaccharidoses, graft failure is also facilitated by the absence of previous treatment with cytotoxic and immunosuppressive drugs. In thalassemia, graft failure is promoted by expansion of recipient hematopoietic cells. GVHD prophylaxis with methotrexate, an antimetabolite, and antiinfective prophylaxis with TMP/SMX or ganciclovir may also delay engraftment.

Treatment of graft failure usually requires removing all potentially myelotoxic agents from the treatment regimen and attempting a short trial of hematopoietic growth factors, such as granulocyte colony-stimulating factor. A 2nd transplant, usually preceded by a highly immunosuppressive regimen, is frequently employed to rescue patients experiencing graft failure. High-intensity regimens are generally tolerated poorly if administered within 100 days from a 1st transplant because of cumulative toxicities, but this risk must be balanced with the risk of infection from prolonged neutropenia and lymphocytopenia.

Venoocclusive Disease

Hepatic venoocclusive disease (**VOD**), also known as **sinusoidal obstruction syndrome** , presents with hepatomegaly, right upper quadrant tenderness, jaundice, and weight gain from fluid retention and ascites. It results from endothelial damage within the liver, which can then progress to multiorgan dysfunction. Onset is usually within 30 days of transplantation, with an incidence of approximately 15%, depending on the intensity of the conditioning protocol. Risk factors include young age, prior hepatic disease (fibrosis, cirrhosis), abdominal radiation, repeated transplantations, neuroblastoma, osteopetrosis, and familial hemophagocytic lymphohistiocytosis. The severe form of VOD has a high mortality rate (>80%) without treatment.

Prophylaxis has traditionally used ursodeoxycholic acid and occasionally heparin; only **defibrotide** has demonstrated some efficacy in preventing and treating VOD. A phase 3 study demonstrated improvement in survival and response rate to VOD in patients treated with defibrotide. Defibrotide is a combination of porcine oligodeoxyribonucleotides that reduces procoagulant activity and enhances fibrinolytic properties of endothelial cells. Defibrotide is U.S. Food and Drug Administration (FDA) approved for the treatment of VOD in adult and pediatric patients with renal or pulmonary dysfunction after HSCT. Defibrotide is often used as prophylaxis in Europe, with data showing efficacy, but this use is not yet approved in the United States.

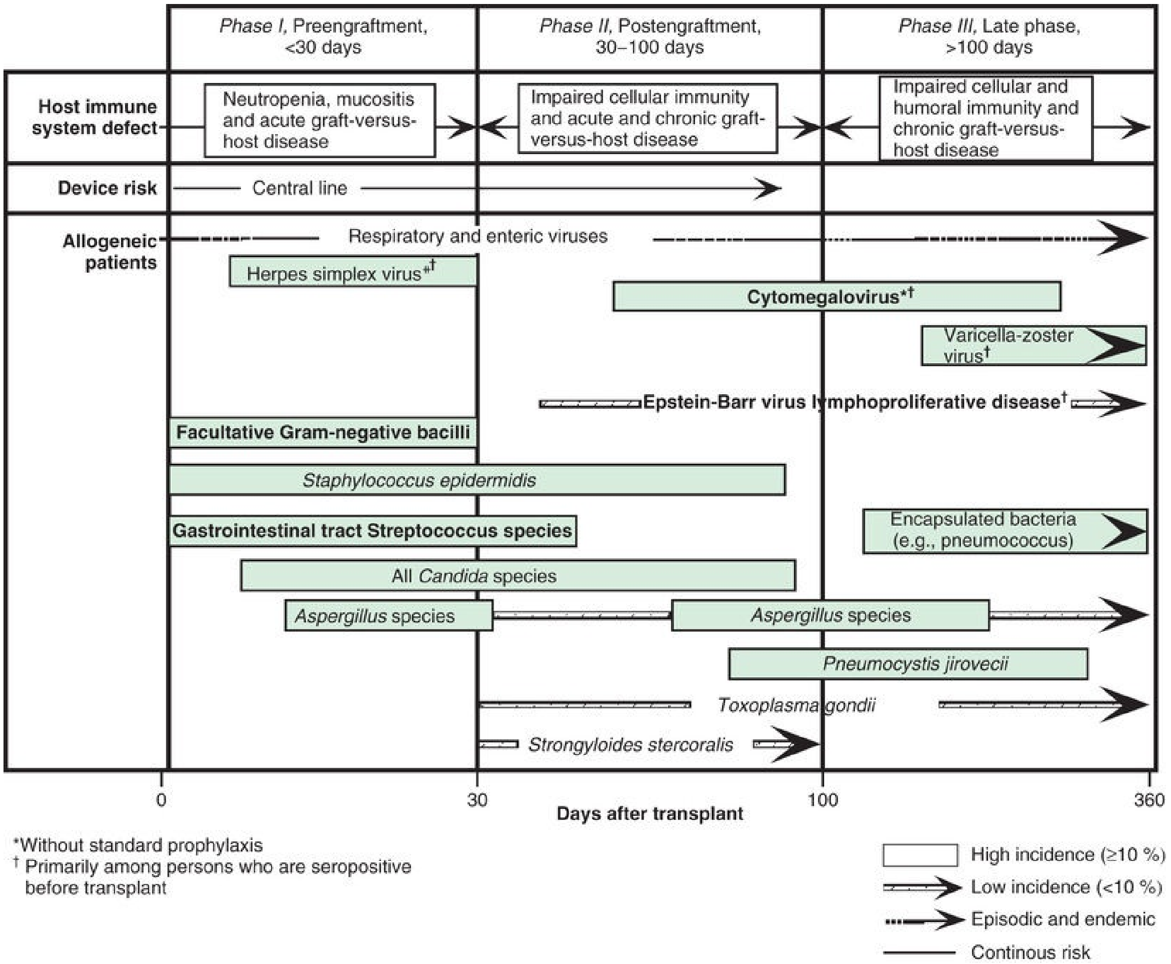
CHAPTER 164

Infectious Complications of Hematopoietic Stem Cell Transplantation

Anna R. Huppler

Hematopoietic stem cell transplantation (HSCT) recipients experience a transient but profound state of immune deficiency. The risk of infection depends on the stage after transplantation (pre- vs postengraftment), ongoing immunosuppression, disruption in barrier functions (indwelling catheters, graft-versus-host disease [GVHD], mucositis) and preexisting infections (Fig. 164.1). Management approaches may include the use of prophylactic antimicrobials, preemptive antimicrobials for infection prior to symptomatic disease, or antimicrobial treatment of documented or suspected infection.



Phase I, Preengraftment, <30 days
Phase II, Postengraftment, 30–100 days
Phase III, Late phase, >100 days
Host immune system defect
Neutropenia, mucositis and acute graft-versus-host disease
Impaired cellular immunity and acute and chronic graft-versus-host disease
Impaired cellular and humoral immunity and chronic graft-versus-host disease
Device risk
Central line
Allogeneic patients
Respiratory and enteric viruses
Herpes simplex virus*†
Cytomegalovirus*†
Varicella-zoster virus†
Epstein-Barr virus lymphoproliferative disease†
Facultative Gram-negative bacilli

Continous risk

FIG. 164.1 **Phases of opportunistic infections among allogenic HSCT recipients. (From Centers for Disease Control and Prevention: Guidelines for preventing opportunistic infections among hematopoietic sickle cell transplant recipients, *MMWR* 49(RR-10):1–128, 2000.)**

Immediately after transplantation, the absence or paucity of neutrophils (**neutropenia**) renders patients susceptible to bacterial and fungal infections. Consequently, most centers start antipseudomonal and antifungal prophylaxis during the conditioning regimen. Despite these prophylactic measures, the majority of patients will develop fever and signs of infection in the early posttransplantation period. The common pathogens include enteric gram-negative bacteria and fungi. An indwelling central venous line, routinely employed in all children given HSCT, is a significant risk factor for infection. Staphylococcal species and *Candida* are the most frequent pathogens in catheter-related infections (see Chapter 206). Multidrug-resistant strains of *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* are an emerging problem, with prevalence highly variable among centers. Severe lower respiratory tract disease caused by seasonal respiratory viruses, such as influenza, respiratory syncytial virus (RSV), parainfluenza virus, and human metapneumovirus, can occur during the pre- or postengraftment phase. Published guidelines from the Infectious Disease Society of America and the U.S. Centers for Disease Control and Prevention (CDC) address the management of fever and neutropenia after HSCT.

HSCT recipients remain at increased risk of developing severe infections even after the neutrophil count has normalized because of prolonged depression in T-cell number and function. The manifestations of GVHD, as well as the associated immunosuppressive therapy, are additional risk factors for fungal and viral opportunistic infections. After umbilical cord blood transplant (UCBT), infections are the consequence of both slow neutrophil engraftment and donor T-cell naïveté. In haploidentical transplantation, T-cell depletion results in an increased risk of infection in the first 4-6 mo. Recipients of this type of transplantation, as well as those receiving UBCT, do not have the benefit of adoptive transfer of donor-derived, antigen-experienced T cells. For HSCT recipients after engraftment, invasive fungal disease, herpesviruses, and adenovirus infections represent life-threatening complications that significantly affect outcomes. Additional pathogens to consider include nontuberculous mycobacteria, BK virus, *Clostridium difficile*, and norovirus.

Invasive fungal disease (IFD) remains a significant cause of infectious morbidity and mortality in allogeneic HSCT recipients. Empirical treatment for IFD is considered for HSCT patients with persistent fever despite 96 hr of broad-spectrum antibiotic treatment. The most common organisms are *Aspergillus* and *Candida* species. Infections also occur with non-*Aspergillus* molds, including *Mucor* and *Rhizopus* species (among other agents of mucormycosis), *Fusarium,* and *Scedosporium* species. *Pneumocystis jiroveci* is a unique, noncultivatable cause of fungal pneumonia in immunocompromised patients. Despite prompt and aggressive administration of potent antifungal agents, proven cases of IFD carry case fatality rates of 20–70%. IFD can present early after transplant, although there is a shift toward presentation of infection in the postengraftment period in the presence of GVHD. The risk of developing IFD is mainly influenced by history of previous fungal infection, duration of neutropenia, use of corticosteroid therapy, mucosal tissue damage (GVHD, posttransplant CMV infection, viral respiratory tract infections), and for candidiasis, presence of central venous catheters.

Disseminated candidiasis presents frequently as a central venous catheter–associated infection. However, up to 50% of patients with disseminated candidiasis do not present with positive blood cultures. Patients with and without candidemia can have infection of normally sterile organs, including liver, spleen, kidney, brain, heart, and eye. Mortality rates in pediatric series range from 10–25%. **Echinocandins** (micafungin, caspofungin) are the initial drugs of choice for candidiasis in immunocompromised patients.

The most common presentation of invasive **aspergillosis** is pulmonary aspergillosis. The upper airway mucosa (nose and sinuses) can also be a site of initial infection. Infection progresses from lung or sinus sites by direct extension across tissue or angioinvasion resulting in hematogenous dissemination to brain and other organs. The earliest imaging finding is classically 1 or more small pulmonary nodules (Figs. 164.2 and 164.3). As a nodule enlarges, the dense central core of infarcted tissue may become surrounded by edema or hemorrhage, forming a hazy rim known as the *halo sign.* When bone marrow function recovers, the infarcted central core may cavitate, creating the *crescent sign.* Unfortunately, radiographic signs, including the halo sign, crescent sign, and cavitation, have low sensitivity in pediatric patients. Clinical criteria are used to diagnose proven or probable IFD, requiring direct or indirect microbiologic data. Direct, culture-based diagnosis requires invasive procedures, such as sinus endoscopy or lung biopsy. Indirect measures, known as *fungal biomarkers,* are used in adult HSCT patients to screen or diagnose for aspergillosis. Fewer data are available for pediatric patients, and currently no major guidelines support routine use of fungal biomarkers to diagnose IFD in immunocompromised children. **Galactomannan** from serum or bronchoalveolar lavage fluid is a promising adjunct to current diagnostic strategies because of a high negative predictive value for aspergillosis; however, lack of detection of mucormycosis limits its utility as a single diagnostic test. Other tests used in adult patients, such as (1→3)-β-D -glucan, are insufficiently studied for routine use in pediatric patients.

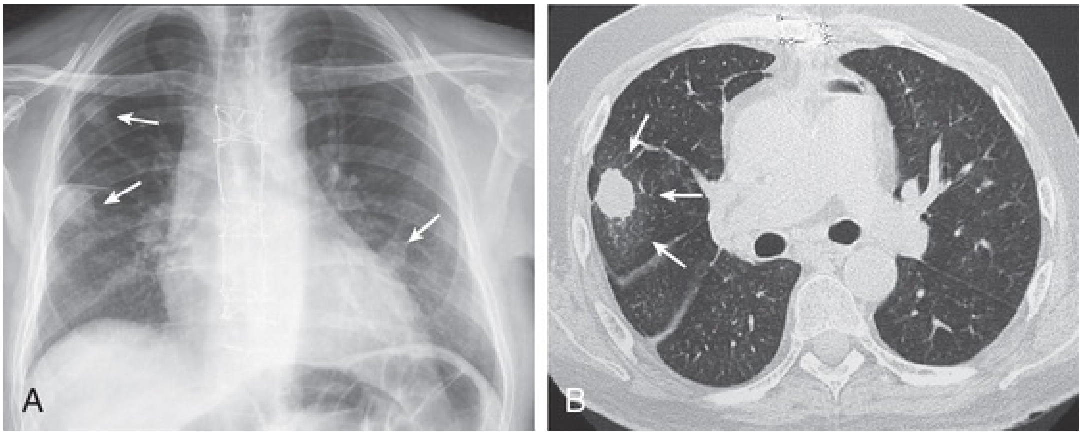

FIG. 164.2 Angioinvasive aspergillosis. A, Posteroanterior radiograph shows multiple nodules in the lungs *(arrows).* B, CT section at the level of the intermediary bronchus shows a nodule surrounded by a halo of ground-glass attenuation *(arrows).* (From Haaga JR, Boll DT, editors: *CT and MRI of the whole body,* ed 6, vol 1, Philadelphia, 2017, Elsevier, p 933.)

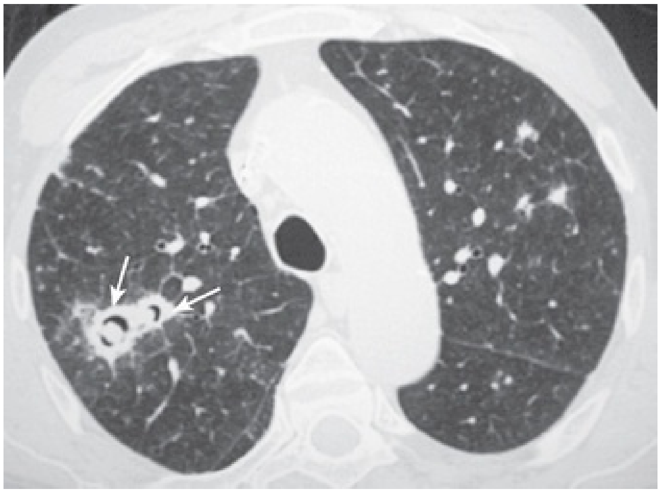

FIG. 164.3 Angioinvasive aspergillosis. CT section at the level of the lower trachea shows a consolidation with an eccentric cavitation and air crescent sign *(arrows).* This finding in this neutropenic patient is highly diagnostic of angioinvasive aspergillosis. (From Haaga JR, Boll DT, editors: *CT and MRI of the whole body,* ed 6, vol 1, Philadelphia, 2017, Elsevier, p 933.)

Fungal infection prevention includes isolation of the patient in a laminar airflow or positive pressure room. Universal prophylaxis to prevent *Pneumocystis* pneumonia is advocated until the return of T-cell function in HSCT patients; the primary agent for prophylaxis is trimethoprim/sulfamethoxazole. Alternative agents are pentamidine, dapsone, and atovaquone. For prevention and treatment of other IFD, liposomal amphotericin B, azole compounds (itraconazole, voriconazole, posaconazole) and echinocandins (caspofungin, micafungin) are used. **Voriconazole** represents the treatment of choice for adult patients with invasive aspergillosis, but achieving adequate trough levels can be challenging in young children. The agents of mucormycosis are resistant to most azole and echinocandin medications, which makes liposomal **amphotericin B** the initial drug of choice. IFD often does not respond satisfactorily to antifungal agents alone, and infection may persist until immune function recovers.

Herpesviruses , including cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV1 and HSV2), and varicella-zoster virus (VZV) are pathogens that can cause significant disease after HSCT. Because herpesviruses can establish latency in the human host, symptomatic infection can occur from viral reactivation as well as acquisition from the donor or de novo infection. Baseline susceptibility to disease and viremia before symptom development can be established with laboratory monitoring (pretransplant donor-recipient serology, posttransplant viral load monitoring) and can inform decisions on prophylactic and preemptive antiviral treatment.

CMV infection remains the most common and potentially severe viral complication in patients receiving allogeneic HSCT. Risk factors for CMV viremia include recipient seropositivity, UCBT, and acute GVHD. The period of maximal risk for CMV disease is 1-4 mo after transplantation. Late presentation of CMV disease is associated with GVHD. Until CMV-specific T-cell responses develop months after transplant, CMV infection may result in a variety of syndromes, including fever, leukopenia, thrombocytopenia, hepatitis, pneumonitis, retinitis, esophagitis, gastritis, and colitis. CMV pneumonia has been reported to occur in up to 15–20% of bone marrow transplant recipients, with a case fatality rate of 85% in the absence of early treatment. Tachypnea, hypoxia, and nonproductive cough signal respiratory involvement. Chest radiography often reveals bilateral interstitial or reticulonodular infiltrates, which begin in the periphery of the lower lobes and spread centrally and superiorly. Gastrointestinal CMV involvement may lead to ulcers of the esophagus, stomach, small intestine, and colon with complications of bleeding or perforation. Fatal CMV infections are often associated with persistent viremia and multiorgan involvement.

CMV disease has largely been prevented through prophylaxis or preemptive approaches. Prophylaxis is based on administration of antiviral drugs to at-risk transplanted patients for a median duration of 3 mo after transplantation. The major drawbacks of this approach are drug toxicity, late CMV disease after withdrawal of prophylaxis, potential unnecessary treatment of patients who would not have reactivated CMV infection, and low cost-effectiveness. Preemptive therapy aims at treating only patients who experience CMV reactivation and thus are at risk of developing overt disease; it starts on detection of CMV in blood but before symptom development. The major drawback of this strategy is the need of serial monitoring of CMV by polymerase chain reaction (PCR) in blood. First-line therapy is usually ganciclovir, with foscarnet as an alternative for resistant strains or ganciclovir intolerance.

EBV-related posttransplant lymphoproliferative disease (PTLD) is a major complication in HSCT and solid-organ transplantation. In patients receiving HSCT, selective procedures of T-cell depletion–sparing B lymphocytes and use of HLA–partially matched family and unrelated donors are risk factors for the development of PTLD. PTLD usually presents in the first 4-6 mo after transplantation as high-grade, diffuse, large-cell B-cell lymphomas that are oligoclonal or monoclonal. High EBV viral loads in blood by PCR predict development of PTLD. Standard treatment of PTLD includes the reduction of immunosuppression, monoclonal antibodies directed against CD20 on B cells (rituximab), or cytotoxic chemotherapy. Prophylactic strategies with rituximab for EBV-positive recipients during conditioning for HSCT have also been employed. Histologic diagnosis of PTLD is required to assess for the emergence of neoplasms in which cells are $CD19^+$ but $CD20^-$, thus eliminating susceptibility to rituximab.

Disseminated adenovirus infection is a life-threatening complication of HSCT recipients. Clinical manifestations include fever, hepatitis, enteritis, meningoencephalitis, and pneumonia. Young children or recipients of donor cells naïve to adenovirus (T-cell–depleted grafts or UCBT) are at particular risk of developing this complication. Diagnosis is based on the demonstration of high viral loads by PCR in blood or recovery of virus in tissue biopsies. Pharmacologic treatment of adenovirus infections is with the antiviral cidofovir, which has significant renal toxicity and limited potency at controlling viral replication. Alternative delivery systems for this drug, such as enterally available prodrugs, are currently being investigated in research settings. Recovery of immune system function is associated with improved survival with disseminated adenovirus infection.

In immunocompromised hosts, severe viral infections, including PTLD and adenovirus infection, originate from a deficiency of virus-specific **cytotoxic T**

lymphocytes (CTLs). This finding provides the rationale for developing strategies of adoptive cell therapy to restore virus-specific immune competence. Multiple protocols are under development and available at some centers for the rapid generation of specific CTL lines of donor or third-party origin.

CHAPTER 165

Late Effects of Hematopoietic Stem Cell Transplantation

Rachel A. Phelan, David Margolis

Pediatric hematopoietic stem cell transplantation (HSCT) is considered standard-of-care treatment for a number of malignant and nonmalignant conditions. Treatment generally involves exposure to chemotherapy and occasionally radiation to encourage engraftment of donor stem cells and prevent donor and recipient rejection. The period of time immediately after transplant is associated with the risk for a number of serious acute complications, including profound immunosuppression and subsequent risk for infection, graft-versus-host disease (GVHD), and organ toxicities. Fortunately, significant progress has been made in supportive care strategies to reduce the risk of acute complications and treat them more effectively if they do arise. This has resulted in a growing number of pediatric patients who are now long-term survivors following HSCT. The estimated total number of HSCT survivors in 2009 was 108,900, and this is expected to increase 5 times by 2030 to 502,000. Of these survivors, approximately 14% (64,000) in 2030 will have received a transplant in childhood (<18 yr of age).

Exposure to chemotherapy, radiation, or both places patients at similar long-term risks as the pediatric cancer population; the high doses and types of chemotherapy and radiation often amplify the risk for issues such as ovarian failure/infertility and neurocognitive difficulties. Total body irradiation (TBI) has been shown to increase dramatically the risk for late complications after transplant. In addition, late effects may be additive if the patient received therapy before HSCT for their underlying malignancy. Moreover, the indication for transplant in pediatric patients is not always related to malignancy, but rather an underlying immunodeficiency, bone marrow failure syndrome, or metabolic disorder. These patients are potentially at risk for late effects related to this underlying disease alone and require different types of monitoring.

Essentially, every organ system can be impacted by the long-term effects of therapy, and each must be considered when undergoing late effects surveillance (Table 165.1). As a result of growing evidence of the importance of lifelong care for HSCT survivors, multiple groups have published recent consensus guidelines to help in caring for this patient population. As the field of survivorship continues to expand, *we recommend the following reference for real-time evidence-based recommendations from the* ***Children's Oncology Group*** : http://survivorshipguidelines.org .

Table 165.1

Summary of Late Effects After Hematopoietic Stem Cell Transplantation (HSCT) in Childhood

EXPOSURE	LATE EFFECT*
HSCT experience in general	Dental abnormalities Renal toxicity Hepatic toxicity Low BMD Avascular necrosis Increased risk of second cancers Adverse psychosocial/quality-of-life effects Mental health disorders, risk behaviors Psychosocial disability caused by pain or fatigue
TRANSPLANTATION CONDITIONING	
Alkylating agent	Cataract (busulfan) Pulmonary fibrosis (busulfan) Renal toxicity Urinary tract toxicity Gonadal dysfunction Therapy-related AML/MDS Bladder cancer
Epipodophyllotoxin** DNA intersecting and cross-linking agents (i.e., platinum, heavy metal)	Therapy-related AML/MDS Ototoxicity Renal toxicity Gonadal toxicity
TBI †	Neurocognitive deficits Leukoencephalopathy Cataract Dental abnormalities GH deficiency Hypothyroidism, thyroid nodule Pulmonary toxicity Breast tissue hypoplasia Cardiac toxicity Renal toxicity Gonadal dysfunction

	Uterine vascular insufficiency Diabetes Dyslipidemia Musculoskeletal growth problems Second cancers
PRETRANSPLANTATION EXPOSURES (Not Listed Above)	
Anthracycline/anthraquinone	Cardiac toxicity Therapy-related AML/MDS
Bleomycin	Pulmonary toxicity
Cytarabine	Neurocognitive deficits Leukoencephalopathy
Methotrexate	Neurocognitive deficits Leukoencephalopathy Renal toxicity Low BMD
Corticosteroid	Cataract Low BMD Avascular necrosis
Cranial radiation [‡]	Neurocognitive deficits Leukoencephalopathy Cerebrovascular disease Cataract Craniofacial abnormalities Dental abnormalities, xerostomia GH deficiency Hypothyroidism thyroid nodule Increased obesity Precocious puberty Brain tumor
Spinal radiation (in addition to cranial dose)	Cardiac toxicity Scoliosis/kyphosis, musculoskeletal problems
AFTER TRANSPLANTATION (Not Listed Above)	
Chronic GVHD	Xerophthalmia Xerostomia, dental abnormalities Pulmonary toxicity Gastrointestinal strictures Genitourinary strictures Skin and joint changes Immunodeficiency Second cancers, especially skin, oral, cervical, lymphoma
Tyrosine kinase inhibitor	Acute cardiac toxicity reported, but not known to cause late cardiotoxicity
OTHER EXPOSURES	
Blood transfusions	Hepatitis C, HIV

[*] Focused on those late effects that can develop or persist even after cessation of therapy.

[†] At given total dose, risks greater for single-fraction vs fractionated total body irradiation (TBI); single-fraction myeloablative TBI (>500 cGy) now rarely used.

[‡] Effects listed are those more likely to be associated with doses used in HSCT survivors (e.g., those given for leukemia treatment, <25 Gy); late effects are more likely if TBI also given.

[**] Include etoposide, teniposide.

AML/MDS, Acute myeloid leukemia/myelodysplastic syndrome; BMD, bone mineral density; GH, growth hormone; GVHD, graft-vs-host disease; HIV, human immunodeficiency virus.

From Chow EJ, Anderson L, Baker KS, et al: Late effects surveillance recommendations among survivors of childhood hematopoietic cell transplantation: a Children's Oncology Group report, *Biol Blood Marrow Transplant* 22:783–784, 2016.

Endocrine Effects

Children given HSCT before puberty may develop **growth impairment** , precluding achievement of the genetic target for adult height. The decrease in growth velocity is similar for boys and girls and is more frequently observed in patients given TBI as part of the preparative regimen. Chronic GVHD and its treatment with corticosteroids may also contribute to growth impairment.

Growth impairment of patients given TBI is mainly a result of direct damage of cartilage plates and to the effect of TBI on the hypothalamic-pituitary axis, which leads to an inappropriately low production of **growth hormone** (GH). GH deficiency is susceptible to at least partial correction through administration of hormonal replacement therapy. Annual growth evaluation should be performed in all children after HSCT. Children showing a decreased growth velocity should be further investigated through evaluation of bone age and secretion of GH in response to pharmacologic stimulus.

The use of TBI during the preparative regimen involves the thyroid gland in the irradiation field and may result in **hypothyroidism** . Younger children are at greater risk of developing hypothyroidism. Chemotherapy-only preparative regimens have far fewer adverse effects on normal thyroid function. The site of injury by irradiation is at the level of the thyroid gland rather than at the pituitary or hypothalamus. Therapy with thyroxine is very effective for overt hypothyroidism. The cumulative incidence of hypothyroidism increases over time, underscoring the importance of annual thyroid function studies.

Gonadal hormones are essential for normal pubertal growth, as well as for development of secondary sexual characteristics. A significant proportion of patients receiving TBI-containing preparative regimens as well as high doses of alkylating agents show delayed development of secondary sexual characteristics, resulting from primary ovarian or testicular failure. Laboratory evaluation of these patients reveals elevated follicle-stimulating hormone and luteinizing hormone levels with depressed estradiol and testosterone serum levels. These patients benefit from careful follow-up with evaluation of annual sexual maturity rating (Tanner) scores and endocrine function. Supplementation of gonadal hormones is useful for primary gonadal failure and is administered with GH to promote pubertal growth. **Infertility** during adulthood remains a common problem of these children, especially those undergoing traditional myeloablative conditioning for HSCT. The use of reduced-intensity regimens may result in sparing fertility in a large proportion of patients, although conditioning regimens vary and studies are limited.

Bone health of HSCT survivors can also be impacted by hormonal changes as well as lifestyle practices, such as inadequate exercise and/or dietary intake of vitamin D. Prior exposures, including corticosteroid use, can result in changes to bone density as well as predispose to the development of avascular necrosis. Dual-energy x-ray absorptiometry (DXA) scans are routinely incorporated into the care of those patients at risk for low bone mineral density.

Cardiovascular Effects

Survivors of childhood HSCT are at risk for the future development of cardiovascular complications. This population can be prone to developing **metabolic syndrome** (dyslipidemia, hypertension, diabetes mellitus, obesity), especially those with a history of TBI exposure and subsequent hormonal derangements. Prior exposures such as anthracycline chemotherapy and chest radiation further increase the risk for **cardiomyopathy** as well as **atherosclerosis** . As a result, routine anthropometric, imaging, and laboratory screening should be performed in survivors of childhood HSCT to assess and monitor their cardiovascular health.

Secondary Malignancy

The overall risk of developing a secondary form of cancer is significantly higher after HSCT than in the general population. Although few studies have specifically analyzed pediatric patients, available evidence indicates that the cumulative incidence of 2nd malignancies shows a slight, but continuous, tendency to increase over time. The development of myelodysplastic syndrome as well as secondary leukemias must be considered in survivors of HSCT. Several other types of secondary tumors have been identified in patients given HSCT. The most frequently diagnosed neoplasms are thyroid carcinoma, brain tumors, and epithelial cancers. Young age, male gender, use of TBI during the preparative regimen, chronic GVHD, and an intrinsic genetic predisposition to develop cancer (Fanconi anemia) have been reported to be risk factors for development of secondary malignancies after HSCT. Routine physical exams, including yearly skin in exams in those that received TBI are important in the care of these patients.

Graft-Versus-Host Disease

In the posttransplant period, multiple studies have shown that quality of life is severely impacted by the presence of GVHD**,** which is an issue that is also unique to HSCT (see Chapter 163).

Other Effects

HSCT patients can also experience complications related to their pulmonary function, renal function, dental health, and gastrointestinal system, often related to prior exposures as well as their conditioning regimen. It is also important to note that long-term survivors must be monitored for psychological issues because of their prior and current underlying health conditions. They may need extra assistance with school and vocational attainment. These patients are also often at higher risk for depression and anxiety; yearly psychosocial assessments can identify survivors who need additional therapy or psychotropic medication. Parents may also have posttraumatic stress from the experience.

Special Considerations

Certain patient populations who undergo HSCT are at increased risk for late effects. Young children appear to be at a heightened risk for late complications related to TBI, especially those related to growth, thyroid function, and neurocognition. Patients with an **underlying genetic condition** must also be monitored more closely for specific consequences of therapy, such as specific secondary malignancies in the Fanconi anemia population caused by an underlying DNA repair defect and patients with sickle cell anemia and thalassemia who are predisposed to iron overload.

CHAPTER 166

Allergy and the Immunologic Basis of Atopic Disease

Cezmi A. Akdis, Scott H. Sicherer

Allergic or atopic patients have an altered state of reactivity to common environmental and food antigens that do not cause clinical reactions in unaffected people. Patients with clinical allergy usually produce immunoglobulin E (IgE) antibodies to the antigens that trigger their illness. The term *allergy* represents the clinical expression of IgE-mediated allergic diseases that have a familial predisposition and that manifest as hyperresponsiveness in target organs such as the lung, skin, gastrointestinal (GI) tract, and nose. The significant increase in the prevalence of allergic diseases in the last few decades is attributed to changes in environmental factors such as exposure to tobacco smoke, air pollution, indoor and outdoor allergens, respiratory viruses, obesity, and perhaps a decline in certain infectious diseases (hygiene hypothesis).

Key Elements of Allergic Diseases

Allergens

Allergens are almost always *proteins*, but not all proteins are allergens. For a protein antigen to display allergenic activity, it must induce IgE production, which must lead to a type 1 hypersensitivity response on subsequent exposure to the same protein. Biochemical properties of the allergen; stimulating factors of the innate immune response around the allergen substances at the time of exposure; stability of the allergen in the tissues, digestive system, skin, or mucosa; and the dose and time of stay in lymphatic organs during the interaction with the immune system are factors that may cause an antigen to become an allergen. This is distinguished from general antigen responses, which induce a state of immune responsiveness without associated IgE production.

Most allergens are proteins with molecular weight of 10-70 kDa. Molecules <10 kDa do not bridge adjacent IgE antibody molecules on the surfaces of mast cells or basophils. Most molecules >70 kDa do not pass through mucosal surfaces, a feature needed to reach **antigen-presenting cells (APCs)** for stimulation of the immune system. Allergens frequently contain **proteases** , which promote skin and mucosal epithelial barrier dysfunction and increase allergen penetration into host tissues. Low-molecular-weight moieties, such as drugs, can become allergens by reacting with serum proteins or cell membrane proteins to be recognized by the immune system. Carbohydrate structures can also be allergens and are most relevant with the increasing use of *biologics* in clinical practice; patients with cetuximab-induced anaphylaxis have IgE antibodies specific for galactose-α-1,3-galactose.

T Cells

Everyone is exposed to potential allergens. Atopic individuals respond to allergen exposure with rapid expansion of **T-helper type 2 (Th2)** cells that secrete cytokines, such as interleukin (IL)-4, IL-5, and IL-13, favoring IgE synthesis and eosinophilia. Allergen-specific IgE antibodies associated with atopic response are detectable by serum testing or positive immediate reactions to allergen extracts on skin-prick testing. The Th2 cytokines IL-4 and IL-13 play a key role in immunoglobulin isotype switching to IgE (Fig. 166.1). IL-5 and IL-9 are important in differentiation and development of eosinophils. The combination of IL-3, IL-4, and IL-9 contributes to mast cell activation. IL-9 is responsible for mucus production. Th2 cytokines are important effector molecules in the pathogenesis of asthma and allergic diseases; acute allergic reactions are characterized by infiltration of Th2 cells into affected tissues. In addition, IL-25, IL-33, and **thymic stromal lymphopoietin (TSLP)** secreted from epithelial cells on exposure to allergens and respiratory viruses contribute to Th2 response and eosinophilia.

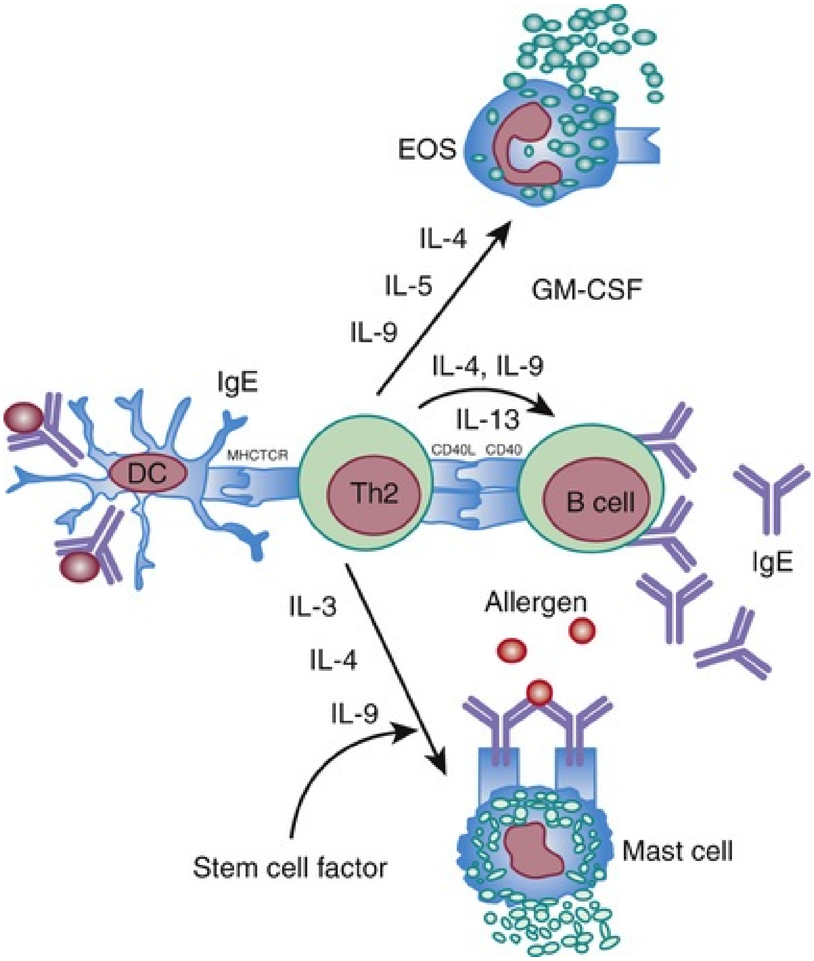

FIG. 166.1 **Role of Th2 cytokines in allergic cascade. DC, Dendritic cell; EOS, eosinophil; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; Th2, T-helper type 2 cell.**

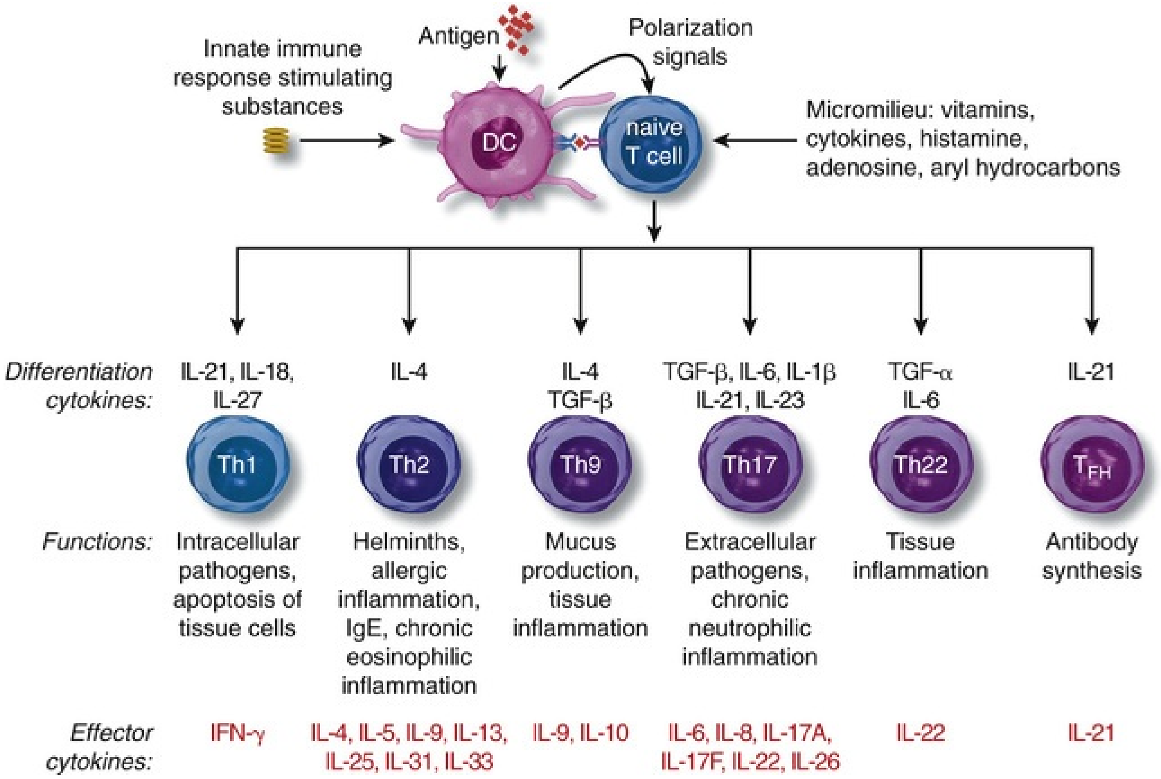
A fraction of the immune response to allergen results in proliferation of **T-helper type 1 (Th1)** cells. Th1 cells are typically involved in the eradication of intracellular organisms, such as mycobacteria, because of the ability of Th1 cytokines to activate phagocytes and promote the production of opsonizing and complement-fixing antibodies. The Th1 component of allergen-specific immune response contributes to chronicity and the effector phase in allergic disease. Activation and apoptosis of epithelial cells induced by Th1 cell–secreted interferon-γ (IFN-γ), tumor necrosis factor (TNF)-α, and Fas ligand constitute an essential pathogenetic event for the formation of eczematous lesions in atopic dermatitis and bronchial epithelial cell shedding in asthma.

Chronic lesions of allergic reactions are characterized by infiltration of Th1 and **Th17 cells** . This is important because Th1 cytokines such as IFN-γ can potentiate the function of allergic inflammatory effector cells such as eosinophils and thereby contribute to disease severity. Th17 and Th22 cells link the immune response to tissue inflammation; IL-17A and IL-17F and IL-22 are their respective prototype cytokines. Although both T-helper cell subsets play roles in immune defense to extracellular bacteria, IL-17 augments inflammation, whereas IL-22 plays a tissue-protective role. Cytokines in the IL-17 family act on multiple cell types, including epithelial cells and APCs, to cause the release of chemokines, antimicrobial peptides, and proinflammatory cytokines to enhance inflammation and antimicrobial responses. In addition, Th9 cells produce IL-9, but not other typical Th1, Th2, and Th17 cytokines, and constitute a distinct population of effector T cells that promotes tissue inflammation. Fig. 166.2 depicts the complex cytokine cascades involving Th1, Th2, Th9, Th17, and Th22 cells.



Antigen
Polarization signals

FIG. 166.2 Effector T-cell subsets. Following antigen presentation by dendritic cells (DCs), naïve T cells differentiate into Th1, Th2, Th9, Th17, Th22, and follicular helper (TFH) effector subsets. Their differentiation requires cytokines and other cofactors that are released from DCs and also expressed in the micromilieu. T-cell activation in the presence of interleukin-4 (IL-4) enhances differentiation and clonal expansion of Th2 cells, perpetuating the allergic response. IFN-γ, Interferon-γ; TGF-β, transforming growth factor-β. (From Akdis M, Palomares O, van de Veen W, et al: TH17 and TH22 cells: a confusion of antimicrobial response with tissue inflammation versus protection, *J Allergy Clin Immunol* 129:1438–1449, 2012.)

T-regulatory (or regulatory T) **cells (Tregs)** are a subset of T cells thought to play a critical role in expression of allergic and autoimmune diseases. These cells have the ability to suppress effector T cells of Th1, Th2, Th9, Th17, and Th22 phenotypes (Fig. 166.3). Tregs express $CD4^+$ $CD25^+$ surface molecules and immunosuppressive cytokines such as IL-10 and transforming growth factor-β (TGF-β_1). The forkhead box/winged-helix transcription factor gene *FOXP3* is expressed specifically by $CD4^+$ $CD25^+$ Tregs and programs their development and function. Adoptive transfer of Tregs inhibits the development of airway eosinophilia and protects against airway hyperreactivity in animal models of asthma. T-cell response to allergens in healthy individuals shows a wide range, from no detectable response to involvement of active peripheral tolerance mechanisms mediated by different subsets of Tregs. Individuals who are not allergic even though they are exposed to high doses of allergens, such as beekeepers and cat owners, show a detectable allergen-specific IgG4 response accompanied by IL-10–producing Tregs. It is thought that $CD4^+$ $CD25^+$ Tregs play an important role in mitigating the allergic immune response, and that the lack of such cells may predispose to the development of allergic diseases. Patients with mutations in the human *FOXP3* gene lack $CD4^+$ $CD25^+$ Tregs and develop severe immune dysregulation, with polyendocrinopathy, food allergy, and high serum IgE levels (XLAAD/IPEX disease) (see Chapter 152). In addition to Treg cells, IL-10–secreting and allergen-specific Breg cells increase during allergen-specific immunotherapy and may play a role in allergen tolerance.

FIG. 166.3 Control of allergen-specific immune responses. FoxP3$^+$, CD4$^+$, CD25$^+$, and Tr1 cells contribute to the control of allergen-specific immune responses in several major ways: Suppression of dendritic cells (DCs) that support the generation of effector T cells; suppression of Th1, Th2, and Th17 cells; suppression of allergen-specific IgE, and induction of IgG$_4$ and/or IgA; suppression of mast cells, basophils, and eosinophils; interaction with resident tissue cells and remodeling, and suppression of effector T-cell migration to tissues. IL-10, Interleukin-10. (From Akdis CA, Akdis M: Mechanisms and treatment of allergic disease in the big picture of regulatory T cells, *J Allergy Clin Immunol* 123:735–746, 2009.)

Innate Lymphoid Cells

Immune responses in populations of lymphoid cells that lack rearranged T- and B-cell antigen receptors and surface markers for myeloid and lymphoid lineages, such as T, B, and natural killer (NK) cells, show similarities to Th1, Th2, and Th17/Th22 types of immune responses. These latter cells are defined as the innate lymphoid cells **ILC1s, ILC2s,** and **ILC3s,** respectively, based on their transcription factors and cytokine production patterns. ILC1s mainly produce IFN-γ; ILC2s produce IL-5, IL-9, and IL-13; and ILC3s produce IL-17 and IL-22 without any need of antigen/allergen exposure. Strong evidence indicates that ILCs play substantial roles in protection against infection and the pathogenesis of inflammatory diseases, such as asthma, allergic diseases, and autoimmune diseases. ILCs control the mucosal environment through close interaction with epithelial cells and other tissue cells, cytokine production, and induction of chemokines that recruit suitable cell populations to initiate and promote distinct types of immune response development and tissue inflammation. ILC2s are likely involved in the induction of asthma, allergic rhinitis, eosinophilic esophagitis, and atopic dermatitis through activation by epithelium-derived cytokines (e.g., IL-33, IL-25, TSLP) and interaction with other immune cells.

Antigen-Presenting Cells

Dendritic cells (DCs), Langerhans cells, monocytes, and macrophages have the ability to present allergens to T cells and thereby modulate allergic inflammation by controlling the type of T-cell development. APCs are a heterogeneous group of cells that share the property of antigen presentation in the context of the major histocompatibility complex (MHC) and are found primarily in lymphoid organs and the skin. DCs and Langerhans cells are unique in their ability to prime naïve T cells and are responsible for the primary immune response, or the **sensitization phase** of allergy. Monocytes and macrophages are thought to contribute to activating memory T-cell responses on reexposure to allergen, which characterizes the **elicitation phase** of allergy.

Peripheral DCs residing in sites such as the skin, intestinal lamina propria, and lung are relatively immature. These immature DCs take up antigens in tissues and then migrate to the T-cell areas in locally draining lymph nodes. The DCs undergo phenotypic and functional changes during migration, characterized by increased expression of MHC class I, MHC class II, and co-stimulatory molecules that react with CD28 expressed on T cells. In the lymph nodes, they directly present processed antigens to resting T cells to induce their proliferation and differentiation.

Mature DCs have been designated as **myeloid** or **plasmacytoid** on the basis of their ability to favor Th1 or Th2 differentiation, respectively. The critical factor for polarization to Th1 cells is the level of IL-12 produced by myeloid DC. By contrast, plasmacytoid DCs have low levels of IL-12. Plasmacytoid DC particularly play a role in antiviral immunity by rapid production of high amounts of IFN-α and also help B cells for antibody production. There is considerable interest in the role of TSLP, which is overexpressed in the mucosal surfaces and skin of atopic individuals. TSLP enhances Th2 differentiation by inducing expression of OX40L on immature myeloid DCs in the absence of IL-12 production.

Presence of allergen-specific IgE on the cell surfaces of APCs is a unique feature of atopy. Importantly, the formation of high-affinity IgE receptor I (**FcεRI**)/IgE/allergen complexes on APC surfaces greatly facilitates allergen uptake and presentation. The clinical importance of this phenomenon is supported by the observation that FcεRI-positive Langerhans cells bearing IgE molecules are a prerequisite for skin-applied, aeroallergen provocation of eczematous lesions in patients with atopic dermatitis. The role of the low-affinity IgE receptor II (**FcεRII, CD23**) on monocytes/macrophages is less clear, although under certain conditions it apparently can also facilitate antigen capture. Cross-linking of FcεRII, as well as FcεRI, on monocytes/macrophages leads to the release of inflammatory mediators. There is a critical role for DCs in induction of oral tolerance; tolerogenic DCs are compartmentalized within the mucosa and present antigen through a mechanism designed to produce a Th1/Treg-suppressive response that ablates allergen-specific T cells.

Immunoglobulin E and Its Receptors

The acute allergic response depends on IgE and its ability to bind selectively to the α chain of the high-affinity FcεRI or the low-affinity FcεRII (CD23). Cross-linking of receptor-bound IgE molecules by allergen initiates a complex intracellular signaling cascade, followed by the release of various mediators of allergic inflammation from mast cells and basophils. The FcεRI molecule is also found on the surface of antigen-presenting DCs (e.g., Langerhans cells), but differs from the structure found on mast cells/basophils in that the FcεRI molecule found on DCs lacks the β chain. CD23 is found on B cells, eosinophils, platelets, and DCs. Cross-linking and FcεRI aggregation on mast cells and basophils can also lead to anaphylaxis (see Chapter 174). Differential expression of tyrosine kinases responsible for positive and negative regulation of mast cell/basophil degranulation are thought to be responsible for this aberrant allergic response.

The induction of IgE synthesis requires 2 major signals. The 1st signal (signal 1) initiates IL-4 or IL-13 activation of germline transcription at the ε Ig locus, which dictates isotype specificity. The 2nd signal (signal 2) involves the engagement of CD40 on B cells by CD40 ligand expressed on T cells. This engagement results in activation of the recombination machinery, resulting in

DNA switch recombination. Interactions between several co-stimulatory molecule pairs (CD28 and B7; lymphocyte function–associated antigen-1 and intercellular adhesion molecule-1; CD2 and CD58) can further amplify signal 1 and signal 2 to enhance IgE synthesis. Factors that inhibit IgE synthesis include Th1-type cytokines (IL-12, IFN-α, IFN-γ), IL-10 from Tregs, Breg cells, as well as regulatory DCs and microbial DNA containing CpG (cytosine-phosphate-guanine) repeats.

Eosinophils

Allergic diseases are characterized by peripheral blood and tissue eosinophilia. Eosinophils participate in both innate and adaptive immune responses and, like mast cells, contain dense intracellular granules that are sources of inflammatory proteins (see Fig. 155.1). These granule proteins include major basic protein, eosinophil-derived neurotoxin, peroxidase, and cationic protein. Eosinophil granule proteins damage epithelial cells, induce airway hyperresponsiveness, and cause degranulation of basophils and mast cells. Major basic protein released from eosinophils can bind to an acidic moiety on the M2 muscarinic receptor and block its function, thereby leading to increased acetylcholine levels and the development of increased airway hyperreactivity. Eosinophils are also a rich source of prostaglandins and leukotrienes; in particular, cysteinyl leukotriene C4 contracts airway smooth muscle and increases vascular permeability. Other secretory products of eosinophils include cytokines (IL-4, IL-5, TNF-α), proteolytic enzymes, and reactive oxygen intermediates, all of which significantly enhance allergic tissue inflammation.

Several cytokines regulate the function of eosinophils in allergic disease. Eosinophils develop and mature in the bone marrow from myeloid precursor cells activated by IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Allergen exposure of allergic patients causes resident hematopoietic CD34 cells to express the IL-5 receptor. The IL-5 receptor activation induces eosinophil maturation, causing eosinophils to synthesize granule proteins, prolonging their survival, potentiating degranulation of eosinophils, and stimulating release of eosinophils from the bone marrow. GM-CSF also enhances proliferation, cell survival, cytokine production, and degranulation of eosinophils. Certain chemokines, such as RANTES (regulated on activation, normal T-cell expressed and secreted), macrophage inflammatory protein-1α (MIP-1α), and eotaxins, are important for recruiting eosinophils into local allergic tissue inflammatory reactions. Eotaxins mobilize IL-5–dependent eosinophil colony–forming progenitor cells from the bone marrow. These progenitors are rapidly cleared from the blood and either return to the bone marrow or are recruited to inflamed tissue sites.

Mast Cells

Mast cells are derived from CD34 hematopoietic progenitor cells that arise in bone marrow. On entering the circulation, they travel to peripheral tissue, where they undergo tissue-specific maturation. Mast cell development and survival relies on interactions between the tyrosine kinase receptor c-kit expressed on the surface of mast cells and the fibroblast-derived c-kit ligand, the stem cell factor. Unlike mature basophils, mature mast cells do not typically circulate in the blood. They are instead widely distributed throughout connective tissues, where they often lie adjacent to blood vessels and beneath epithelial surfaces that are exposed to the external environment, such as the respiratory tract, gastrointestinal (GI) tract, and skin. So placed, mast cells are positioned anatomically to participate in allergic reactions. At least 2 subpopulations of human mast cells are recognized: mast cells with tryptase and mast cells with both tryptase and chymase. Mast cells with tryptase are the predominant type found in the lung and small intestinal mucosa, whereas mast cells with both tryptase and chymase are the predominant type found in skin, the GI submucosa, and blood vessels.

Mast cells contain, or produce on appropriate stimulation, a diverse array of mediators that have different effects on allergic inflammation and organ function. They include preformed granule-associated mediators (histamine, serine proteases, proteoglycans) and membrane-derived lipid, cytokine, and chemokine mediators arising from de novo synthesis and release. The most important mast cell–derived lipid mediators are the **cyclooxygenase** and **lipoxygenase** metabolites of arachidonic acid, which have potent inflammatory activities. The major cyclooxygenase product of mast cells is **prostaglandin D_2** , and the major lipoxygenase products are the sulfidopeptide **leukotrienes** (LTs): LTC_4 and its peptidolytic derivatives LTD_4 and LTE_4 . Mast cells also can produce cytokines that promote Th2-type responses (IL-4, IL-13, GM-CSF) and inflammation (TNF-α, IL-6) and regulate tissue remodeling (TGF, vascular endothelial cell growth factor). Immunologic activation of mast cells and basophils typically begins with cross-linkage of IgE bound to the FcεRI with multivalent allergen. Mast cell surface FcεRI is increased by IL-4 and IgE. Surface levels of FcεRI decrease in patients receiving treatment with anti-IgE antibody that lowers serum IgE, which is of potential therapeutic interest.

Mechanisms of Allergic Tissue Inflammation

IgE-mediated immune responses can be classified chronologically according to 3 reaction patterns. The **early-phase response** is the immediate response after allergen is introduced into target organs. This response is characterized by mast cell degranulation and release of preformed mediators, occurring within an immediate time frame of 1-30 min after allergen exposure and resolving within 1-3 hr. Acute reactions are associated with increased local vascular permeability, which leads to leakage of plasma proteins, tissue swelling, and increased blood flow, as well as itching, sneezing, wheezing, and acute abdominal cramps in the skin, nose, lung, and GI tract, respectively, depending on the targeted organ.

A 2nd, **late-phase response** can occur within hours of allergen exposure, reaching a maximum at 6-12 hr and resolving by 24 hr. Late-phase responses are characterized in the skin by edema, redness, and induration; in the nose by sustained nasal blockage; and in the lung by airway obstruction and persistent wheezing. In general, late-phase responses are associated with early infiltration of neutrophils and eosinophils, followed by basophils, monocytes, macrophages, and Th2-type cells. Recruitment of inflammatory cells from the circulation requires increased expression of adhesion molecules on their cell surfaces and expression of their ligand on endothelial cells, which are under the control of cytokines. Several hours after allergen exposure, TNF-α released by activated mast cells induces the vascular endothelial expression of cell adhesion molecules, and this change leads to transendothelial migration of various inflammatory cells. Preferential accumulation of eosinophils occurs through interactions between selective adhesion molecules on the eosinophil cell surface (e.g., α_4 β_1 integrin or very late antigen-4); vascular cell adhesion molecule-1 surface expression can be enhanced by IL-4 and IL-13 on endothelial cells. ILC2s receive signals from the epithelial cells, such as IL-33, TSLP, and IL-25, and are activated and start to release their cytokines IL-5 and IL-13 to initiate a type 2 immune response.

Chemokines are chemotactic cytokines that play a central role in tissue-directed migration of inflammatory cells. RANTES, MIP-1α, monocyte chemotactic protein (MCP)-3, and MCP-4 are chemoattractants for eosinophils and mononuclear cells, whereas eotaxins are relatively selective for eosinophils. These chemoattractants have been detected in epithelium, macrophages, lymphocytes, and eosinophils at sites of late-phase responses and allergic tissue inflammation. Blockade of these chemokines leads to significant reduction in tissue-directed migration of allergic effector cells.

In the 3rd reaction pattern, **chronic allergic disease** , tissue inflammation can persist for days to years. Several factors contribute to persistent tissue inflammation, including recurrent exposure to allergens and microbial agents. The repeated stimulation of allergic effector cells such as mast cells, basophils, eosinophils, and Th2 cells contributes to unresolved inflammatory conditions. Additionally, Th2-type cytokines (IL-3, IL-5, GM-CSF) secreted during allergic reactions can prolong survival of allergic effector cells by delaying apoptosis. Local differentiation of tissue-infiltrating eosinophil precursors induced by IL-5 results in self-generation of eosinophils, further sustaining damage of local tissue. Tissue remodeling leading to irreversible changes in target organs is also a feature of chronic allergic disease. In asthma, **remodeling** involves thickening of the airway walls and submucosal tissue, as well as smooth muscle hypertrophy and hyperplasia, which are associated with a decline in lung function. This is an unexpected role for eosinophils in airway remodeling as well as chronic inflammation. In atopic dermatitis, lichenification is an obvious manifestation of skin remodeling.

Generally, it is considered that a type 2 immune response underlines a majority of asthma cases, atopic dermatitis, chronic rhinosinusitis, and allergic rhinitis as a general characteristic of an immune/inflammatory response. Type 2 immune response involves Th2 cells, type 2 B cells, ILC2, IL-4 secreting NK T cells, basophils, eosinophils and mast cells and their major cytokines. From a complex network of cytokines, IL-4, IL-5, IL-9, and IL-13 are mainly secreted from the immune system cells, and IL-25, IL-31, IL-33, and TSLP from tissue cells, particularly epithelial cells. Many asthma-related antigens, such as protease allergens, fungal extracts, and viral infection, trigger IL-33, TSLP, and IL-25 production from epithelial cells and various immune cells and induce eosinophilic asthma–like airway inflammation through activation of lung ILC2s.

IL-31, on the other hand, plays a role in pruritus in atopic dermatitis. Th2 cytokines do not only maintain allergic inflammation but also influence tissue remodeling by activating resident cells in target organs; IL-4, IL-9, and IL-13 induce mucus hypersecretion and metaplasia of mucus cells; IL-4 and IL-13 stimulate fibroblast growth and synthesis of extracellular matrix proteins; and IL-5 and IL-9 increase subepithelial fibrosis. TGF-β produced by eosinophils and fibroblasts can also enhance subepithelial fibrosis. IL-11 expressed by eosinophils and epithelial cells contributes to subepithelial fibrosis, in addition to enhancing deposition of collagen and the accumulation of fibroblasts. The resulting tissue injury amplifies further epithelial injury through proinflammatory cytokine release, extracellular matrix deposition in target organs, and angiogenesis. Genetic predisposition to aberrant injury-repair responses may contribute to chronicity of illness. Once the allergic immune response is established, it can be self-perpetuating due to a general type 2 immune response and can lead to chronic disease in genetically predisposed individuals. The subsequent infiltration of Th1 cells and Th17 cells enhances the inflammatory potential of allergic effector cells and contributes to chronic tissue inflammatory responses through the release of proinflammatory cytokines and chemokines. In addition, an autoimmune response might be playing a causative role in allergic inflammation resulting from possible mechanisms through IgE autoantibodies, IgG autoantibodies, and Th1-cell and Th17-cell autoreactivity.

Genetic Basis of Atopy

Allergic diseases are complex genetic conditions susceptible to environmental triggers. Several major groups of genes are associated with allergic diseases: genes that regulate systemic expression of atopy (increased IgE synthesis, eosinophilia, mast cell responses) and that are usually expressed among various allergic diseases, genes that control barrier function in specific target organs (e.g., skin in atopic dermatitis, lung in asthma, GI tract in food allergy), and genes encoding pattern-recognition receptors of the innate immune system that engage microbial pathogens and influence adaptive immune responses. Once allergic responses have been initiated, a genetic predisposition to chronic allergic inflammation and aberrant injury-repair responses contribute to tissue remodeling and persistent disease.

Atopic diseases have a strong familial predisposition, with approximately 60% heritability found in twin studies of asthma and atopic dermatitis. The 5q23-35 region comprises several genes implicated in allergic disease pathogenesis, including genes coding for Th2 cytokines (IL-3, IL-4, IL-5, IL-9, IL-13, GM-CSF). Among these, *IL4* is a well-studied potential candidate gene. A nucleotide change at position 589 of the *IL4* promoter region is associated with the formation of a unique binding site for NF-AT (**n** uclear **f** actor for **a** ctivated **T** cells) transcription factor, increased IL-4 gene transcription, higher NF-AT binding affinity, and increased IgE production. Similarly, *IL13* coding region variants have been associated with asthma and atopic dermatitis. An association has been found between atopy and a gain-of-function polymorphism on chromosome 16, which codes for the α subunit of the IL-4R. This finding is consistent with the important role of IL-4, IL-13, and their receptors in the immunopathogenesis of allergic diseases.

Genome-wide searches have also linked atopy to chromosome region 11q13. The gene encoding the β subunit of FcεRI-β has been proposed to be the candidate gene in this region. The β subunit gene modifies the FcεRI activity on mast cells, and several genetic variants of FcεRI-β are associated with asthma and atopic dermatitis. Chromosome 6 contains genes coding for human leukocyte antigen class I and class II molecules, which regulate the specificity and intensity of the immune responses to specific allergens. IgE responses to specific allergens, such as ragweed antigen Amb a V and mite allergen *Der p* I, have been linked to specific MHC class II loci. TNF-α, a key cytokine that contributes to the influx of inflammatory cells, is also located on chromosome 6. TNF-α polymorphisms are associated with asthma. A recent genome-wide association study showed that genetic polymorphisms in the gene encoding IL-33, which is a major activator of ILC2s, and its receptor IL-1RL1 (ST2) are strongly linked to asthma development.

Barrier dysfunction has a key role in the pathogenesis of allergic diseases. Genetic linkage studies of atopic dermatitis have demonstrated the importance of chromosome 1q21, which contains a cluster of genes involved in epidermal differentiation. **Filaggrin** is a protein that is essential in the formation of the stratum corneum. Null mutations of the filaggrin gene are strongly associated with early onset and severe atopic dermatitis. Mutations in the gene encoding the serine protease inhibitor SPINK5 has been shown to cause **Netherton disease** , a single-gene disorder associated with erythroderma, food allergy, and high serum IgE levels. A common polymorphism in SPINK5 (in particular, Glu420Lys) increases the risk of developing atopic dermatitis and asthma. SPINK5 is expressed in the outer epidermis and is thought to be critical to neutralizing the proteolytic activity of *Staphylococcus aureus* and common allergens such as *Der p* I, which use these proteases to penetrate the skin to induce allergic responses. Barrier dysfunction is involved in other allergic diseases, such as asthma and rhinosinusitis, but likely involves other barrier genes, such as those encoding gap junctions.

Candidate genes associated with asthma susceptibility have been identified by positional cloning: *GPRA* (G-protein coupled receptor for asthma susceptibility on chromosome 7p14), *ADAM-33* (a disintegrin and metalloproteinase 33 on chromosome 20p), and *DPP10* (dipeptidyl peptidase 10 on chromosome 2q14). The functions of these genes do not fit into classical pathways of atopy and therefore provide new insights into asthma pathogenesis. *GPRA* encodes a G-protein coupled receptor, with isoforms expressed in bronchial epithelial cells and smooth muscle in asthmatic persons, suggesting an important role for these tissues in asthma. *ADAM-33* is expressed in bronchial smooth muscle and has been linked to bronchial hyperresponsiveness. *DPP10* encodes a dipeptidyl dipeptidase that can remove the terminal 2 peptides from certain proinflammatory chemokines, a change that may modulate allergic inflammation.

Pattern-recognition receptors of the innate immune system, which are expressed by epithelial cells and DCs, are associated with disease susceptibility. These receptors recognize specific microbial components. Polymorphisms in CD14 (engages endotoxin), Toll-like receptor 2 (which engages *S. aureus*), and T-cell immunoglobulin domain and mucin domain (which engage hepatitis A virus) correlate with asthma and/or atopic dermatitis susceptibility. Dysregulation of these frontline immune defense systems would permit abnormal response to common environmental allergens.

CHAPTER 167

Diagnosis of Allergic Disease

Supinda Bunyavanich, Jacob Kattan, Scott H. Sicherer

Allergy History

Obtaining a complete history from the allergic patient involves eliciting a description of all symptoms along with their timing and duration, exposure to common allergens, and responses to previous therapies. Because patients often suffer from more than one allergic disease, the presence or absence of other allergic diseases, including allergic rhinoconjunctivitis, asthma, food allergy, eosinophilic esophagitis, atopic dermatitis, and drug allergy, should be determined. A family history of allergic disease is common and is one of the most important factors predisposing a child to the development of allergies. The risk of allergic disease in a child approaches 50% when 1 parent is allergic and 66% when both parents are allergic, with maternal history of atopy having a greater effect than paternal history.

Several characteristic behaviors are often seen in allergic children. Because of nasal pruritus and rhinorrhea, children with allergic rhinitis often perform the **allergic salute** by rubbing their nose upward with the palm of their hand. This repeated maneuver may give rise to the **nasal crease** , a horizontal wrinkle over the bridge of the nose. Characteristic vigorous **grinding** of the eyes with the thumb and side of the fist is frequently observed in children with allergic conjunctivitis. The **allergic cluck** is produced when the tongue is placed against the roof of the mouth to form a seal and withdrawn rapidly in an effort to scratch the palate. The presence of other symptoms, such as fever, unilateral nasal obstruction, and purulent nasal discharge, suggests other diagnoses.

The timing of onset and the progression of symptoms are relevant. The onset of recurrent or persistent nasal symptoms coinciding with placement in a daycare center might suggest recurrent infection rather than allergy. When patients present with a history of episodic acute symptoms, it is important to review the setting in which symptoms occur as well as the activities and exposures that immediately precede their onset. Symptoms associated with lawn mowing suggest allergy to grass pollen or fungi, whereas if symptoms occur in homes with pets, animal dander sensitivity is an obvious consideration. Reproducible reactions after ingestion of a specific food raise the possibility of food allergy. When symptoms wax and wane but evolve gradually and are more chronic in duration, a closer look at whether the timing and progression of symptoms correlate with exposure to a seasonal aeroallergen is warranted.

Aeroallergens , such as pollens and fungal spores, are prominent causes of allergic disease. The concentrations of these allergens in outdoor air fluctuate seasonally. Correlating symptoms with seasonal pollination patterns of geographically relevant plants and trees along with information provided by local pollen counts can aid in identifying the allergen. Throughout most of the United States, trees pollinate in the early spring, grasses pollinate in the late spring and early summer, and weeds pollinate in late summer through the fall. The presence of fungal spores in the atmosphere follows a seasonal pattern in the northern United States, with spore counts rising with the onset of warmer weather and peaking in late summer months, only to recede again with the first frost through the winter. In warmer regions of the southern United States, fungal spores and grass pollens may cause symptoms on a perennial basis.

Rather than experiencing seasonal symptoms, some patients suffer allergic symptoms year-round. In these patients, sensitization to perennial allergens usually found indoors, such as dust mites, animal dander, cockroaches, and fungi, warrants consideration. Species of certain fungi, such as *Aspergillus* and *Penicillium,* are found indoors, whereas *Alternaria* is found in both indoor and outdoor environments. Cockroach and rodent allergens are often problematic in inner-city environments. Patients sensitive to perennial allergens often also become sensitized to seasonal allergens and experience baseline symptoms year-round with worsening during the pollen seasons.

The age of the patient is an important consideration in identifying potential allergens. Infants and young children are first sensitized to allergens that are in their environment on a continuous basis, such as dust mites, animal dander, and fungi. Sensitization to seasonal allergens usually takes several seasons of exposure to develop and is thus unlikely to be a significant trigger of symptoms in infants and toddlers.

Food allergies are more common in infants and young children, resulting primarily in cutaneous, gastrointestinal, and, less frequently, respiratory and cardiovascular symptoms. Symptoms of immediate or IgE-mediated hypersensitivity food reactions develop within minutes to 2 hr after ingestion of the offending food. Symptoms of non–IgE-mediated food allergies are often delayed or chronic (see Chapter 176).

Complete information from previous evaluations and prior treatments for allergic disease should be reviewed, including impact of changes in local environment (e.g., home vs school), response to medications, elimination diets, and duration and impact of allergen immunotherapy (if applicable). Improvement in symptoms with medications or avoidance strategies used to treat allergic disease provides additional evidence for an allergic process.

A thorough environmental survey should be performed, focusing on potential sources of allergen and/or irritant exposure, particularly when respiratory symptoms (upper/lower) are reported. The age and type of the dwelling, how it is heated and cooled, the use of humidifiers or air filtration units, and any history of water damage should be noted. Forced air heating may stir up dust mite, fungi, and animal allergens. The irritant effects of wood-burning stoves, fireplaces, and kerosene heaters may provoke respiratory symptoms. Increased humidity or water damage in the home is often associated with greater exposure to dust mites and fungi. Carpeting serves as a reservoir for dust mites, fungi, and animal dander. The number of domestic pets and their movements about the house should be ascertained. Special attention should be focused on the bedroom, where a child spends a significant proportion of time. The age and type of bedding, the use of dust mite covers on pillows and mattresses, the number of stuffed animals, type of window treatments, and the accessibility of pets to the room should be reviewed. The number of smokers in the home, and what and where they smoke is useful information. Activities that might result in exposure to allergens or respiratory irritants such as paint fumes, cleansers, sawdust, or glues should be identified. Similar information should be obtained in other environments where the child spends long periods, such as a relative's home or school setting.

Physical Examination

In patients with **asthma** , *spirometry* should be performed. If **respiratory distress** is observed, *pulse oximetry* should be performed.

The child presenting with a chief complaint of rhinitis or rhinoconjunctivitis should be observed for mouth breathing, paroxysms of sneezing, sniffing/snorting, throat clearing, and rubbing of the nose and eyes (representing pruritus). Infants should be observed during feeding for nasal obstruction severe enough to interfere with feeding or for more obvious signs of aspiration or gastroesophageal reflux. The frequency and nature of coughing that occurs during the interview and any positional change in coughing or wheezing should be noted. Children with asthma should be observed for congested or wet cough, tachypnea at rest, retractions, and audible wheezes, which may worsen with crying. Patients with atopic dermatitis should be monitored for repetitive scratching and the extent of skin involvement.

Because children with severe asthma as well as those receiving chronic or frequent oral corticosteroids may experience growth suppression, an accurate height should be plotted at regular intervals. Long-term follow-up studies suggest that use of inhaled glucocorticoids in prepubertal children is associated with a small initial decrease in attained height (1 cm) that may persist as a reduction in adult height. Poor weight gain in a child with chronic chest symptoms should prompt consideration of cystic fibrosis. Anthropometric measures are also important to monitor in those on restricted diets because of multiple food allergies or eosinophilic esophagitis. Blood pressure should be measured to evaluate for steroid-induced hypertension. The patient with acute asthma may present with **pulsus paradoxus** , defined as a drop in systolic blood pressure during inspiration >10 mm Hg. Moderate to severe airway obstruction is indicated by a decrease of >20 mm Hg. An increased heart rate may be the result of an asthma flare or the use of a β-agonist or decongestant. Fever is not caused by allergy alone and should prompt consideration of an infectious process, which may exacerbate asthma.

Parents are often concerned about blue-gray to purple discolorations beneath their child's lower eyelids, which can be attributed to venous stasis and are referred to as **allergic shiners** (Fig. 167.1). They are found in up to 60% of allergic patients and almost 40% of patients *without* allergic disease. Thus, “shiners” may suggest, but are not diagnostic of, allergic disease. In contrast, the **Dennie-Morgan folds** (Dennie lines) are a feature of atopic dermatitis (Fig. 167.1). These are prominent infraorbital skin folds that extend in an arc from the inner canthus beneath and parallel to the lower lid margin.

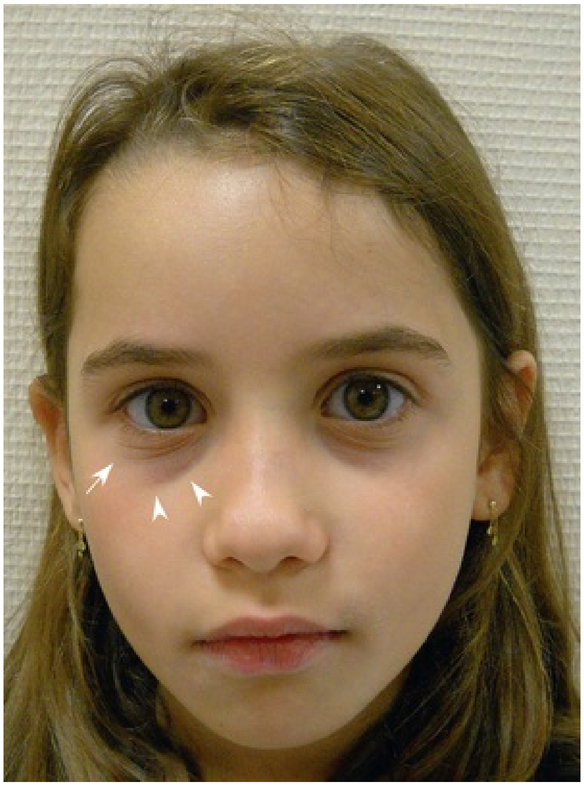

FIG. 167.1 Bilateral Dennie-Morgan folds. Several linear wrinkles beneath the lower eyelashes *(white arrow)* associated with bilateral allergic shiners: dark circles beneath the lower eyelid *(arrowheads).* (From Blanc S, Bourrier T, Albertini M, et al: Dennie-Morgan fold plus dark circles: suspect atopy at first sight, *J Pediatr* 166:1541, 2015.)

In patients with **allergic conjunctivitis** , involvement of the eyes is typically bilateral. Examination of the conjunctiva reveals varying degrees of lacrimation, conjunctival injection, and edema. In severe cases, periorbital edema involving primarily the lower eyelids or **chemosis** (conjunctival edema that is gelatinous in appearance) may be observed. The classic discharge associated with allergic conjunctivitis is usually described as “stringy” or “ropy.” In children with vernal conjunctivitis, a more severe, chronic phenotype, examination of the tarsal conjunctiva may reveal cobblestoning. **Keratoconus** , or protrusion of the cornea, may occur in patients with vernal conjunctivitis or periorbital atopic dermatitis as a result of repeated trauma produced by persistent rubbing of the eyes. Children treated with high-dose or chronic corticosteroids are at risk for development of posterior subcapsular cataracts.

The external ear should be examined for eczematous changes in patients with atopic dermatitis, including the postauricular area and base of the earlobe. Because otitis media with effusion is common in children with allergic rhinitis, pneumatic otoscopy should be performed to evaluate for the presence of fluid in the middle ear and to exclude infection.

Examination of the nose in allergic patients may reveal the presence of a nasal crease. Nasal patency should be assessed, and the nose examined for structural abnormalities affecting nasal airflow, such as septal deviation, turbinate hypertrophy, and nasal polyps. Decrease or absence of the sense of smell should raise concern about chronic sinusitis or nasal polyps. Nasal polyps in children should raise concerns of cystic fibrosis. The nasal mucosa in allergic rhinitis is classically described as pale to purple compared with the beefy-red mucosa of patients with nonallergic rhinitis. Allergic nasal secretions are typically thin and clear. Purulent secretions suggest another cause of rhinitis. The frontal and maxillary sinuses should be palpated to identify tenderness to pressure that might be associated with acute sinusitis.

Examination of the lips may reveal cheilitis caused by drying of the lips from continuous mouth breathing or repeated licking of the lips in an attempt to replenish moisture and relieve discomfort (**lip licker's dermatitis**). Tonsillar and adenoidal hypertrophy along with a history of impressive snoring raises the possibility of obstructive sleep apnea. The posterior pharynx should be examined for the presence of postnasal drip and posterior pharyngeal lymphoid hyperplasia (“cobblestoning”).

Chest findings in asthmatic children vary significantly and may depend on disease duration, severity, and activity. In a child with well-controlled asthma, the chest should appear entirely normal on examination between asthma exacerbations. Examination of the same child during an acute episode of asthma may reveal hyperinflation, tachypnea, use of accessory muscles (retractions), wheezing, and decreased air exchange with a prolonged expiratory time. Tachycardia may be caused by the asthma exacerbation or accompanied by jitteriness after treatment with β-agonists. Decreased airflow or rhonchi and wheezes over the right chest may be noted in children with mucus plugging and right middle lobe atelectasis. The presence of cyanosis indicates severe respiratory compromise. Unilateral wheezing after an episode of coughing and choking in a small child without a history of previous respiratory illness suggests **foreign body aspiration** . Wheezing limited to the larynx in association with inspiratory stridor may be seen in older children and adolescents with **vocal cord dysfunction.** Digital clubbing is rarely seen in patients with uncomplicated asthma and should prompt further evaluation to rule out other potential chronic diagnoses, such as cystic fibrosis.

The skin of the allergic patient should be examined for evidence of urticaria/angioedema or atopic dermatitis. **Xerosis** , or dry skin, is the most common skin abnormality of allergic children. **Keratosis pilaris** , often found on facial cheeks and extensor surfaces of the upper arms and thighs, is a benign condition characterized by skin-colored or slightly pink papules caused by keratin plugs lodged in the openings of hair follicles. Examination of the skin of the palms and soles may reveal thickened skin and exaggerated palmar and plantar creases (**hyperlinearity**) in children with moderate to severe atopic dermatitis.

Diagnostic Testing

In Vitro Tests

Allergic diseases are often associated with increased numbers of eosinophils circulating in the peripheral blood and invading the tissues and secretions of target organs. **Eosinophilia** , defined as the presence of >500 eosinophils/µL in peripheral blood, is the most common hematologic abnormality of allergic patients. Seasonal increases in the number of circulating eosinophils may be observed in sensitized patients after exposure to allergens such as tree, grass, and weed pollens. The number of circulating eosinophils can be suppressed by certain infections and systemic corticosteroids. In certain pathologic conditions, such as drug reactions, eosinophilic pneumonias, and eosinophilic esophagitis, significantly increased numbers of eosinophils may be present in the target organ in the absence of peripheral blood eosinophilia. Increased numbers of eosinophils are observed in a wide variety of disorders in addition to allergy; eosinophil counts >1500 without an identifiable etiology should suggest 1 of the 2 hypereosinophilic syndromes (Table 167.1 ; see Chapter 155).

Table 167.1

Differential Diagnosis of Childhood Eosinophilia

Physiologic

Prematurity
Infants receiving hyperalimentation
Hereditary

Infectious

Parasitic (with tissue-invasive helminths, e.g., trichinosis, strongyloidiasis, pneumocystosis, filariasis, cysticercosis, cutaneous and visceral larva migrans, echinococcosis)
Bacterial (brucellosis, tularemia, cat-scratch disease, *Chlamydia*)
Fungal (histoplasmosis, blastomycosis, coccidioidomycosis, allergic bronchopulmonary aspergillosis)
Mycobacterial (tuberculosis, leprosy)
Viral (HIV-1, HTLV-1, hepatitis A, hepatitis B, hepatitis C, Epstein-Barr virus)

Pulmonary

Allergic (rhinitis, asthma)
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)
Loeffler syndrome
Hypersensitivity pneumonitis
Eosinophilic pneumonia (chronic, acute)
Pulmonary interstitial eosinophilia

Dermatologic

Atopic dermatitis
Pemphigus
Dermatitis herpetiformis
Infantile eosinophilic pustular folliculitis
Eosinophilic fasciitis (Schulman syndrome)
Eosinophilic cellulitis (Wells syndrome)
Kimura disease (angiolymphoid hyperplasia with eosinophilia)

Hematologic/Oncologic

Neoplasm (lung, gastrointestinal, uterine)
Leukemia/lymphoma

Myelofibrosis
Myeloproliferative (FIP1L1-PDGFRA–positive) hypereosinophilic syndrome
Lymphatic hypereosinophilic syndrome
Systemic mastocytosis

Immunologic

T-cell immunodeficiencies
Hyper-IgE (Job) syndrome
Wiskott-Aldrich syndrome
Graft-versus-host disease
Drug hypersensitivity
Postirradiation
Postsplenectomy

Endocrine

Addison disease
Hypopituitarism

Cardiovascular

Loeffler disease (fibroplastic endocarditis)
Congenital heart disease
Hypersensitivity vasculitis
Eosinophilic myocarditis

Gastrointestinal

Benign proctocolitis
Inflammatory bowel disease
Eosinophilic gastrointestinal diseases (EGID)

FIP1L1-PDGFRA, FIP1-like 1–platelet-derived growth factor receptor α.

Nasal and bronchial secretions may be examined for the presence of eosinophils. The presence of eosinophils in the sputum of asthmatic patients is classic. An increased number of eosinophils in a smear of nasal mucus with Hansel stain is a more sensitive indicator of nasal allergies than peripheral blood eosinophilia and can aid in distinguishing allergic rhinitis from other causes of rhinitis. An elevated IgE value is often found in the serum of allergic patients, because IgE is the primary antibody associated with immediate hypersensitivity reactions. IgE values are measured in international units (IU), with 1 IU equal to 2.4 ng of IgE. Maternal IgE (unlike IgG) does not cross the placenta. Serum IgE levels gradually rise over the first years of life to peak in the teen years and decrease steadily thereafter. Additional factors, such as genetic influences, race, gender, certain diseases, and exposure to cigarette smoke and allergens, also affect serum IgE levels. Total serum IgE levels may increase 2- to 4-fold during and immediately after the pollen season and then gradually decline until the next pollen season. Comparison of total IgE levels among patients with allergic diseases reveals that those with atopic dermatitis tend to have the highest levels, whereas patients with allergic asthma generally have higher levels than those with allergic rhinitis. Although average total IgE levels are higher in populations of allergic patients than in comparable populations without allergic disease, the overlap in levels is such that the diagnostic value of a total IgE level is poor. Approximately half of patients with allergic disease have total IgE levels in the normal range. However, measurement of total IgE is indicated when the diagnosis of **allergic bronchopulmonary aspergillosis** is suspected because total serum IgE concentration >1,000 ng/mL is a criterion for diagnosis of this disorder (see Chapter 264.1). Total serum IgE may also be elevated in several nonallergic diseases (Table 167.2 ; see Chapter 152).

Table 167.2

Nonallergic Diseases Associated With Increased Serum IgE Concentrations

Parasitic Infestations

Ascariasis
Capillariasis
Echinococcosis
Fascioliasis

Filariasis
Hookworm
Onchocerciasis
Malaria
Paragonimiasis
Schistosomiasis
Strongyloidiasis
Trichinosis
Visceral larva migrans

Infections

Allergic bronchopulmonary aspergillosis
Candidiasis, systemic
Coccidioidomycosis
Cytomegalovirus mononucleosis
HIV type 1 infections
Infectious mononucleosis (Epstein-Barr virus)
Leprosy
Pertussis
Viral respiratory infections

Immunodeficiency

Autosomal dominant hyper-IgE syndrome (*STAT3* mutations)
Autosomal recessive hyper-IgE syndrome (*DOCK8, TYK2* mutations)
IgA deficiency, selective
Nezelof syndrome (cellular immunodeficiency with immunoglobulins)
Thymic hypoplasia (DiGeorge anomaly)
Wiskott-Aldrich syndrome

Neoplastic Diseases

Hodgkin disease
IgE myeloma
Bronchial carcinoma

Other Diseases and Disorders

Alopecia areata
Bone marrow transplantation
Burns
Cystic fibrosis
Dermatitis, chronic acral
Erythema nodosum, streptococcal infection
Guillain-Barré syndrome
Kawasaki disease
Liver disease
Medication related
Nephritis, drug-induced interstitial
Nephrotic syndrome
Pemphigus, bullous
Polyarteritis nodosa, infantile
Primary pulmonary hemosiderosis
Juvenile idiopathic arthritis

The presence of IgE specific for a particular allergen can be documented in vivo by skin testing or in vitro by the measurement of **allergen-specific IgE (sIgE)** levels in the serum (Table 167.3). The first test for documenting the presence of sIgE was called the radioallergosorbent test (RAST) because it used a radiolabeled anti-IgE antibody. The RAST has been replaced by an improved generation of automated enzymatic sIgE immunoassays. These assays use solid-phase supports to which allergens of an individual allergen extract are bound. A small amount of the patient's serum is incubated with the allergen-coated support. The allergen-coated support bound to the patient's sIgE is then incubated with enzyme-conjugated antihuman IgE. Incubation of this sIgE–antihuman IgE complex with a fluorescent substrate of the conjugated enzyme results in the generation of fluorescence that is proportional to the amount of sIgE in the serum sample. The amount of sIgE is calculated by interpolation from a standard calibration curve and reported in arbitrary mass units (kilo-IU of allergen-specific antibody per unit volume of sample, kU_A /L). Laboratory reports may specify classes, counts, or units, but quantification of results in kU_A /L is most useful. The 3 commercial detection systems approved by the U.S.

Food and Drug Administration have excellent performance characteristics, but the individual systems do not measure sIgE antibodies with comparable efficiencies and thus are not interchangeable. **Component testing** refers to diagnostic tests where sIgE is measured to specific proteins that comprise allergens (e.g., Ara h 2 from peanut, Bet v 1 from birch pollen), rather than to a mixture of the allergens extracted from the source. Testing sIgE to component allergens may add additional diagnostic value by differentiating immune responses that are directed toward clinically relevant allergenic proteins.

Table 167.3

Determination of Allergen-Specific IgE by Skin Testing vs In Vitro Testing

VARIABLE	SKIN TEST*	sIgE ASSAY
Risk of allergic reaction	Yes (especially ID)	No
Relative sensitivity	High	High
Affected by antihistamines	Yes	No
Affected by corticosteroids	Usually not	No
Affected by extensive dermatitis or dermographism	Yes	No
Broad selection of antigens	Fewer	Yes
Immediate results	Yes	No
Expensive	No	Yes
Lability of allergens	Yes	No
Results evident to patient	Yes	No

* Skin testing may be the prick test or intradermal (ID) injection.

In Vivo Tests

Allergen skin testing is the primary in vivo procedure for the diagnosis of allergic disease. Mast cells with sIgE antibodies attached to high-affinity receptors on their surface reside in the skin of allergic patients. The introduction of minute amounts of an allergen into the skin of the sensitized patient results in cross-linking of IgE antibodies on the mast cell surface, thereby triggering local mast cell activation. Once activated, these mast cells release a variety of preformed and newly generated mediators that act on surrounding tissues. **Histamine** is the mediator most responsible for the immediate **wheal and flare reactions** observed in skin testing. Examination of the site of a positive skin test result reveals a pruritic wheal surrounded by erythema. The time course of these reactions is rapid in onset, reaching a peak within 10-20 min and usually resolving over the next 30 min.

Skin testing is performed using the **prick/puncture technique.** With this technique, a small drop of allergen is applied to the skin surface, and a tiny amount is introduced into the epidermis by lightly pricking or puncturing the outer layer of skin through the drop of extract with a small needle or other device. When the **skin-prick test (SPT)** result is negative but the history suggestive, selective skin testing (for vaccines, venom, drugs, and aeroallergens) using the **intradermal technique** may be performed. This technique involves using a 26-gauge needle to inject 0.01-0.02 mL of an allergen extract diluted 1,000- to 10-fold into the dermis of the arm. Intradermal skin tests are *not recommended for use with food allergens* because of the risk of triggering anaphylaxis. Irritant rather than allergic reactions can occur with intradermal skin testing if higher concentrations of extracts are used. Although skin-prick testing is less sensitive than intradermal skin testing, positive SPT results tend to correlate better with clinical symptoms.

The number of skin tests performed should be individualized, with the allergens suggested by the history. A positive and negative control SPT, using histamine and saline, respectively, is performed with each set of skin tests. A negative control is necessary to assess for **dermatographism** , in which reactions are caused merely by applying pressure to overly sensitive skin. A positive control is necessary to establish the presence of a cutaneous response to histamine. Medications with antihistaminic properties, in addition to adrenergic agents such as ephedrine and epinephrine, suppress skin test responses and should be avoided for appropriate intervals (approximately 5 half-lives) before skin testing. Prolonged courses of systemic corticosteroids may suppress cutaneous reactivity by decreasing the number of tissue mast cells as well as their ability to release mediators.

Whether identified via serologic or skin testing, detection of sIgE denotes a sensitized state (i.e., atopy or a tendency toward development of allergic disease) but is not equivalent to a clinically relevant allergic diagnosis. *Many children with positive tests have no clinical symptoms on exposure to the allergen* . Increasingly strong test results (higher serum sIgE results or larger SPT wheal sizes) generally correlate with increasing likelihood of clinical reactivity (but not severity). Neither serologic testing nor skin testing for allergy is predictive of reaction severity or threshold of reactivity, and these tests will be negative when the allergy is not IgE mediated, such as in food protein–induced enterocolitis syndrome. The limitations of these test modalities underscore the need for a detailed medical history that can guide the selection and interpretation of test results. Large panels of indiscriminately performed screening tests may provide misleading information and are not recommended.

Both serum sIgE tests and SPT are sensitive and have similar diagnostic properties. The benefits of the serologic immunoassays are that performance is not limited by presence of skin disease (i.e., active atopic dermatitis) or medication use (i.e., antihistamines). Advantages of skin testing are that they provide rapid results to the patient/family during the clinic visit, do not require venipuncture, and are less costly.

Under certain circumstances, **provocation testing** is performed to examine the association between allergen exposure and the development of symptoms. The bronchial provocation test most frequently performed clinically is the **methacholine challenge,** which causes potent bronchoconstriction of asthmatic but not of normal airways; it is performed to document the presence and degree of bronchial hyperreactivity in a patient with suspected asthma. After baseline spirometry values are obtained, increasing concentrations of nebulized methacholine are inhaled until a drop occurs in lung function, specifically a 20% decrease in FEV_1 (forced expiratory volume in 1st second of expiration), or the patient is able to tolerate the inhalation of a set concentration of methacholine, typically 25 mg/mL.

Oral **food challenges** are performed to determine whether a specific food causes symptoms or whether a suspected food can be added to the diet. Food challenges are performed when the history and results of skin tests and immunoassays for sIgE fail to clarify the diagnosis of an allergy. These challenges may be performed in an open single-blind, double-blind, or double-blind placebo-controlled manner and involve the ingestion of gradually increasing amounts of the suspected food at set intervals until the patient either experiences a reaction or tolerates a normal portion (i.e., 1 serving size) of the food openly. Although the double-blind placebo-controlled food challenge is currently the gold standard test for diagnosing food allergy, it is typically only performed in research studies due to the time and labor-intensive nature of this method. Because of the potential for significant allergic reactions, oral food challenges should be performed only in an appropriately equipped facility with personnel experienced in the performance of food challenges and the treatment of anaphylaxis, including cardiopulmonary resuscitation.

Upper gastrointestinal **endoscopy** is required to confirm the diagnosis of eosinophilic esophagitis. One or more biopsy specimens from the proximal and distal esophagus must show eosinophil-predominant inflammation. With few exceptions, 15 eosinophils/hpf (high-power field) (peak value) is considered a minimum threshold for the diagnosis.

CHAPTER 168

Allergic Rhinitis

Henry Milgrom, Scott H. Sicherer

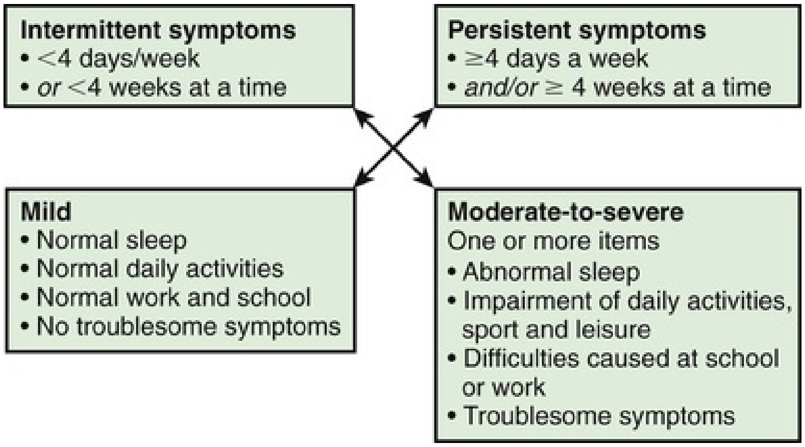
Allergic rhinitis (AR) is a common chronic disease affecting 20–30% of children. AR is an inflammatory disorder of the nasal mucosa marked by nasal congestion, rhinorrhea, and itching, often accompanied by sneezing and conjunctival inflammation. Its recognition as a major chronic respiratory disease of children derives from its high prevalence, detrimental effects on quality of life and school performance, and comorbidities. Children with AR often have related conjunctivitis, sinusitis, otitis media, serous otitis, hypertrophic tonsils and adenoids, and eczema. Childhood AR is associated with a 3-fold increase in risk for asthma at an older age. Over the past 50 yr an upsurge in AR has been observed throughout the world, with some symptom surveys reporting incidence rates approaching 40%. Heritability of allergic conditions attests to genetic factors, but the increase stems from changes in the environment, diet, and the microbiome. The symptoms may appear in infancy; with the diagnosis generally established by the time the child reaches age 6 yr. The prevalence peaks late in childhood.

Risk factors include family history of atopy and serum IgE higher than 100 IU/mL before age 6 yr. Early life exposures and/or their absence have a profound influence on the development of the allergic phenotype. The risk increases in children whose mothers smoke heavily, even before delivery and above all before the infants reach 1 yr, and those with heavy exposure to indoor allergens. A critical period exists early in infancy when the genetically susceptible child is at greatest risk of sensitization. Delivery by cesarean section is associated with AR and atopy in children with a parental history of asthma or allergies. This association may be explained by the lack of exposure to the maternal microbiota through fecal/vaginal flora during delivery.

Children between 2 and 3 yr old who have elevated anticockroach and antimouse IgE are at increased risk of wheezing, AR, and atopic dermatitis. The occurrence of 3 or more episodes of rhinorrhea in the 1st yr of life is associated with AR at age 7 yr. Favorably, the exposure to dogs, cats, and endotoxin early in childhood protects against the development of atopy. Prolonged breastfeeding, not necessarily exclusive, is beneficial. There is also a decreased risk of asthma, AR, and atopic sensitization with early introduction to wheat, rye, oats, barley, fish, and eggs. However, reduced diversity of the intestinal microbiota during infancy is associated with increased risk of allergic disease at school age.

Etiology and Classification

Two factors necessary for expression of AR are sensitivity to an allergen and the presence of the allergen in the environment. AR classification as **seasonal** or **perennial** is giving way to the designations **intermittent** and **persistent.** The 2 sets of terms are based on different suppositions, but inhalant allergens are the main cause of all forms of AR irrespective of terminology. AR may also be categorized as **mild-intermittent, moderate-severe intermittent, mild-persistent,** and **moderate-severe persistent** (Fig. 168.1). The symptoms of intermittent AR occur on <4 days per week or for <4 consecutive weeks. In persistent AR, symptoms occur on >4 days per week and/or for >4 consecutive weeks. The symptoms are considered mild when they are not troublesome, the sleep is normal, there is no impairment in daily activities, and there is no incapacity at work or school. Severe symptoms result in sleep disturbance and impairment in daily activities and school performance.



Intermittent symptoms
• <4 days/week
• or <4 weeks at a time
Persistent symptoms
• ≥4 days a week
• and/or ≥ 4 weeks at a time
Mild
• Normal sleep
• Normal daily activities
• Normal work and school
• No troublesome symptoms
Moderate-to-severe
One or more items
• Abnormal sleep
• Impairment of daily activities, sport and leisure
• Difficulties caused at school or work
• Troublesome symptoms

FIG. 168.1 ARIA classification of allergic rhinitis. Every box can be subclassified

further into seasonal or perennial on the basis of timing of symptoms or when causative and allergen therapeutic factors are considered. For example, a UK patient with grass pollen allergy might have moderate-severe persistent seasonal rhinitis in June and July and may be suitable for specific allergen immunotherapy. ARIA, Global Allergic Rhinitis and its Impact on Asthma. (From Scadding GK, Durham SR, Mirakian R, et al: BASCI guidelines for the management of allergic and non-allergic rhinitis, *Clin Exp Allergy* 38:19–42, 2008.)

In temperate climates, airborne pollen responsible for exacerbation of intermittent AR appear in distinct phases: trees pollinate in the spring, grasses in the early summer, and weeds in the late summer. In temperate climates, mold spores persist outdoors only in the summer, but in warm climates they persist throughout the year. Symptoms of intermittent AR typically cease with the appearance of frost. Knowledge of the time of symptom occurrence, the regional patterns of pollination and mold sporulation, and the patient's allergen-specific IgE (**sIgE**) is necessary to recognize the cause of intermittent AR. Persistent AR is most often associated with the indoor allergens: house dust mites, animal danders, mice, and cockroaches. Cat and dog allergies are of major importance in the United States. The allergens from saliva and sebaceous secretions may remain airborne for a prolonged time. The ubiquitous major cat allergen, Fel d 1, may be carried on cat owners’ clothing into such “cat-free” settings as schools and hospitals.

Pathogenesis

The exposure of an atopic host to an allergen leads to the production of sIgE, which is strongly associated with eczema throughout childhood and with asthma and rhinitis after age 4 yr. The clinical reactions on reexposure to the allergen have been designated as *early-phase* and *late-phase* allergic responses. Bridging of the IgE molecules on the surface of mast cells by allergen initiates the early-phase allergic response, characterized by degranulation of mast cells and release of preformed and newly generated inflammatory mediators, including histamine, prostaglandin 2, and the cysteinyl leukotrienes. The late-phase allergic response appears 4-8 hr following allergen exposure. Inflammatory cells, including basophils, eosinophils, neutrophils, mast cells, and mononuclear cells, infiltrate the nasal mucosa. Eosinophils release proinflammatory mediators, including cysteinyl leukotrienes, cationic proteins, eosinophil peroxidase, and major basic protein, and serve as a source of interleukin-3 (IL-3), IL-5, granulocyte-macrophage colony-stimulating factor, and IL-13. Repeated intranasal introduction of allergens causes “priming”—a more brisk response even with a lesser provocation. Over the course of an allergy season, a multifold increase in submucosal mast cells takes place. These cells, once thought to have a role exclusively in the early-phase allergic response, have an important function in sustaining chronic allergic disease.

Clinical Manifestations

Symptoms of AR may be ignored or mistakenly attributed to a respiratory infection. Older children blow their noses, but younger children tend to sniff and snort. Nasal itching brings on grimacing, twitching, and picking of the nose that may result in epistaxis. Children with AR often perform the **allergic salute** , an upward rubbing of the nose with an open palm or extended index finger. This maneuver relieves itching and briefly unblocks the nasal airway. It also gives rise to the **nasal crease** , a horizontal skin fold over the bridge of the nose. The diagnosis of AR is based on symptoms in the absence of an upper respiratory tract infection and structural abnormalities. Typical complaints include intermittent nasal congestion, itching, sneezing, clear rhinorrhea, and conjunctival irritation. Symptoms increase with greater exposure to the responsible allergen. The patients may lose their sense of smell and taste. Some experience headaches, wheezing, and coughing. Preschoolers with chronic wheezing and rhinitis experience more severe wheezing than children without rhinitis. Nasal congestion is often more severe at night, inducing mouth breathing and snoring, interfering with sleep, and rousing irritability.

Signs on physical examination include abnormalities of facial development, dental malocclusion, the **allergic gape** (continuous open-mouth breathing), chapped lips, **allergic shiners** (dark circles under the eyes; see Fig. 167.1), and the transverse nasal crease. Conjunctival edema, itching, tearing, and hyperemia are frequent findings. A nasal exam performed with a source of light and a speculum may reveal clear nasal secretions; edematous, boggy, and bluish mucus membranes with little or no erythema; and swollen turbinates that may block the nasal airway. It may be necessary to use a topical decongestant to perform an adequate examination. Thick, purulent nasal secretions indicate the presence of infection.

Differential Diagnosis

Evaluation of AR entails a thorough history, including details of the patient's environment and diet and a family history of allergic conditions (e.g., eczema, asthma, AR), physical examination, and laboratory evaluation. The history and laboratory findings provide clues to the provoking factors. Symptoms such as sneezing, rhinorrhea, nasal itching, and congestion and lab findings of elevated IgE, sIgE antibodies, and positive allergy skin test results typify AR. Intermittent AR differs from persistent AR by history and skin test results. **Nonallergic rhinitides** give rise to sporadic symptoms; their causes are often unknown. Nonallergic inflammatory rhinitis with eosinophils imitates AR in presentation and response to treatment, but without elevated IgE antibodies. **Vasomotor rhinitis** is characterized by excessive responsiveness of the nasal mucosa to physical stimuli. Other nonallergic conditions, such as infectious rhinitis, structural problems (e.g., nasal polyps, septal deviation), **rhinitis medicamentosa** (caused by overuse of topical vasoconstrictors), hormonal rhinitis associated with pregnancy or hypothyroidism, neoplasms, vasculitides, and granulomatous disorders may mimic AR (Table 168.1 and Fig. 168.2). Occupational risks for rhinitis include exposure to allergens (grain dust, insects, latex, enzymes) and irritants (wood dust, paint, solvents, smoke, cold air).

Table 168.1

Causes of Rhinitis

ALLERGIC RHINITIS

- Seasonal
- Perennial
- Perennial with seasonal exacerbations

NONALLERGIC RHINITIS

Structural/Mechanical Factors

- Deviated septum/septal wall anomalies
- Hypertrophic turbinates
- Adenoidal hypertrophy
- Foreign bodies
- Nasal tumors
    - Benign

    - Malignant
- Choanal atresia

Infectious

- Acute infections
- Chronic infections

Inflammatory/Immunologic

- Granulomatosis with polyangiitis
- Sarcoidosis
- Midline granuloma
- Systemic lupus erythematosus
- Sjögren syndrome
- Nasal polyposis

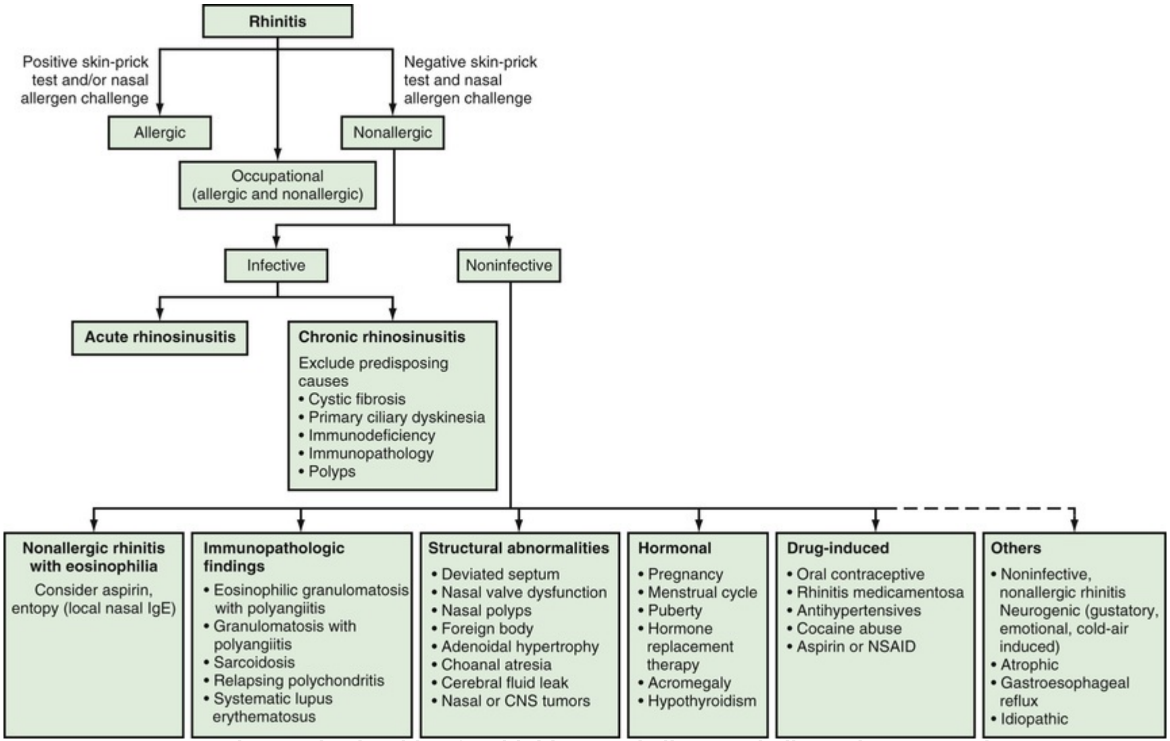
Physiologic

- Ciliary dyskinesia syndrome
- Atrophic rhinitis
- Hormonally induced
    - Hypothyroidism
    - Pregnancy
    - Oral contraceptives
    - Menstrual cycle
    - Exercise
    - Atrophic
- Drug induced
    - Rhinitis medicamentosa
    - Oral contraceptives
    - Antihypertensive therapy
    - Aspirin
    - Nonsteroidal antiinflammatory drugs
- Reflex induced
    - Gustatory rhinitis

    - Chemical or irritant induced
    - Posture reflexes
    - Nasal cycle
- Environmental factors
    - Odors
    - Temperature
    - Weather/barometric pressure
    - Occupational

NONALLERGIC RHINITIS WITH EOSINOPHILIA SYNDROME
PERENNIAL NONALLERGIC RHINITIS (VASOMOTOR RHINITIS)
EMOTIONAL FACTORS

From Skoner DP: Allergic rhinitis: definition, epidemiology, pathophysiology, detection, and diagnosis, *J Allergy Clin Immunol* 108(1 Suppl);108:S2–S8, 2001 (original source).



Rhinitis
Positive skin-prick test and/or nasal allergen challenge
Negative skin-prick test and nasal allergen challenge
Allergic
Nonallergic
Occupational (allergic and nonallergic)
Infective
Noninfective
Acute rhinosinusitis
Chronic rhinosinusitis
Exclude predisposing causes
• Cystic fibrosis
• Primary ciliary dyskinesia
• Immunodeficiency
• Immunopathology
• Polyps
Nonallergic rhinitis with eosinophilia
Consider aspirin, entopy (local nasal IgE)
Immunopathologic findings
• Eosinophilic granulomatosis with polyangiitis
• Granulomatosis with polyangiitis
• Sarcoidosis
• Relapsing polychondritis
• Systematic lupus erythematosus
Structural abnormalities
• Deviated septum
• Nasal valve dysfunction
• Nasal polyps
• Foreign body
• Adenoidal hypertrophy
• Choanal atresia
• Cerebral fluid leak
• Nasal or CNS tumors
Hormonal
• Pregnancy
• Menstrual cycle
• Puberty
• Hormone replacement therapy
• Acromegaly
• Hypothyroidism
Drug-induced
• Oral contraceptive
• Rhinitis medicamentosa
• Antihypertensives
• Cocaine abuse
• Aspirin or NSAID
Others
• Noninfective, nonallergic rhinitis Neurogenic (gustatory, emotional, cold-air induced)
• Atrophic
• Gastroesophageal reflux
• Idiopathic

FIG. 168.2 **Diagnostic algorithm for rhinitis. Nasal allergen challenge is a research procedure and is not undertaken routinely. CNS, Central nervous system; NSAID, nonsteroidal antiinflammatory drug. (From Greiner AN, Hellings PW, Rotiroti G, Scadding GK: Allergic rhinitis, *Lancet* 378:2112–2120, 2011.)**

Complications

AR is associated with complications and comorbid conditions. Undertreated AR detracts from the quality of life, aggravates asthma, and enhances its progression. Children with AR experience frustration over their appearance. Allergic conjunctivitis, characterized by itching, redness, and swelling of the conjunctivae, has been reported in at least 20% of the population and >70% of patients with AR, most frequently in older children and young adults. The 2 conditions share pathophysiologic mechanisms and epidemiologic characteristics (see Chapter 172). Chronic sinusitis is a common complication of AR, sometimes associated with purulent infection, but most patients have negative bacterial cultures despite marked mucosal thickening, and sinus opacification. The inflammatory process is characterized by marked eosinophilia.

Allergens, possibly fungal, are the inciting agents. The sinusitis of **triad asthma** (asthma, sinusitis with nasal polyposis, and aspirin sensitivity) often responds poorly to therapy. Patients who undergo repeated endoscopic surgery derive diminishing benefit with each successive procedure.

Rhinitis that coexists with asthma may be taken too lightly or completely overlooked. Up to 78% of patients with asthma have AR, and 38% of patients with AR have asthma. Aggravation of AR coincides with exacerbation of asthma, and treatment of nasal inflammation reduces bronchospasm, asthma-related emergency department visits, and hospitalizations. Postnasal drip associated with AR commonly causes persistent or recurrent cough. Eustachian tube obstruction and middle ear effusion are frequent complications. Chronic allergic inflammation causes hypertrophy of adenoids and tonsils that may be associated with eustachian tube obstruction, serous effusion, otitis media, and obstructive sleep apnea. AR is linked to snoring in children. The association between rhinitis and sleep abnormalities and subsequent daytime fatigue is well documented and may require multidisciplinary intervention.

The Pediatric Rhinoconjunctivitis Quality of Life Questionnaire (PRQLQ) is suitable for children 6-12 yr old, and the Adolescent Rhinoconjunctivitis Quality of Life Questionnaire (ARQLQ) is appropriate for patients 12-17 yr. Children with rhinitis have anxiety and physical, social, and emotional issues that affect learning and the ability to integrate with peers. The disorder contributes to headaches and fatigue, limits daily activities, and interferes with sleep. There is evidence of impaired cognitive functioning and learning that may be exacerbated by the adverse effects of sedating medications. AR causes an estimated 824,000 missed school days and 4,230,000 days of decline in quality-of-life activities. Patients with AR report an impairment in the activities of daily living similar to patients with moderate to severe asthma. Some (but not many) patients improve during their teenage years, only to develop symptoms again as young adults. Symptoms often abate in the 5th decade of life.

Laboratory Findings

Epicutaneous skin tests provide the best method for detection of sIgE, with a positive predictive value (PPV) of 48.7% for epidemiologic diagnosis of AR. Skin tests are inexpensive and sensitive, and the risks and discomfort are minimal. Responses to seasonal respiratory allergens are rare before 2 seasons of exposure, and children <1 yr old seldom display positive skin test responses to these allergens. To avoid false-negative results, montelukast should be withheld for 1 day, most sedating antihistamine preparations for 3-4 days, and nonsedating antihistamines for 5-7 days. Serum immunoassays for sIgE provide a suitable alternative (PPV of 43.5%) for patients with dermatographism or extensive dermatitis, those taking medications that interfere with mast cell degranulation, others at high risk for anaphylaxis, and some who cannot cooperate with the procedure. Presence of eosinophils in the nasal smear supports the diagnosis of AR, and neutrophils suggest infectious rhinitis. Eosinophilia and measurements of total serum IgE concentrations have relatively low sensitivity.

Treatment

Guideline-directed management has been shown to improve disease control. **Global Allergic Rhinitis and its Impact on Asthma (ARIA)** provides an evidence-based approach to treatment and includes quality-of-life measures useful for the evaluation of symptoms and the assessment of the response to therapy. Safe effective prevention and relief of symptoms are the current goals of treatment. *Specific measures to limit indoor allergen exposure may reduce the risk of sensitization and symptoms of allergic respiratory disease.* Sealing the patient's mattress, pillow, and covers in allergen-proof encasings reduces the exposure to mite allergen. Bed linen and blankets should be washed every week in hot water (>54.4°C [130°F]). The only effective measure for avoiding animal allergens in the home is the removal of the pet. Avoidance of pollen and outdoor molds can be accomplished by staying in a controlled environment. Air conditioning allows for keeping windows and doors closed, reducing the pollen exposure. High-efficiency particulate air (HEPA) filters lower the counts of airborne mold spores.

Oral antihistamines help reduce sneezing, rhinorrhea, and ocular symptoms. Administered as needed, antihistamines provide acceptable treatment for mild-intermittent disease. Antihistamines have been classified as **first generation** (relatively sedating) or **second generation** (relatively nonsedating). Antihistamines usually are administered by mouth but are also available for topical ophthalmic and intranasal use. Both first- and second-generation antihistamines are available as nonprescription drugs. *Second-generation antihistamines are preferred because they cause less sedation* . Preparations containing **pseudoephedrine** , typically in combination with other agents, are used for relief of nasal and sinus congestion and pressure and other symptoms such as rhinorrhea, sneezing, lacrimation, itching eyes, oronasopharyngeal itching, and cough. Pseudoephedrine is available without prescription (generally in fixed combination with other agents such as first-generation antihistamines: brompheniramine, chlorpheniramine, triprolidine; second-generation antihistamines: desloratadine, fexofenadine, loratadine; antipyretics: acetaminophen, ibuprofen; antitussives: guaifenesin, dextromethorphan; anticholinergic: methscopolamine). Pseudoephedrine is an oral vasoconstrictor distrusted for causing irritability and insomnia and for its association with infant mortality. Because younger children (2-3 yr) are at increased risk of overdosage and toxicity, some manufacturers of oral nonprescription cough and cold preparations have voluntarily revised their product labeling to warn against the use of preparations containing pseudoephedrine for children <4 yr old. Pseudoephedrine is misused as a starting material for the synthesis of methamphetamine and methcathinone. Tables 168.2 , 168.3 , and 168.4 provide examples of prescription, nonprescription, and combined oral agents, respectively, for treatment of AR.

Table 168.2

Oral Allergic Rhinitis Treatments (Prescription, Examples)

GENERIC/BRAND	**STRENGTH**	**FORMULATIONS**	**DOSING**
SECOND-GENERATION ANTIHISTAMINES			
Desloratadine			
Clarinex Reditabs*	2.5 mg, 5 mg	Orally disintegrating tablet	Children 6-11 mo of age: 1 mg once daily
Clarinex Tablets	5 mg	Tabs	Children 12 mo-5 yr: 1.25 mg once daily
Clarinex Syrup	0.5 mg/mL	Syrup	Children 6-11 yr: 2.5 mg once daily
			Adults and adolescents ≥12 yr: 5 mg once daily
Levocetirizine dihydrochloride			
Xyzal Oral Solution	0.5 mg/mL	Solution	6 mo-5 yr: max 1.25 mg once daily in the PM
			6-11 yr: max 2.5 mg once daily in the PM
LEUKOTRIENE ANTAGONIST			
Montelukast			
Singulair	10 mg	Tablets	6 mo-5 yr: 4 mg daily
Singulair Chewables*	4 mg, 5 mg	Chewable tablets	6-14 yr: 5 mg daily
Singulair Oral Granules	4 mg/packet	Oral granules	>14 yr: 10 mg daily

* Contains phenylalanine.

Dosing recommendations taken in part from Engorn B, Flerlage J, for the Johns Hopkins Hospital: *The Harriet Lane Handbook* , ed 20, Philadelphia, 2015, Elsevier/Saunders.

Table 168.3

Oral Allergic Rhinitis Treatments (Nonprescription, Examples)

GENERIC/BRAND	**STRENGTH**	**FORMULATIONS**	**DOSING**
FIRST-GENERATION H_1 ANTAGONISTS			
Chlorpheniramine maleate			
Chlor-Trimeton OTC (over the counter)	4 mg	Tablets	2-5 yr: 1 mg every 4-6 hr (max 6 mg/day) 6-11 yr: 2 mg every 4-6 hr (max 12 mg/day)
Chlor-Trimeton Syrup OTC	2 mg/5 mL	Syrup	>12 yr: 4 mg every 4-6 hr (max 24 mg/day)
SECOND-GENERATION H_1 ANTAGONISTS			
Cetirizine			
Children's Zyrtec Allergy Syrup OTC	1 mg/mL	Syrup	6-12 mo: 2.5 mg once daily
Children's Zyrtec Chewable OTC	5 mg, 10 mg	Chewable tablets	12-23 mo: initial: 2.5 mg once daily; dosage may be increased to 2.5 mg twice daily
Zyrtec tablets	5 mg, 10 mg	Tablets	2-5 yr: 2.5 mg/day; may be increased to max of 5

OTC			mg/day given either as a single dose or divided into 2 doses
Zyrtec Liquid Gels OTC	10 mg	Liquid-filled gels	≥6 yr: 5-10 mg/day as a single dose or divided into 2 doses
Levocetirizine Xyzal	5 mg 0.5 mg/mL	Tablet Oral solution	2-5 yr: 1.25 mg once daily in the evening 6-11 yr: 2.5 mg orally once daily in the evening ≥12 yr: 5 mg orally once daily in the evening
Desloratadine Clarinex	0.5 mg/mL	Oral solution	6-11 mo: 2 mL once daily 12 mo-5 yr: 2.5 mL once daily 6-11 yr: 5 mL once daily
Desloratadine Clarinex	5 mg	Tablet	12-adult: 5 mg once daily
Fexofenadine HCl OTC	30 mg, 60 mg, 180 mg	Tablet	6-11 yr: 30 mg twice daily 12-adult: 60 mg twice daily; 180 mg once daily
Children's Claritin OTC	5 mg/5 mL	Syrup	2-5 yr: 5 mg once daily 6-adult: 10 mg once daily
Children's Allegra OTC ODT*	30 mg	Orally disintegrating tablets	6-11 yr: 30 mg twice daily
Children's Allegra Oral Suspension OTC	30 mg/5 mL	Suspension	>2-11 yr: 30 mg every 12 hr
Allegra OTC	Tabs 30, 60, 180 mg	Tablet	>12 yr-adult: 60 mg every 12 hr; 180 mg once daily
Loratadine			
Alavert OTC ODT*	10 mg 10 mg 10 mg 5 mg 1 mg/mL	Orally disintegrating tablets Tablets Liquid-filled caps Chewable tablets Syrup	2-5 yr: 5 mg once daily >6 yr: 10 mg once daily or 5 mg twice daily

* Contains phenylalanine.

Table 168.4

Combined Antihistamine + Sympathomimetic (Examples)

GENERIC	STRENGTH	FORMULATIONS	DOSING
Chlorpheniramine maleate Phenylephrine	4 mg 10 mg	Tablets	>12 yr: 1 tablet every 4 hr, not to exceed 6 tablets per day

HCl Sudafed Sinus & Allergy			
Cetirizine + pseudoephedrine Zyrtec-D 12 hour	5 mg cetirizine + 120 mg pseudoephedrine	Extended-release tablet	>12 yr: 1 tablet every 12 hr

Dosing recommendations taken in part from Engorn B, MD, Flerlage J for the Johns Hopkins Hospital: *The Harriet Lane Handbook* , ed 20. Philadelphia, 2015 Elsevier/Saunders.

The anticholinergic **nasal spray** ipratropium bromide is effective for the treatment of *serous* rhinorrhea (Table 168.5). **Intranasal decongestants** (oxymetazoline and phenylephrine) should be used for <5 days and should not to be repeated more than once a month to avoid rebound nasal congestion. Sodium cromoglycate (available as nonprescription drug) is effective but requires frequent administration, every 4 hr. Leukotriene-modifying agents have a modest effect on rhinorrhea and nasal blockage (see Chapter 169 for additional indications and side effects). Nasal saline irrigation is a good adjunctive option with all other treatments of AR. Patients with more persistent, severe symptoms require **intranasal corticosteroids** , the most effective therapy for AR, which may also be beneficial for concomitant allergic conjunctivitis (Table 168.6). These agents reduce the symptoms of AR with eosinophilic inflammation, but not those of rhinitis associated with neutrophils or free of inflammation. Beclomethasone, triamcinolone, and flunisolide are absorbed from the gastrointestinal tract, as well as from the respiratory tract; budesonide, fluticasone, mometasone, and ciclesonide offer greater topical activity with lower systemic exposure. More severely affected patients may benefit from simultaneous treatment with oral antihistamines and intranasal corticosteroids.

Table 168.5

Miscellaneous Intranasal Sprays

DRUG	INDICATIONS (I), MECHANISM(s) OF ACTION (M), AND DOSING	COMMENTS, CAUTIONS, ADVERSE EVENTS, AND MONITORING
Ipratropium bromide:	*I:* Symptomatic relief of rhinorrhea *M:* Anticholinergic	Atrovent inhalation aerosol is contraindicated in patients with hypersensitivity to soy lecithin. Safety and efficacy of use beyond 4 days in patients with the common cold have not been established. *Adverse effects:* Epistaxis, nasal dryness, nausea
Atrovent nasal spray (0.06%)	Colds (symptomatic relief of rhinorrhea): 5-12 yr: 2 sprays in each nostril tid ≥12 yr and adults: 2 sprays in each nostril tid-qid	
Azelastine:	*I:* Treatment of rhinorrhea, sneezing, and nasal pruritus	May cause drowsiness *Adverse effects:* Headache, somnolence,

	M: Antagonism of histamine H_1 receptor	bitter taste
Astelin	6-12 yr: 1 spray bid >12 yr: 1-2 sprays bid	
Cromolyn sodium:	*I:* AR. *M:* Inhibition of mast cell degranulation	Not effective immediately; requires frequent administration
NasalCrom	>2 yr: 1 spray tid-qid; max 6 times daily	
Oxymetazoline: Afrin Nostrilla	*I:* Symptomatic relief of nasal mucosal congestion *M:* Adrenergic agonist, vasoconstricting agent 0.05% solution: instill 2-3 sprays into each nostril bid; therapy should not exceed 3 days.	Excessive dosage may cause profound central nervous system (CNS) depression. Use in excess of 3 days may result in severe rebound nasal congestion. Do not repeat more than once a month. Use with caution in patients with hyperthyroidism, heart disease, hypertension, or diabetes. *Adverse effects:* Hypertension, palpitations, reflex bradycardia, nervousness, dizziness, insomnia, headache, CNS depression, convulsions, hallucinations, nausea, vomiting, mydriasis, elevated intraocular pressure, blurred vision
Phenylephrine:	*I:* Symptomatic relief of nasal mucosal congestion *M:* Adrenergic, vasoconstricting agent	Use in excess of 3 days may result in severe rebound nasal congestion. Do not repeat more than once a month. 0.16% and 0.125% solutions are not commercially available. *Adverse effects:* Reflex bradycardia, excitability, headache, anxiety, dizziness
Neo-Synephrine	2-6 yr: 1 drop every 2-4 hr of 0.125% solution as needed. *Note:* Therapy should not exceed 3 continuous days. 6-12 yr: 1-2 sprays or 1-2 drops every 4 hr of 0.25% solution as needed. *Note:* Therapy should not exceed 3 continuous days. >12 yr: 1-2 sprays or 1-2 drops every 4 hr of 0.25% to 0.5% solution as needed; 1% solution may be used in adults with extreme nasal congestion. *Note:* Therapy should not exceed 3 continuous days.	

bid, 2 times daily; tid, 3 times daily; qid, 4 times daily.

Intranasal Inhaled Corticosteroids

DRUG	INDICATIONS (I), MECHANISM(s) OF ACTION (M), AND DOSING	COMMENTS, CAUTIONS, ADVERSE EVENTS, AND MONITORING
Beclomethasone: OTC (over the	*I:* AR *M:* Antiinflammatory,	Shake container before use; blow nose; occlude 1 nostril, administer dose to the other nostril.

counter)	immune modulator	*Adverse effects:* Burning and irritation of nasal mucosa, epistaxis Monitor growth.
Beconase AQ (42 µg/spray) Qnasl (80 µg/spray) OTC	6-12 yr: 1 spray in each nostril bid; may increase if needed to 2 sprays in each nostril bid >12 yr: 1 or 2 sprays in each nostril bid	
Flunisolide OTC	6-14 yr: 1 spray each nostril tid *or* 2 sprays in each nostril bid; not to exceed 4 sprays/day in each nostril ≥15 yr: 2 sprays each nostril bid (morning and evening); may increase to 2 sprays tid; maximum dose: 8 sprays/day in each nostril (400 µg/day)	Shake container before use; blow nose; occlude 1 nostril, administer dose to the other nostril. *Adverse effects:* Burning and irritation of nasal mucosa, epistaxis Monitor growth.
Triamcinolone Nasacort AQ (55 µg/spray) OTC Fluticasone propionate (available as generic preparation): OTC	*I:* AR *M:* Antiinflammatory, immune modulator	Shake container before use; blow nose; occlude 1 nostril, administer dose to the other nostril. *Adverse effects:* Burning and irritation of nasal mucosa, epistaxis Monitor growth.
	2-6 yr: 1 spray in each nostril qd 6-12 yr: 1-2 sprays in each nostril qd ≥12 yr: 2 sprays in each nostril qd	
	I: AR *M:* Antiinflammatory, immune modulator	Shake container before use; blow nose; occlude 1 nostril, administer dose to the other nostril. Ritonavir significantly increases fluticasone serum concentrations and may result in systemic corticosteroid effects. Use fluticasone with caution in patients receiving ketoconazole or other potent cytochrome P450 3A4 isoenzyme inhibitor. *Adverse effects:* Burning and irritation of nasal mucosa, epistaxis Monitor growth.
Flonase (50 µg/spray) OTC	≥4 yr: 1-2 sprays in each nostril qd	
Fluticasone furoate: Veramyst (27.5 µg/spray)	2-12 yr: Initial dose: 1 spray (27.5 µg/spray) per nostril qd (55 µg/day) Patients who do not show adequate response may use 2 sprays per nostril qd (110 µg/day) Once symptoms are controlled, dosage may be reduced to 55 µg qd Total daily dosage should not exceed 2 sprays in each nostril	

	(110 μg)/day ≥12 yr and adolescents: Initial dose: 2 sprays (27.5 μg/spray) per nostril qd (110 μg/day) Once symptoms are controlled, dosage may be reduced to 1 spray per nostril qd (55 μg/day). Total daily dosage should not exceed 2 sprays in each nostril (110 μg)/day.	
Mometasone:	*I:* AR *M:* Antiinflammatory, immune modulator	Mometasone and its major metabolites are undetectable in plasma after nasal administration of recommended doses. Preventive treatment of seasonal AR should begin 2-4 wk prior to pollen season. Shake container before use; blow nose; occlude 1 nostril, administer dose to the other nostril. *Adverse effects:* Burning and irritation of nasal mucosa, epistaxis Monitor growth.
Nasonex (50 μg/spray)	2-12 yr: 1 spray in each nostril qd >12 yr: 2 sprays in each nostril qd	
Budesonide: OTC	*I:* AR *M:* Antiinflammatory, immune modulator	Shake container before use; blow nose; occlude 1 nostril, administer dose to the other nostril. *Adverse effects:* Burning and irritation of nasal mucosa, epistaxis Monitor growth.
Rhinocort Aqua (32 μg/spray) OTC	6-12 yr: 2 sprays in each nostril qd >12 yr: up to 4 sprays in each nostril qd (max dose)	
Ciclesonide:	*I:* AR *M:* Antiinflammatory, immune modulator	Prior to initial use, gently shake, then prime the pump by actuating 8 times. If the product is not used for 4 consecutive days, gently shake and reprime with 1 spray or until a fine mist appears.
Omnaris Zetonna (50 μg/spray)	2-12 yr: 1-2 sprays in each nostril qd >12 yr: 2 sprays in each nostril qd	
Azelastine/fluticasone (137 μg azelastine/50 μg fluticasone) Dymista	>12 yr: 1 spray in each nostril bid	Shake bottle gently before using. Blow nose to clear nostrils. Keep head tilted downward when spraying. Insert applicator tip ¼ to ½ inch into nostril, keeping bottle upright, and close off the other nostril. Breathe in through nose. While inhaling, press pump to release spray.

qd, Once daily; bid, 2 times daily; tid, 3 times daily.

Allergen-specific immunotherapy is a well-defined treatment for IgE-mediated allergic disease. It may be administered by subcutaneous or sublingual routes. **Sublingual immunotherapy** (SLIT) has been used successfully in Europe and South America and is now approved by the U.S. Food and Drug Administration.

Allergy immunotherapy (AIT) is an effective treatment for AR and allergic conjunctivitis. In addition to reducing symptoms, it may change the course of allergic disease and induce allergen-specific immune tolerance. Immunotherapy should be considered for children in whom IgE-mediated allergic symptoms cannot be adequately controlled by avoidance and medication, especially in the presence of comorbid conditions. Immunotherapy for AR prevents the onset of asthma. Moreover, progress in molecular characterization of allergens raises the possibility of defined vaccines for allergen immunotherapy. Omalizumab (anti-IgE antibody) is effective for difficult-to-control asthma and is likely to have a beneficial effect on coexisting AR.

Typically, treatment of AR with oral antihistamines and nasal corticosteroids provides sufficient relief for most patients with coexisting **allergic conjunctivitis** . If it fails, additional therapies directed primarily at allergic conjunctivitis may be added (see Chapter 172). Intranasal corticosteroids are of some value for the treatment of ocular symptoms, but ophthalmic corticosteroids remain the most potent pharmacologic agents for ocular allergy, although they carry the risk of adverse effects such as delayed wound healing, secondary infection, elevated intraocular pressure, and formation of cataracts. Ophthalmic corticosteroids are only suited for the treatment of allergic conjunctivitis that does not respond to the medications previously discussed. Sound practice calls for the assistance of an ophthalmologist.

Prognosis

Therapy with nonsedating antihistamines and topical corticosteroids, when taken appropriately, improves health-related quality-of-life measures in patients with allergic rhinitis. The reported rates of remission among children are 10–23%. Pharmacotherapy that will target cells and cytokines involved in inflammation and treat allergy as a systemic process is on the horizon, and more selective targeting of drugs based on the development of specific biomarkers and genetic profiling may soon be realized.

CHAPTER 169

Childhood Asthma

Andrew H. Liu, Joseph D. Spahn, Scott H. Sicherer

Asthma is a chronic inflammatory condition of the lung airways resulting in episodic airflow obstruction. This chronic inflammation heightens the twitchiness of the airways—**airways hyperresponsiveness (AHR)—** to common provocative exposures. Asthma management is aimed at reducing airways inflammation by minimizing proinflammatory environmental exposures, using daily controller antiinflammatory medications, and controlling comorbid conditions that can worsen asthma. Less inflammation typically leads to better asthma control, with fewer exacerbations and decreased need for quick-reliever asthma medications. Nevertheless, exacerbations can still occur. Early intervention with systemic corticosteroids greatly reduces the severity of such episodes. Advances in asthma management and especially pharmacotherapy enable all but the uncommon child with difficult asthma to live normally.

Etiology

Although the cause of childhood asthma has not been determined, a combination of environmental exposures and inherent biologic and genetic susceptibilities has been implicated (Fig. 169.1). In the susceptible host, immune responses to common airways exposures (e.g., respiratory viruses, allergens, tobacco smoke, air pollutants) can stimulate prolonged, pathogenic inflammation and aberrant repair of injured airways tissues (Fig. 169.2). Lung dysfunction (AHR, reduced airflow) and airway remodeling develop. These pathogenic processes in the growing lung during early life adversely affect airways growth and differentiation, leading to altered airways at mature ages. Once asthma has developed, ongoing inflammatory exposures appear to worsen it, driving disease persistence and increasing the risk of severe exacerbations.

FIG. 169.2 Asthmatic inflammation (effector phase). Epithelial cell activation with production of proinflammatory cytokines and chemokines induces inflammation and contributes to a T-helper cell type 2 (Th2) response with tumor necrosis factor (TNF)-α, interleukin (IL)-13, thymic stromal lymphopoietin (TSLP), IL-25, IL-31, and IL-33. Migration of inflammatory cells to asthmatic tissues is regulated by chemokines. Th2 and eosinophil migration are induced by eotaxin, monocyte-derived chemokine (MDC), and activation-regulated chemokine (TARC). Epithelial apoptosis and shedding is observed, mainly mediated by interferon (IFN)-γ and TNF-α. The adaptive Th2 response includes the production of IL-4, IL-5, IL-9, and IL-13. Innate lymphoid cells, particularly ILC2, also secrete IL-5 and IL-13. Tissue eosinophilia is regulated by IL-5, IL-25, and IL-33. Local and systemic IgE production is observed in bronchial mucosa. Cross-linking of IgE receptor FcεRI on the surface of mast cells and basophils and their degranulation take place on allergen challenge. (From Leung DYM, Szefler SJ, Bonilla FA, et al, editors: *Pediatric allergy principles and practice,* ed 3, Philadelphia, 2016, Elsevier, p 260).

Genetics

To date, more than 100 genetic loci have been linked to asthma, although relatively few have consistently been linked to asthma in different study cohorts. Consistent loci include genetic variants that underlie susceptibility to common exposures such as respiratory viruses and air pollutants.

Environment

Recurrent wheezing episodes in early childhood are associated with common respiratory viruses, especially rhinoviruses, respiratory syncytial virus (RSV), influenza virus, adenovirus, parainfluenza virus, and human metapneumovirus. This association implies that host features affecting immunologic host defense, inflammation, and the extent of airways injury from ubiquitous viral pathogens underlie susceptibility to recurrent wheezing in early childhood. Other airways exposures can also exacerbate ongoing airways inflammation, increase disease severity, and drive asthma persistence. Home allergen exposures in sensitized individuals can initiate airways inflammation and hypersensitivity to other irritant exposures and are causally linked to disease severity, exacerbations, and persistence. Consequently, eliminating the offending allergen(s) can lead to resolution of asthma symptoms and can sometimes cure asthma. Environmental tobacco smoke and common air pollutants can aggravate airways inflammation and increase asthma severity. Cold, dry air, hyperventilation from physical play or exercise, and strong odors can trigger bronchoconstriction. Although many exposures that trigger and aggravate asthma are well recognized, the causal environmental features underlying the development of host susceptibilities to the various common airway exposures are not as well defined. Living in rural or farming communities may be a protective environmental factor.

Epidemiology

Asthma is a common chronic disease, causing considerable morbidity. In 2011, >10 million children (14% of U.S. children) had ever been diagnosed with asthma, with 70% of this group reporting current asthma. Male gender and living in poverty are demographic risk factors for having childhood asthma in the United States. About 15% of boys vs 13% of girls have had asthma; and 18% of all children living in poor families (income <$25,000/yr), vs 12% of children in families not classified as poor, have had asthma.

Childhood asthma is among the most common causes of childhood emergency department visits, hospitalizations, and missed school days. In the United States in 2006, childhood asthma accounted for 593,000 emergency department (ED) visits, 155,000 hospitalizations, and 167 deaths. A disparity in asthma outcomes links high rates of asthma hospitalization and death with poverty, ethnic minorities, and urban living. In the past 2 decades, black children have had 2-7 times more ED visits, hospitalizations, and deaths as a result of asthma than nonblack children. Although current asthma prevalence is higher in black than in nonblack U.S. children (in 2011, 16.5% vs 8.1% for white and 9.8% for Latino children), prevalence differences cannot fully account for this disparity in asthma outcomes.

Worldwide, childhood asthma appears to be increasing in prevalence, despite considerable improvements in our management and pharmacopeia to treat asthma. Although childhood asthma may have plateaued in the United States after 2008, numerous studies conducted in other countries have reported an increase in asthma prevalence of approximately 50% per decade. Globally, childhood asthma prevalence varies widely in different locales. A study of childhood asthma prevalence in 233 centers in 97 countries (International Study of Asthma and Allergies in Childhood, Phase 3) found a wide range in the prevalence of current wheeze in 6-7 yr (2.4–37.6%) and 13-14 yr old children (0.8–32.6%). Asthma prevalence correlated well with reported allergic rhinoconjunctivitis and atopic eczema prevalence. Childhood asthma seems more prevalent in modern metropolitan locales and more affluent nations, and is strongly linked with other allergic conditions. In contrast, children living in rural areas of developing countries and farming communities with domestic animals are less likely to experience asthma and allergy.

Approximately 80% of all asthmatic patients report disease onset prior to 6 yr of age. However, of all young children who experience recurrent wheezing, only a minority go on to have persistent asthma in later childhood. Early childhood risk factors for persistent asthma have been identified (Table 169.1) and have been described as major (parent asthma, eczema, inhalant allergen sensitization) and minor (allergic rhinitis, wheezing apart from colds, ≥4% peripheral blood eosinophils, food allergen sensitization) risk factors. *Allergy in young children with recurrent cough and/or wheeze* is the strongest identifiable factor for the persistence of childhood asthma.

Table 169.1

Early Childhood Risk Factors for Persistent Asthma

Parental asthma*
Allergy:
  - Atopic dermatitis (eczema)*
  - Allergic rhinitis
  - Food allergy
  - Inhalant allergen sensitization*
  - Food allergen sensitization

Severe lower respiratory tract infection:
  - Pneumonia
  - Bronchiolitis requiring hospitalization

Wheezing apart from colds
Male gender
Low birthweight
Environmental tobacco smoke exposure
Reduced lung function at birth
Formula feeding rather than breastfeeding

---

[*] Major risk factors.

Types of Childhood Asthma

There are 2 common types of childhood asthma based on different natural courses: (1) **recurrent wheezing** in *early* childhood, primarily triggered by common respiratory viral infections, usually resolves during the preschool/lower school years; and (2) **chronic asthma** associated with *allergy* that persists into later childhood and often adulthood (Table 169.2). School-age children with mild-moderate persistent asthma generally improve as teenagers, with some (about 40%) developing intermittent disease. Milder disease is more likely to remit. Inhaled corticosteroid controller therapy for children with persistent asthma does not alter the likelihood of outgrowing asthma in later childhood; however, because children with asthma generally improve with age, their need for controller therapy subsequently lessens and often resolves. Reduced growth and progressive decline in lung function can be features of persistent, problematic disease.

Table 169.2

Asthma Patterns in Childhood, Based on Natural History and Asthma Management

Transient Nonatopic Wheezing

Common in early preschool years

Recurrent cough/wheeze, primarily triggered by common respiratory viral infections

Usually resolves during the preschool and lower school years, without increased risk for asthma in later life

Reduced airflow at birth, suggestive of relatively narrow airways; AHR near birth; improves by school age

Persistent Atopy-Associated Asthma

Begins in early preschool years

Associated with atopy in early preschool years:

- Clinical (e.g., atopic dermatitis in infancy, allergic rhinitis, food allergy)
- Biologic (e.g., early inhalant allergen sensitization, increased serum IgE, increased blood eosinophils)
- Highest risk for persistence into later childhood and adulthood

Lung function abnormalities:

- Those with onset before 3 yr of age acquire reduced airflow by school age.
- Those with later onset of symptoms, or with later onset of allergen sensitization, are less likely to experience airflow limitation in childhood.

Asthma With Declining Lung Function

Children with asthma with progressive increase in airflow limitation

Associated with hyperinflation in childhood, male gender

Asthma Management Types

(From national and international asthma management guidelines)

Severity Classification*

- Intrinsic disease severity while not taking asthma medications

Intermittent

Persistent:

- Mild
- Moderate
- Severe

Control Classification*

- Clinical assessment while asthma being managed and treated

Well controlled

Not well controlled

Very poorly controlled

Management Patterns

- **Easy-to-control:** well controlled with low levels of daily controller therapy
- **Difficult-to-control:** well controlled with multiple and/or high levels of controller therapies
- **Exacerbators:** despite being well controlled, continue to have severe exacerbations
- **Refractory:** continue to have poorly controlled asthma despite multiple and high levels of controller therapies

AHR, Airways hyperresponsiveness.

---

* From National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3): *Guideline for the diagnosis and management of asthma*, NIH Pub No 07-4051, Bethesda, MD, 2007, US Department of Health and Human Services;

National Institutes of Health; National Heart, Lung, and Blood Institute; National Asthma Education and Prevention Program. https://www.nhlbi.nih.gov/health-pro/guidelines/current/asthma-guidelines/full-report .

Asthma is also classified by **disease severity** (e.g., intermittent or persistent [mild, moderate, or severe]) or **control** (e.g., well, not well, or very poorly controlled), especially for asthma management purposes. Because most children with asthma can be well controlled with conventional management guidelines, children with asthma can also be characterized according to treatment response and medication requirements as being (1) **easy to control** : well controlled with low levels of controller therapy; (2) **difficult to control** : not as well controlled with multiple and/or high levels of controller therapies; (3) **exacerbators** : despite being controlled, continue to have severe exacerbations; and (4) **refractory asthma** : continue to have poorly controlled asthma despite multiple and high levels of controller therapies (Table 169.2). Different airways pathologic processes, causing airways inflammation, AHR, and airways congestion and blockage, are believed to underlie these different types of asthma.

Pathogenesis

Airflow obstruction in asthma is the result of numerous pathologic processes. In the small airways, airflow is regulated by smooth muscle encircling the airway lumen; bronchoconstriction of these bronchiolar muscular bands restricts or blocks airflow. A cellular inflammatory infiltrate and exudates distinguished by eosinophils, but also including other inflammatory cell types (neutrophils, monocytes, lymphocytes, mast cells, basophils), can fill and obstruct the airways and induce epithelial damage and desquamation into the airways lumen. Helper T lymphocytes and other immune cells that produce proallergic, proinflammatory cytokines (interleukin [IL]-4, IL-5, IL-13), and chemokines (eotaxins) mediate this inflammatory process (see Fig. 169.2). Pathogenic immune responses and inflammation may also result from a breach in normal immune regulatory processes (e.g., regulatory T lymphocytes that produce IL-10 and transforming growth factor-β) that dampen effector immunity and inflammation when they are no longer needed. Hypersensitivity or susceptibility to a variety of provocative exposures or triggers (Table 169.3) can lead to airways inflammation, AHR, edema, basement membrane thickening, subepithelial collagen deposition, smooth muscle and mucous gland hypertrophy, and mucus hypersecretion—all processes that contribute to airflow obstruction.

Table 169.3

Asthma Triggers

COMMON VIRAL INFECTIONS OF RESPIRATORY TRACT

AEROALLERGENS IN SENSITIZED ASTHMATIC PATIENTS

Indoor Allergens

- Animal dander
- Dust mites
- Cockroaches
- Molds

Seasonal Aeroallergens

- Pollens (trees, grasses, weeds)
- Seasonal molds

AIR POLLUTANTS

- Environmental tobacco smoke
- Ozone
- Nitrogen dioxide
- Sulfur dioxide
- Particulate matter
- Wood- or coal-burning smoke
- Mycotoxins
- Endotoxin
- Dust

STRONG OR NOXIOUS ODORS OR FUMES

- Perfumes, hairsprays
- Cleaning agents

OCCUPATIONAL EXPOSURES

- Farm and barn exposures
- Formaldehydes, cedar, paint fumes

COLD DRY AIR
EXERCISE
CRYING, LAUGHTER, HYPERVENTILATION
COMORBID CONDITIONS

- Rhinitis
- Sinusitis
- Gastroesophageal reflux

DRUGS

- Aspirin and other nonsteroidal antiinflammatory drugs
- β-Blocking agents

Clinical Manifestations and Diagnosis

Intermittent dry coughing and expiratory wheezing are the most common chronic symptoms of asthma. Older children and adults report associated shortness of breath and chest congestion and tightness; younger children are more likely to report intermittent, nonfocal chest pain. Respiratory symptoms can be worse at night, associated with sleep, especially during prolonged exacerbations triggered by respiratory infections or inhalant allergens. Daytime symptoms, often linked with physical activities (exercise-induced) or play, are reported with greatest frequency in children. Other asthma symptoms in children can be subtle and nonspecific, including self-imposed limitation of physical activities, general fatigue (possibly resulting from sleep disturbance), and difficulty keeping up with peers in physical activities. Asking about previous experience with asthma medications (bronchodilators) may provide a history of symptomatic improvement with treatment that supports the diagnosis of asthma. Lack of improvement with bronchodilator and corticosteroid therapy is inconsistent with underlying asthma and should prompt more vigorous consideration of asthma-masquerading conditions.

Asthma symptoms can be triggered by numerous common events or exposures: physical exertion and hyperventilation (laughing), cold or dry air, and airways irritants (see Table 169.3). Exposures that induce airways inflammation, such as infections with common respiratory pathogens (rhinovirus, RSV, metapneumovirus, parainfluenza virus, influenza virus, adenovirus, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*), and inhaled allergens in sensitized children, also increase AHR to dry, cold air and irritant exposures. An environmental history is essential for optimal asthma management.

The presence of risk factors, such as a history of other allergic conditions (allergic rhinitis, allergic conjunctivitis, atopic dermatitis, food allergies), parental asthma, and/or symptoms apart from colds, supports the diagnosis of asthma. During routine clinic visits, children with asthma typically present without abnormal signs, emphasizing the importance of the medical history in diagnosing asthma. Some may exhibit a dry, persistent cough. The chest findings are often normal. Deeper breaths can sometimes elicit otherwise undetectable wheezing. In clinic, quick resolution (within 10 min) or convincing improvement in symptoms and signs of asthma with administration of an **inhaled short-acting β-agonist** (**SABA** ; e.g., albuterol) is supportive of the diagnosis of asthma.

Asthma exacerbations can be classified by their severity based on symptoms, signs, and functional impairment (Table 169.4). Expiratory wheezing and a prolonged exhalation phase can usually be appreciated by auscultation. Decreased breath sounds in some of the lung fields, commonly the right lower posterior lung field, are consistent with regional hypoventilation caused by airways obstruction. **Rhonchi** and **crackles** (or **rales**) can sometimes be heard, resulting from excess mucus production and inflammatory exudate in the airways. The combination of segmental crackles and poor breath sounds can indicate lung segmental atelectasis that is difficult to distinguish from bronchial pneumonia and can complicate acute asthma management. In severe exacerbations the greater extent of airways obstruction causes labored breathing and respiratory distress, which manifests as inspiratory and expiratory wheezing, increased prolongation of exhalation, poor air entry, suprasternal and intercostal retractions, nasal flaring, and accessory respiratory muscle use. In extremis, airflow may be so limited that wheezing cannot be heard (**silent chest**).

Table 169.4

Formal Evaluation of Asthma Exacerbation Severity in the Urgent or Emergency Care Setting[*]

	MILD	**MODERATE**	**SEVERE**	**SUBSET: RESPIRATORY ARREST IMMINENT**
SYMPTOMS				
Breathlessness	While walking	While at rest (infant—softer, shorter cry, difficulty feeding)	While at rest (infant—stops feeding)	Extreme dyspnea Anxiety
	Can lie down	Prefers sitting	Sits upright	Upright, leaning forward
Talks in…	Sentences	Phrases	Words	Unable to talk
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
SIGNS				
Respiratory rate[†]	Increased	Increased	Often >30 breaths/min	
Use of accessory muscles; suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate; often only end-expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absence of wheeze
Pulse rate (beats/min)[‡]	<100	100-120	>120	Bradycardia
Pulsus paradoxus	Absent <10 mm Hg	May be present 10-25 mm Hg	Often present >25 mm Hg (adult) 20-40 mm Hg (child)	Absence suggests respiratory muscle fatigue
FUNCTIONAL ASSESSMENT				
Peak expiratory flow (value predicted or personal best)	≥70%	Approx. 40–69% or response lasts <2 hr	<40%	<25%[§]
PaO$_2$ (breathing air)	Normal (test not usually necessary)	≥60 mm Hg (test not usually necessary)	<60 mm Hg; possible cyanosis	
and/or				
PCO$_2$	<42 mm Hg (test not usually necessary)	<42 mm Hg (test not usually necessary)	≥42 mm Hg; possible respiratory failure	
SaO$_2$ (breathing air) at	>95% (test not	90–95% (test not usually	<90%	Hypoxia despite

sea level	usually necessary)	necessary)		oxygen therapy
	Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.			

[*] Notes:

[†] Normal breathing rates in awake children by age: <2 mo, <60 breaths/min; 2-12 mo, <50 breaths/min; 1-5 yr, <40 breaths/min; 6-8 yr, <30 breaths/min.

[‡] Normal pulse rates in children by age: 2-12 mo, <160 beats/min; 1-2 yr, <120 beats/min; 2-8 yr, <110 beats/min.

[§] Peak expiratory flow testing may not be needed in very severe attacks.

- The presence of several parameters, but not necessarily all, indicates the general classification of the exacerbation.
- Many of these parameters have not been systematically studied, especially as they correlate with each other; thus they serve only as general guides.
- The emotional impact of asthma symptoms on the patient and family is variable but must be recognized and addressed and can affect approaches to treatment and follow-up.

Adapted from National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3): *Guideline for the diagnosis and management of asthma,* NIH Pub No 07-4051, Bethesda, MD, 2007, US Department of Health and Human Services; National Institutes of Health; National Heart, Lung, and Blood Institute; National Asthma Education and Prevention Program. https://www.nhlbi.nih.gov/health-pro/guidelines/current/asthma-guidelines/full-report .

Differential Diagnosis

Many childhood respiratory conditions can present with symptoms and signs similar to those of asthma (Table 169.5). Besides asthma, other common causes of chronic, intermittent coughing include gastroesophageal reflux (GER) and rhinosinusitis. Both GER and chronic sinusitis can be challeng spirometric lung function testing ing to diagnose in children. Often, GER is clinically silent in children, and children with chronic sinusitis do not report sinusitis-specific symptoms, such as localized sinus pressure and tenderness. In addition, both GER and rhinosinusitis are often comorbid with childhood asthma and, if not specifically treated, may make asthma difficult to manage.

Table 169.5

Differential Diagnosis of Childhood Asthma

Upper Respiratory Tract Conditions

Allergic rhinitis*
Chronic rhinitis*
Sinusitis*
Adenoidal or tonsillar hypertrophy
Nasal foreign body

Middle Respiratory Tract Conditions

Laryngotracheobronchomalacia*
Laryngotracheobronchitis (e.g., pertussis)*
Laryngeal web, cyst, or stenosis
Exercise-induced laryngeal obstruction
Vocal cord dysfunction*
Vocal cord paralysis
Tracheoesophageal fistula
Vascular ring, sling, or external mass compressing on the airway (e.g., tumor)
Endobronchial tumor
Foreign body aspiration*
Chronic bronchitis from environmental tobacco smoke exposure*
Repaired tracheoesophageal fistula
Toxic inhalations

Lower Respiratory Tract Conditions

Bronchopulmonary dysplasia (chronic lung disease of preterm infants)
Viral bronchiolitis*
Gastroesophageal reflux*
Causes of bronchiectasis:
  - Cystic fibrosis
  - Immunodeficiency
  - Allergic bronchopulmonary mycoses (e.g., aspergillosis)
  - Chronic aspiration

Primary ciliary dyskinesia, immotile cilia syndrome
Bronchiolitis obliterans
Interstitial lung diseases

Hypersensitivity pneumonitis
Eosinophilic granulomatosis with angiitis
Eosinophilic pneumonia
Pulmonary hemosiderosis
Tuberculosis
Pneumonia
Pulmonary edema (e.g., congestive heart failure)
Vasculitis
Sarcoidosis
Medications associated with chronic cough:

- Acetylcholinesterase inhibitors
- β-Adrenergic antagonists
- Angiotensin-converting enzyme inhibitors

---

* More common asthma masqueraders.

In early life, chronic coughing and wheezing can indicate recurrent aspiration, **tracheobronchomalacia** (congenital anatomic abnormality of airways), foreign body aspiration, cystic fibrosis, or bronchopulmonary dysplasia.

In older children and adolescents, **vocal cord dysfunction (VCD)** can manifest as intermittent daytime wheezing. The vocal cords involuntarily close inappropriately during inspiration and sometimes exhalation, producing shortness of breath, coughing, throat tightness, and often audible laryngeal wheezing and/or stridor. In most cases of VCD, spirometric lung function testing reveals truncated and inconsistent inspiratory and expiratory flow-volume loops, a pattern that differs from the reproducible pattern of airflow limitation in asthma that improves with bronchodilators. VCD can coexist with asthma. Hypercarbia and severe hypoxia are uncommon in VCD. Flexible rhinolaryngoscopy in the patient with symptomatic VCD can reveal paradoxical vocal cord movements with anatomically normal vocal cords. Prior to the diagnosis, patients with VCD are often treated unsuccessfully with multiple different classes of asthma medications. This condition can be well managed with specialized speech therapy training in the relaxation and control of vocal cord movement. Furthermore, treatment of underlying causes of vocal cord irritability (e.g., high GER/aspiration, allergic rhinitis, rhinosinusitis, asthma) can improve VCD. During acute VCD exacerbations, relaxation breathing techniques in conjunction with inhalation of heliox (a mixture of 70% helium and 30% oxygen) can relieve vocal cord spasm and VCD symptoms.

In some locales, hypersensitivity pneumonitis (farming communities, homes of bird owners), pulmonary parasitic infestations (rural areas of developing countries), or tuberculosis may be common causes of chronic coughing and/or wheezing. Rare mimics of asthma in childhood are noted in Table 169.5 . Chronic pulmonary diseases often produce clubbing, but clubbing is a very unusual finding in childhood asthma.

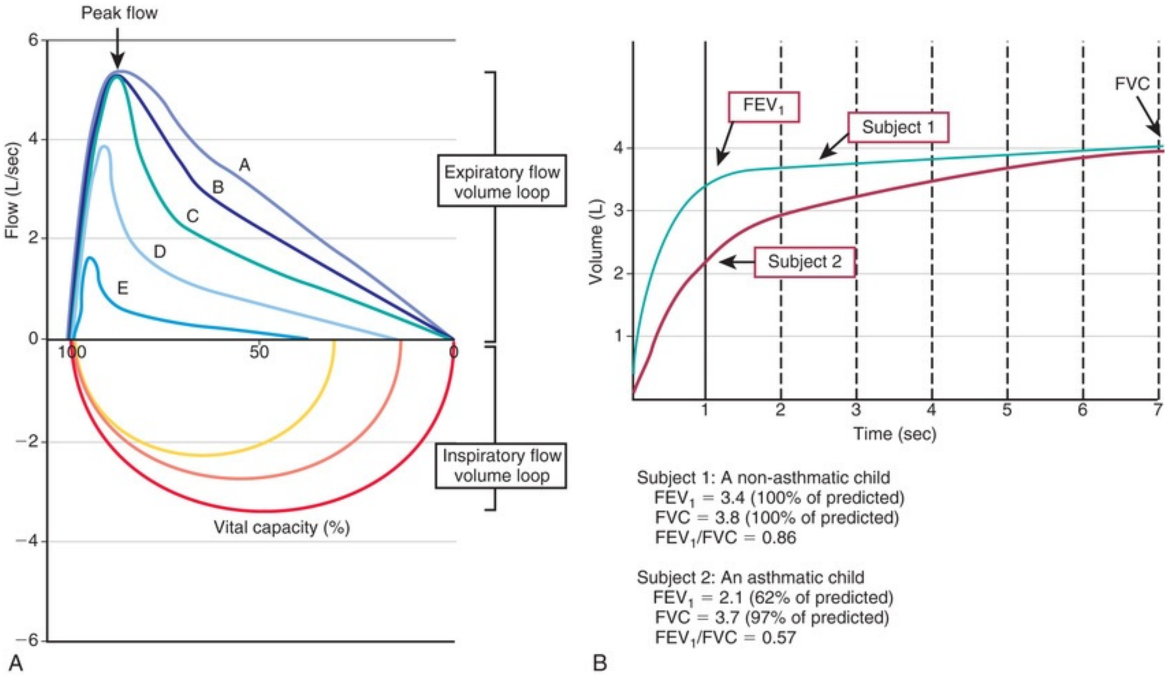
Laboratory Findings

Lung function tests can help to confirm the diagnosis of asthma and to determine disease severity.

Pulmonary Function Testing

Forced expiratory airflow measures are helpful in diagnosing and monitoring asthma and in assessing efficacy of therapy. Lung function testing is particularly helpful in children with asthma who are poor perceivers of airflow obstruction, or when physical signs of asthma do not occur until airflow obstruction is severe.

Many asthma guidelines promote spirometric measures of airflow and lung volumes during forced expiratory maneuvers as standard for asthma assessment. **Spirometry** is a helpful objective measure of airflow limitation (Fig. 169.3). Spirometry is an essential assessment tool in children who are at risk for severe asthma exacerbations and those who have poor perception of asthma symptoms. Valid spirometric measures depend on a patient's ability to properly perform a full, forceful, and prolonged expiratory maneuver, usually feasible in children >6 yr old (with some younger exceptions).



Subject 1: A non-asthmatic child
FEV$_1$ = 3.4 (100% of predicted)
FVC = 3.8 (100% of predicted)
FEV$_1$/FVC = 0.86

Subject 2: An asthmatic child
FEV$_1$ = 2.1 (62% of predicted)
FVC = 3.7 (97% of predicted)
FEV$_1$/FVC = 0.57

FIG. 169.3 **Spirometry. A, Spirometric flow-volume loops. Loop A is an expiratory flow-volume loop of a nonasthmatic person without airflow limitation. B through E are expiratory flow-volume loops in asthmatic patients with increasing degrees of airflow limitation (B is mild; E is severe). Note the "scooped" or concave appearance of the asthmatic expiratory flow-volume loops; with increasing obstruction, there is greater "scooping." B, Spirometric volume-time curves. Subject 1 is a nonasthmatic person; subject 2 is an asthmatic patient. Note how the FEV$_1$ and FVC lung volumes are obtained. The FEV$_1$ is the volume of air exhaled in the 1st sec of a forced expiratory effort. The FVC is the total volume of air exhaled during a forced expiratory effort, or forced vital capacity. Note that subject 2's FEV$_1$ and FEV$_1$:FVC ratio are smaller than subject 1's, demonstrating airflow limitation. Also, subject 2's FVC is very close to what is expected.**

In asthma, airways blockage results in reduced airflow with forced exhalation (see Fig. 169.3). Because asthmatic patients typically have hyperinflated lungs, forced expiratory volume in 1 sec (FEV$_1$) can be simply adjusted for full expiratory lung volume—the forced vital capacity (FVC)—with an FEV$_1$ /FVC ratio. Generally, an FEV$_1$ /FVC ratio <0.80 indicates airflow obstruction (Table 169.6). Normative values for FEV$_1$ have been determined for children by height, gender, and ethnicity. Abnormally low FEV$_1$ as a percentage of predicted norms is 1 of 6 criteria used to determine asthma severity and control in asthma management guidelines sponsored by the U.S. National Institutes of Health (NIH) and the **Global Initiative for Asthma (GINA)** .

Table 169.6

Lung Function Abnormalities in Asthma and

Assessment of Airway Inflammation

Spirometry (in clinic) [‡] [†] :

Airflow limitation:

- Low FEV_1 (relative to percentage of predicted norms)
- FEV_1 /FVC ratio <0.80

Bronchodilator response (to inhaled β-agonist) assesses *reversibility* of airflow limitation.

Reversibility is determined by an increase in either FEV_1 >12% or predicted FEV_1 >10% after inhalation of a short-acting β-agonist (SABA)*

Exercise challenge:

- Worsening in FEV_1 ≥15%*

Daily peak expiratory flow (PEF) [‡] **or FEV_1 monitoring:** day-to-day and/or AM -to-PM variation ≥20%*

Exhaled nitric oxide (FeNO)

- A value of >20 ppb supports the clinical diagnosis of asthma in children
- FeNO can be used to predict response to ICS therapy:
  - <20 ppb: Unlikely to respond to ICS because eosinophilic inflammation unlikely
  - 20-35 ppb: Intermediate, may respond to ICS
  - >35 ppb: Likely to respond to ICS because eosinophilic inflammation is likely

FEV_1 , forced expiratory volume in 1 sec; FVC, forced vital capacity; ICS, inhaled corticosteroid; ppb, parts per billion.

[‡] PEF variability is insensitive, while being highly specific for asthma.

[†] Of note, >50%of children with mild to moderate asthma will have a normal FEV_1 and will not have a significant bronchodilator response.

[*] Main criteria consistent with asthma.

Such measures of airflow alone are not diagnostic of asthma, because numerous other conditions can cause airflow limitation. In addition, approximately 50% of children with mild-moderate persistent asthma will have normal spirometric values when well. **Bronchodilator response** to an inhaled β-agonist (e.g., albuterol) is greater in asthmatic patients than nonasthmatic persons; an improvement in FEV_1 ≥12% is consistent with asthma. **Bronchoprovocation challenges** can be helpful in diagnosing asthma and optimizing asthma management. Asthmatic airways are hyperresponsive and therefore more sensitive to inhaled methacholine, mannitol, and cold or dry air. The degree of AHR to these exposures correlates to some extent with asthma severity and airways inflammation. Although bronchoprovocation challenges are carefully dosed and monitored in an investigational setting, their use is rarely practical in general practice. **Exercise challenges** (aerobic exertion or "running" for 6-8 min) can help to identify children with exercise-induced bronchospasm. Although the airflow response of nonasthmatic persons to exercise is to increase functional lung volumes and improve FEV_1 slightly (5–10%), exercise often provokes airflow obstruction in persons with inadequately treated asthma. Accordingly, in asthmatic patients, FEV_1 typically decreases during or after exercise by >15% (see Table 169.6). The onset of exercise-induced bronchospasm usually begins within 5 min, reaching a peak at 15 min following vigorous exercise, and often spontaneously resolves within 30-60 min. Studies of exercise challenges in school-age children typically identify an additional 5–10% with exercise-induced bronchospasm and previously unrecognized asthma. There are 2 caveats regarding exercise challenges: (1) treadmill challenges in the clinic are not completely reliable and can miss exertional asthma that can be demonstrated on the playing field; and (2) exercise challenges can induce severe exacerbations in at-risk patients. Careful patient selection for exercise challenges and preparedness for severe asthma exacerbations are required.

Peak expiratory flow (PEF) monitoring devices provide simple and inexpensive home-use tools to measure airflow and can be helpful in a number of circumstances (Fig. 169.4). Similar to spirometry in clinics, poor perceivers of asthma may benefit by monitoring PEFs at home to assess their airflow as an indicator of asthma control or problems. PEF devices vary in the ability to detect airflow obstruction; they are less sensitive and reliable than spirometry to detect airflow obstruction, such that, in some patients, PEF values decline only when airflow obstruction is severe. Therefore, PEF monitoring should be started by measuring morning and evening PEFs (best of 3 attempts) for several weeks for patients to practice the technique, to determine diurnal variation and a “personal best,” and to correlate PEF values with symptoms (and ideally spirometry). Diurnal variation in PEF >20% is consistent with asthma (see Fig. 169.4 and Table 169.6).

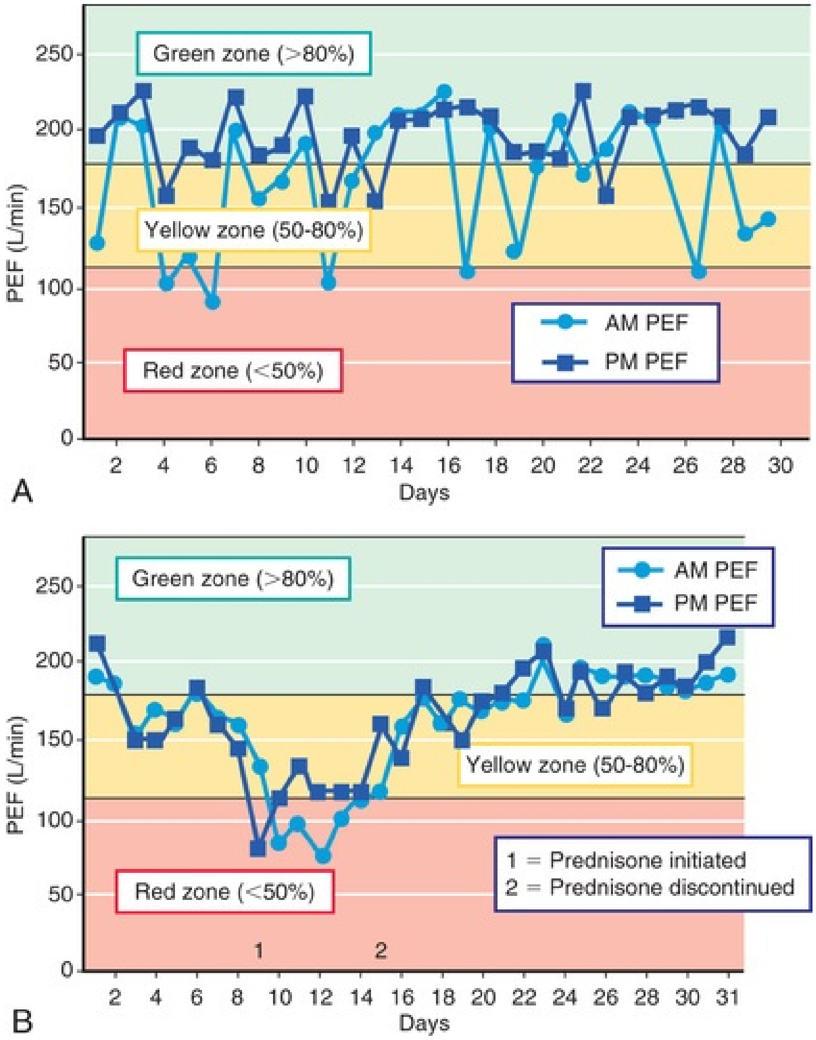


FIG. 169.4 **Example of the role of peak expiratory flow (PEF) monitoring in childhood asthma. A, PEFs performed and recorded twice daily, in the morning (AM) and evening (PM), over 1 mo in an asthmatic child. This child's “personal best” PEF value is 220 L/min; therefore the *green* zone (>80–100% of best) is 175-220 L/min; the *yellow* zone (50–80%) is 110-175 L/min; and the *red* zone (<50%) is <110 L/min. Note that this child's PM PEF values are almost always in the *green* zone, whereas his AM PEFs are often in the *yellow* or *red* zone. This pattern illustrates the typical diurnal AM -to-PM variation of inadequately controlled asthma. B, PEFs performed twice daily, in the morning (AM) and evening (PM), over 1 mo in an asthmatic child in whom an asthma exacerbation developed from a viral respiratory tract infection. Note that the child's PEF values were initially in the *green* zone. A viral respiratory tract infection led to asthma worsening, with a decline in PEF to the *yellow* zone that continued to worsen until PEF values were in the *red* zone. At that point, a 4-day prednisone course was administered, followed by improvement in PEF back to the *green* zone.**

Exhaled Nitric Oxide (FeNO)

Exhaled nitric oxide is a noninvasive measure of allergic airways inflammation used in clinical settings. Nitric oxide (NO) is a marker of allergic/eosinophilic inflammation that is easily and quickly measured in exhaled breath. Children as young as 5 yr can perform this test. FeNO can be used to distinguish asthma from other airways diseases that are mediated by nonallergic/noneosinophilic inflammation, such as GER, VCD, and cystic fibrosis. FeNO can substantiate the diagnosis of asthma, complement the assessment of asthma control, predict response to inhaled corticosteroid (ICS) therapy, assess adherence with ICS therapy, predict loss of control with ICS tapering, and predict future asthma exacerbations.

Radiology

The findings of chest radiographs (posteroanterior and lateral views) in children with asthma often appear to be normal, aside from subtle and nonspecific findings of hyperinflation (e.g., flattening of the diaphragms) and peribronchial thickening (Fig. 169.5). Chest radiographs can help identify abnormalities that are hallmarks of asthma mimics (aspiration pneumonitis, hyperlucent lung fields in bronchiolitis obliterans) and complications during asthma exacerbations (atelectasis, pneumomediastinum, pneumothorax). Some lung abnormalities can be better appreciated with high-resolution, thin-section chest CT scans. **Bronchiectasis** , which is sometimes difficult to appreciate on chest radiograph but is clearly seen on CT scan, implicates an asthma mimic such as cystic fibrosis, allergic bronchopulmonary mycoses (aspergillosis), ciliary dyskinesias, or immune deficiencies.

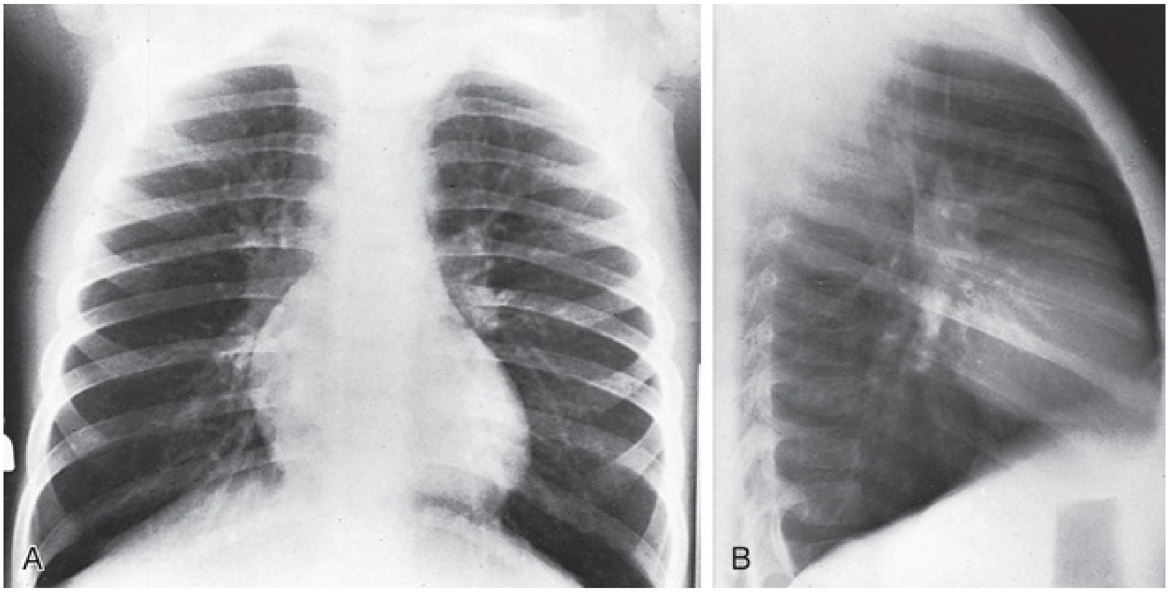

FIG. 169.5 A 4-year-old boy with asthma. Frontal (A) and lateral (B) radiographs show pulmonary hyperinflation, flattening of the diaphragms, and minimal peribronchial thickening. No asthmatic complication is apparent.

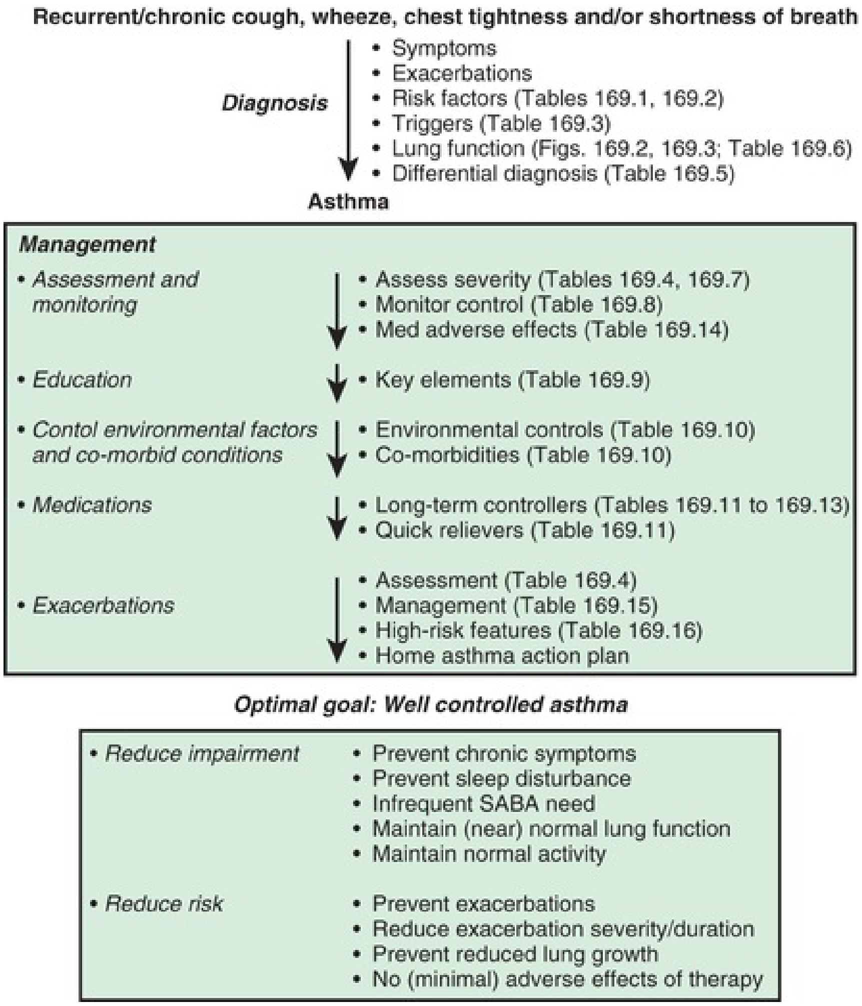
Other tests, such as allergy testing to assess sensitization to inhalant allergens, help with the management and prognosis of asthma. In a comprehensive U.S. study of 5-12 yr old asthmatic children, the **Childhood Asthma Management Program (CAMP)** , 88% of patients had inhalant allergen sensitization according to results of allergy skin-prick testing.

Treatment

The NIH-sponsored **National Asthma Education and Prevention Program's Expert Panel Report 3 (EPR3)** , *Guidelines for the Diagnosis and Management of Asthma 2007,* is available online.* Similar guidelines from GINA, *Global Strategy for Asthma Management and Prevention, 2016* , are also available (www.ginasthma.org). The key components to optimal asthma management are specified (Fig. 169.6). Management of asthma should have the following components: (1) assessment and monitoring of disease activity; (2) education to enhance patient and family knowledge and skills for self-management; (3) identification and management of precipitating factors and comorbid conditions that worsen asthma; and (4) appropriate selection of medications to address the patient's needs. The long-term goal of asthma management is attainment of optimal asthma control.



Recurrent/chronic cough, wheeze, chest tightness and/or shortness of breath
Diagnosis
• Symptoms
• Exacerbations
• Risk factors (Tables 169.1, 169.2)
• Triggers (Table 169.3)
• Lung function (Figs. 169.2, 169.3; Table 169.6)
• Differential diagnosis (Table 169.5)
Asthma
Management
• Assessment and monitoring
• Assess severity (Tables 169.4, 169.7)
• Monitor control (Table 169.8)
• Med adverse effects (Table 169.14)
• Education
• Key elements (Table 169.9)
• Contol environmental factors and co-morbid conditions
• Environmental controls (Table 169.10)
• Co-morbidities (Table 169.10)
• Medications
• Long-term controllers (Tables 169.11 to 169.13)
• Quick relievers (Table 169.11)
• Exacerbations
• Assessment (Table 169.4)
• Management (Table 169.15)
• High-risk features (Table 169.16)
• Home asthma action plan
Optimal goal: Well controlled asthma
• Reduce impairment
• Prevent chronic symptoms
• Prevent sleep disturbance
• Infrequent SABA need
• Maintain (near) normal lung function
• Maintain normal activity
• Reduce risk
• Prevent exacerbations
• Reduce exacerbation severity/duration
• Prevent reduced lung growth
• No (minimal) adverse effects of therapy

FIG. 169.6 **The key elements to optimal asthma management. SABA, Short-acting β-agonist.**

Component 1: Regular Assessment and Monitoring

Regular assessment and monitoring are based on the concepts of asthma severity, asthma control, and responsiveness to therapy. **Asthma severity** is the intrinsic intensity of disease, and assessment is generally most accurate in patients not receiving controller therapy. Therefore, assessing asthma severity directs the initial level of therapy. The 2 general categories are **intermittent** asthma and **persistent** asthma, the latter being further subdivided into **mild, moderate,** and **severe.** In contrast, **asthma control** is dynamic and refers to the day-to-day variability of an asthmatic patient. In children receiving controller therapy, assessment of asthma control is important in adjusting therapy and is categorized in 3 levels: well controlled, not well controlled, and very poorly controlled. **Responsiveness to therapy** is the ease or difficulty with which asthma control is attained by treatment.

Classification of asthma severity and control is based on the domains of **impairment** and **risk** . These domains do not necessarily correlate with each other and may respond differently to treatment. Childhood asthma is characterized by minimal day-to-day impairment, with the potential for frequent, severe exacerbations most often triggered by viral infections, whereas adults with asthma have greater impairment with less potential for risk. The NIH guidelines have distinct criteria for 3 childhood age groups—0-4 yr, 5-11 yr, and ≥12 yr—for the evaluation of both severity (Table 169.7) and control (Table 169.8). The level of asthma severity or control is based on the most severe impairment or risk category. In assessing asthma severity, **impairment** consists of an assessment of the patient's recent symptom frequency (daytime and nighttime, with subtle differences in numeric cutoffs between the 3 age-groups), SABA use for quick relief, ability to engage in normal or desired activities, and airflow compromise evaluated by spirometry in children ≥5 yr. **Risk** refers to the likelihood of developing severe asthma exacerbations. Of note, even in the absence of frequent symptoms, persistent asthma can be diagnosed and long-term controller therapy initiated. For children ≥5 yr, 2 exacerbations requiring oral corticosteroids in 1 yr, and for infants and preschool-aged children who have risk factors for asthma (see earlier) and 4 or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep, or 2 or more exacerbations in 6 mo requiring systemic corticosteroids, qualifies them as having persistent asthma.

Table 169.7

Assessing Asthma Severity and Initiating Treatment for Patients Who Are Not Currently Taking Long-Term Control Medications*

	CLASSIFICATION OF ASTHMA SEVERITY			
	INTERMITTENT	**PERSISTENT**		
		Mild	**Moderate**	**Severe**
COMPONENTS OF SEVERITY				
Impairment				
Daytime symptoms	≤2 days/wk	>2 days/wk but	Daily	Throughout the day

		not daily		
Nighttime awakenings:				
Age 0-4 yr	0	1-2×/mo	3-4×/mo	>1×/wk
Age ≥5 yr	≤2×/mo	3-4×/mo	>1×/wk but not nightly	Often 7×/wk
Short-acting β_2 -agonist use for symptoms (not for EIB prevention)	≤2 days/wk	>2 days/wk but not daily, and not more than 1× on any day	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extreme limitation
Lung function:				
FEV_1 % predicted, age ≥5 yr	Normal FEV_1 between exacerbations >80% predicted	≥80% predicted	60–80% predicted	<60% predicted
FEV_1 /FVC ratio [†] :				
Age 5-11 yr	>85%	>80%	75-80%	<75%
Age ≥12 yr	Normal	Normal	Reduced 5%	Reduced >5%
Risk				
Exacerbations requiring systemic corticosteroids:				
Age 0-4 yr	0-1/yr (see notes)	≥2 exacerbations in 6 mo requiring systemic CS *or* ≥4 wheezing episodes/yr lasting >1 day *and* risk factors for persistent asthma		
Age ≥ 5 yr	0-1/yr (see notes)	≥2/yr (see notes)	≥2/yr (see notes)	≥2/yr (see notes)
Consider severity and interval since last exacerbation. *Frequency and severity may fluctuate over time for patients in any severity category.* *Relative annual risk of exacerbations may be related to FEV_1 .*				
RECOMMENDED STEP FOR INITIATING THERAPY				
(See Table 169.11 for treatment steps.) The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.				
All ages	Step 1	Step 2		
Age 0-4 yr			Step 3 and consider a short course of systemic CS	Step 3 and consider a short course of systemic CS
Age 5-11 yr			Step 3: medium-dose ICS option and consider a short course of systemic CS	Step 3: medium-dose ICS option *or* Step 4 and consider a short course of CS
	In 2-6 wk, depending on severity, evaluate level of asthma control that is achieved. • Children 0-4 yr old: If no clear benefit is observed in 4-6 wk, stop treatment and consider alternative diagnoses or adjusting therapy accordingly. • Children 5-11 yr old: Adjust therapy accordingly.			

[*] Notes:

[†] Normal FEV_1 /FVC: 8-19 yr, 85%; 20-39 yr, 80%.

- Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2-4 wk. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether a patient's asthma is better or worse since the last visit. Assign severity to the most severe category in which any feature occurs.

- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past 6 mo, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma, may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

FEV_1 , Forced expiratory volume in 1 sec; FVC, forced vital capacity; CS corticosteroid; ICS, inhaled corticosteroid: EIB, exercise-induced bronchospasm.

Adapted from the National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3): Guidelines for the diagnosis and management of asthma—summary report 2007, *J Allergy Clin Immunol* 120(Suppl):S94–S138, 2007.

Table 169.8

Assessing Asthma Control and Adjusting Therapy in Children*

	CLASSIFICATION OF ASTHMA CONTROL		
	Well-Controlled	**Not Well-Controlled**	**Very Poorly Controlled**
COMPONENTS OF CONTROL			
Impairment			
Symptoms	≤2 days/wk but not more than once on each day	>2 days/wk or multiple times on ≤2 days/wk	Throughout the day
Nighttime awakenings:			
Age 0-4 yr	≤1×/mo	>1×/mo	>1×/wk
Age 5-11 yr	≤1×/mo	≥2×/mo	≥2×/wk
Age ≥12 yr	≤2×/mo	1-3×/wk	≥4×/wk
Short-acting β_2 -agonist use for symptoms (not for EIB pretreatment)	≤2 days/wk	>2 days/wk	Several times per day
Interference with normal activity	None	Some limitation	Extremely limited
Lung function:			
Age 5-11 yr:			
FEV_1 (% predicted or peak flow)	>80% predicted or personal best	60-80% predicted or personal best	<60% predicted or personal best
FEV_1 /FVC:	>80%	75-80%	<75%
Age ≥12 yr:			
FEV_1 (% predicted or peak flow)	>80% predicted or personal best	60-80% predicted or personal best	<60% predicted or personal best
Validated questionnaires † :			
Age ≥12 yr:			
ATAQ	0	1-2	3-4
ACQ	≤0.75	≤1.5	N/A
ACT	≥20	16-19	≤15

Risk			
Exacerbations requiring systemic corticosteroids:			
Age 0-4 yr	0-1/yr	2-3/yr	>3/yr
Age ≥5 yr	0-1/yr	≥2/yr (see notes)	
Consider severity and interval since last exacerbation.			
Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Reduction in lung growth *or* progressive loss of lung function	Evaluation requires long-term follow-up care.		
RECOMMENDED ACTION FOR TREATMENT			
	Maintain current step. Regular follow-up every 1-6 mo to maintain control. Consider step down if well controlled for at least 3 mo.	Step up [‡] (1 step) and reevaluate in 2-6 wk. If no clear benefit in 4-6 wk, consider alternative diagnoses or adjusting therapy. For side effects, consider alternative options.	Consider short course of oral corticosteroids. Step up [§] (1-2 steps) and reevaluate in 2 wk. If no clear benefit in 4-6 wk, consider alternative diagnoses or adjusting therapy. For side effects, consider alternative options.

[*] Notes:

[†] Validated questionnaires for the impairment domain (the questionnaires do not assess lung function or the risk domain) and definition of minimal important difference (MID) for each:

[‡] ACQ values of 0.76-1.40 are indeterminate regarding well-controlled asthma.

[§] Before step-up therapy: (a) review adherence to medications, inhaler technique, and environmental control; (b) if alternative treatment option was used in a step, discontinue it and use preferred treatment for that step.

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by caregiver's recall of previous 2-4 wk. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or intensive care unit admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- ATAQ, Asthma Therapy Assessment Questionnaire; MID = 1.0.
- ACQ, Asthma Control Questionnaire; MID = 0.5.
- ACT, Asthma Control Test; MID not determined.

FEV$_1$, Forced expiratory volume in 1 sec; FVC, forced vital capacity; EIB, exercise-induced bronchospasm; N/A, not available.

Adapted from the National Asthma Education and Prevention Program Expert Panel Report 3 (EPR 3): Guidelines for the diagnosis and management of asthma—summary report 2007, *J Allergy Clin Immunol* 120(Suppl):S94–S138, 2007.

Asthma management can be optimized through regular clinic visits every 2-6 wk until good asthma control is achieved. For children on controller medication therapy, management is tailored to the child's level of control. The NIH guidelines provide tables for evaluating asthma control for the 3 age-groups (see Table 169.8). In evaluation of asthma control, as in severity assessment, impairment includes an assessment of the patient's symptom frequency (daytime and nighttime), SABA use for quick relief, ability to engage in normal or desired activities, and for older children, airflow measurements. Validated asthma control questionnaires such as the **Asthma Control Test** (ACT, for adults and children ≥12 yr) and the Childhood ACT (C-ACT, for children 4-11 yr) can also be used to assess level of control. An ACT score of ≥20 indicates a child with **well-controlled** asthma, a value of 16-19 indicates **not well-controlled** asthma, and ≤15 indicates **very poorly controlled** asthma. For the C-ACT, a score ≥20 indicates *well controlled* , 13-19 indicates *not well controlled* ; and ≤12 indicates *very poorly controlled* .

Assessment of risk, in addition to considering severity and frequency of exacerbations requiring systemic corticosteroids, includes tracking the lung growth of older children, in an attempt to identify those with reduced and/or progressive loss of lung function, and monitoring adverse effects of medications. The degree of impairment and presence of risk are used to determine the patient's level of asthma control as well controlled, not well controlled, or very poorly controlled. Children with *well-controlled asthma* have daytime symptoms ≤2 days/wk and need a rescue bronchodilator ≤2 days/wk; an FEV_1 of >80% of predicted (and FEV_1 /FVC ratio >80% for children 5-11 yr); no interference with normal activity; and <2 exacerbations in the past year and an ACT score of ≥20. The impairment criteria vary slightly depending on age-group. Children whose status does not meet all the criteria of well-controlled asthma are determined to have either *not well-controlled* or *very poorly controlled* asthma, which is determined by the single criterion with the poorest rating.

Two to four asthma checkups per year are recommended for reassessing and maintaining good asthma control. Lung function testing (spirometry) is recommended at least annually and more often if asthma is poorly perceived, is inadequately controlled, and/or lung function is abnormally low. PEF monitoring at home can be helpful in the assessment of asthmatic children with poor symptom perception, moderate to severe asthma, or a history of severe asthma exacerbations. PEF monitoring is feasible in children as young as 4 yr who are able to master this skill. Use of a **stoplight zone system** tailored to each child's “personal best” PEF values can optimize effectiveness and interest (see Fig. 169.4): The green zone (80–100% of personal best) indicates good control; the yellow zone (50–80%) indicates less-than-optimal control and necessitates increased awareness and treatment; and the red zone (<50%) indicates poor control and greater likelihood of an exacerbation, requiring immediate intervention. In actuality, these ranges are approximate and may need to be adjusted for many asthmatic children by raising the ranges that indicate inadequate control (e.g., yellow zone, 70–90% in children with poor perception and those with lung hyperinflation). Once-daily PEF monitoring is preferable in the morning when peak flows are typically lower. Adherence to PEF monitoring is difficult, results may be variable and PEF monitoring alone is not more effective than symptoms monitoring on influencing asthma outcomes. Therefore, although PEF may be helpful in some circumstances to monitor those who are poor perceivers of airway obstruction, PEF monitoring is no longer generally recommended.

Component 2: Patient Education

Specific educational elements in the clinical care of children with asthma are believed to make an important difference in home management and in adherence of families to an optimal plan of care, eventually impacting patient outcomes (Table 169.9). Every visit presents an important opportunity to educate the child and family, allowing them to become knowledgeable partners in asthma management, because optimal management depends on their daily assessments and implementation of any management plan. Effective communications take into account sociocultural and ethnic factors of children and their families, provide an open forum for concerns about asthma and its treatment to be raised and addressed, and include patients and families as active participants in the development of treatment goals and selection of medications. Self-management skills should be reevaluated regularly (e.g., inhaler medication technique).

Table 169.9

Key Elements of Productive Clinic Visits for

Asthma

Standardize assessment of asthma control (e.g., Asthma Control Test, exacerbations in past 12 mo)

Specify goals of asthma management

Explain basic facts about asthma:

- Contrast normal vs asthmatic airways.
- Link airways inflammation, “twitchiness,” and bronchoconstriction.
- Long-term-control and quick-relief medications
- Address concerns about potential adverse effects of asthma pharmacotherapy.

Teach, demonstrate, and have patient show proper technique for:

- Inhaled medication use (spacer use with metered-dose inhaler)

Investigate and manage factors that contribute to asthma severity:

- Environmental exposures
- Comorbid conditions

Create written 2-part Asthma Action Plan (see Fig. 169.7):

- Daily management
- Action plan for asthma exacerbations

Regular follow-up visits:

- Twice yearly (more often if asthma not well controlled)
- Monitor lung function at least annually

During initial patient visits, a basic understanding of the pathogenesis of asthma (chronic inflammation and AHR underlying a clinically intermittent presentation) can help children with asthma and their parents understand the importance of recommendations aimed at reducing airways inflammation to achieve and maintain good asthma control. It is helpful to specify the expectations of good asthma control resulting from optimal asthma management (see Fig. 169.6). Addressing concerns about potential adverse effects of asthma pharmacotherapeutic agents, especially their risks relative to their benefits, is essential in achieving long-term adherence with asthma pharmacotherapy and environmental control measures.

All children with asthma should benefit from a written Asthma Action Plan (Fig. 169.7). This plan has two main components: (1) a daily “routine” management plan describing regular asthma medication use and other measures to keep asthma under good control; and (2) an action plan to manage worsening asthma, describing indicators of impending exacerbations, identifying what medications to take, and specifying when and how to contact the regular physician and/or obtain urgent/emergency medical care.

Asthma Action Plan

For: ______________________________ Doctor: ______________________________ Date: ______________

Doctor's Phone Number ______________________________ Hospital/Emergency Department Phone Number ______________________________

GREEN ZONE

Doing Well

- No cough, wheeze, chest tightness, or shortness of breath during the day or night
- Can do usual activities

And, if a peak flow meter is used,

Peak flow: more than ______________
(80 percent or more of my best peak flow)

My best peak flow is: ______________

Take these long-term control medicines each day (include an anti-inflammatory).

Medicine	How much to take	When to take it

Before exercise ☐ ______________ ☐ 2 or ☐ 4 puffs ______________ 5 minutes before exercise

YELLOW ZONE

Asthma Is Getting Worse

- Cough, wheeze, chest tightness, or shortness of breath, or
- Waking at night due to asthma, or
- Can do some, but not all, usual activities

-Or-

Peak flow: ________ to ________
(50 to 79 percent of my best peak flow)

First

Add: quick-relief medicine—and keep taking your GREEN ZONE medicine.

______________________________ ☐ 2 or ☐ 4 puffs, every 20 minutes for up to 1 hour
(short-acting beta$_2$-agonist) ☐ Nebulizer, once

Second

If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:
☐ Continue monitoring to be sure you stay in the green zone.

-Or-

If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:
☐ Take: ______________________________ ☐ 2 or ☐ 4 puffs or ☐ Nebulizer
(short-acting beta$_2$-agonist)
☐ Add: ______________________________ mg per day For ________ (3–10) days
(oral steroid)
☐ Call the doctor ☐ before/ ☐ within ________ hours after taking the oral steroid.

RED ZONE

Medical Alert!

- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

-Or-

Peak flow: less than ______________
(50 percent of my best peak flow)

Take this medicine:

☐ ______________________________ ☐ 4 or ☐ 6 puffs or ☐ Nebulizer
(short-acting beta$_2$-agonist)
☐ ______________________________ mg
(oral steroid)

Then call your doctor NOW. Go to the hospital or call an ambulance if:
- You are still in the red zone after 15 minutes AND
- You have not reached your doctor.

DANGER SIGNS
- **Trouble walking and talking due to shortness of breath**
- **Lips or fingernails are blue**

- **Take ☐ 4 or ☐ 6 puffs of your quick-relief medicine AND**
- **Go to the hospital or call for an ambulance ______________ NOW!**
(phone)

See the reverse side for things you can do to avoid your asthma triggers.

How To Control Things That Make Your Asthma Worse

This guide suggests things you can do to avoid your asthma triggers. Put a check next to the triggers that you know make your asthma worse and ask your doctor to help you find out if you have other triggers as well. Then decide with your doctor what steps you will take.

Allergens

☐ Animal Dander

Some people are allergic to the flakes of skin or dried saliva from animals with fur or feathers.

The best thing to do:
- Keep furred or feathered pets out of your home.

If you can't keep the pet outdoors, then:
- Keep the pet out of your bedroom and other sleeping areas at all times, and keep the door closed.
- Remove carpets and furniture covered with cloth from your home. If that is not possible, keep the pet away from fabric-covered furniture and carpets.

☐ Dust Mites

Many people with asthma are allergic to dust mites. Dust mites are tiny bugs that are found in every home—in mattresses, pillows, carpets, upholstered furniture, bedcovers, clothes, stuffed toys, and fabric or other fabric-covered items.

Things that can help:
- Encase your mattress in a special dust-proof cover.
- Encase your pillow in a special dust-proof cover or wash the pillow each week in hot water. Water must be hotter than 130° F to kill the mites. Cold or warm water used with detergent and bleach can also be effective.
- Wash the sheets and blankets on your bed each week in hot water.
- Reduce indoor humidity to below 60 percent (ideally between 30—50 percent). Dehumidifiers or central air conditioners can do this.
- Try not to sleep or lie on cloth-covered cushions.
- Remove carpets from your bedroom and those laid on concrete, if you can.
- Keep stuffed toys out of the bed or wash the toys weekly in hot water or cooler water with detergent and bleach.

☐ Cockroaches

Many people with asthma are allergic to the dried droppings and remains of cockroaches.

The best thing to do:
- Keep food and garbage in closed containers. Never leave food out.
- Use poison baits, powders, gels, or paste (for example, boric acid). You can also use traps.
- If a spray is used to kill roaches, stay out of the room until the odor goes away.

☐ Indoor Mold
- Fix leaky faucets, pipes, or other sources of water that have mold around them.
- Clean moldy surfaces with a cleaner that has bleach in it.

☐ Pollen and Outdoor Mold

What to do during your allergy season (when pollen or mold spore counts are high):
- Try to keep your windows closed.
- Stay indoors with windows closed from late morning to afternoon, if you can. Pollen and some mold spore counts are highest at that time.
- Ask your doctor whether you need to take or increase anti-inflammatory medicine before your allergy season starts.

Irritants

☐ Tobacco Smoke
- If you smoke, ask your doctor for ways to help you quit. Ask family members to quit smoking, too.
- Do not allow smoking in your home or car.

☐ Smoke, Strong Odors, and Sprays
- If possible, do not use a wood-burning stove, kerosene heater, or fireplace.
- Try to stay away from strong odors and sprays, such as perfume, talcum powder, hair spray, and paints.

Other things that bring on asthma symptoms in some people include:

☐ Vacuum Cleaning
- Try to get someone else to vacuum for you once or twice a week, if you can. Stay out of rooms while they are being vacuumed and for a short while afterward.
- If you vacuum, use a dust mask (from a hardware store), a double-layered or microfilter vacuum cleaner bag, or a vacuum cleaner with a HEPA filter.

☐ Other Things That Can Make Asthma Worse
- Sulfites in foods and beverages: Do not drink beer or wine or eat dried fruit, processed potatoes, or shrimp if they cause asthma symptoms.
- Cold air: Cover your nose and mouth with a scarf on cold or windy days.
- Other medicines: Tell your doctor about all the medicines you take. Include cold medicines, aspirin, vitamins and other supplements, and nonselective beta-blockers (including those in eye drops).

April 2007

FIG. 169.7 Asthma action plan for home use. This plan has two main components: (1) a daily management plan to keep asthma in good control; and (2) an action plan to recognize and manage worsening asthma. (From US Department of Health and Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute, NIH Pub No 07-5251, April 2007. https://www.nhlbi.nih.gov/health/resources/lung/asthma-action-plan).

Regular follow-up visits are recommended to help to maintain optimal asthma control. In addition to determining disease control level, revising PEF values daily and exacerbation management plans accordingly, follow-up visits are important teaching opportunities to encourage open communication of concerns with asthma management recommendations (e.g., daily administration of controller medications). Reassessing patients' and parents' understanding of the role of different medications in asthma management and control, and their technique in using inhaled medications, can be insightful and can help guide teaching to improve adherence to a management plan that might not have been adequately or properly implemented.

Adherence

Asthma is a chronic condition that is usually best managed with daily controller medication. However, symptoms wax and wane, severe exacerbations are infrequent, and when asthma is asymptomatic, a natural tendency is to reduce or discontinue daily controller therapies. As such, adherence to a daily controller regimen is frequently suboptimal; ICSs are underused 60% of the time. In one study, children with asthma who required an oral corticosteroid course for an asthma exacerbation had used their daily controller ICS 15% of the time. Misconceptions about controller medication time to onset, efficacy, and safety often underlie poor adherence and can be addressed by asking about such concerns at each visit.

Component 3: Control of Factors Contributing to Asthma Severity

Controllable factors that can worsen asthma can be generally grouped as (1) environmental exposures and (2) comorbid conditions (Table 169.10).

Table 169.10

Control of Factors Contributing to Asthma

Severity

Eliminate or Reduce Problematic Environmental Exposures

Environmental tobacco smoke elimination or reduction in home and automobiles

Allergen exposure elimination or reduction in sensitized asthmatic patients:

- Animal danders: pets (cats, dogs, rodents, birds)
- Pests (mice, rats)
- Dust mites
- Cockroaches
- Molds

Other airway irritants:

- Wood- or coal-burning smoke
- Strong chemical odors and perfumes (e.g., household cleaners)
- Dusts

Treat Comorbid Conditions

- Rhinitis
- Sinusitis
- Gastroesophageal reflux

Eliminating and Reducing Problematic Environmental Exposures

Most children with asthma have an **allergic component** to their disease; steps should be taken to investigate and minimize allergen exposures in sensitized asthmatic patients. The medical history should identify exposure to smoke, pollutant, and potential allergen triggers (see later), especially in the patient's home. Since often patients have chronic symptoms and cannot identify potential triggers, **allergy testing** should be considered for at least those with persistent asthma. For asthmatic patients who are allergic to allergens in their homes and/or schools or daycare centers, reducing or eliminating these indoor allergen exposures can reduce asthma symptoms, medication requirements, AHR, severe exacerbations, and disease persistence. Common home, school, and daycare allergen exposures include furred or feathered animals as pets (cats, dogs, rodents, birds) or as pests (mice, rats, cockroaches), and occult indoor allergens such as dust mites and molds. Although removing or eradicating these exposures from the home, school, and daycare setting of sensitized asthmatic patients is the most effective means of greatly reducing problematic allergen exposures, it can take ≥6 mo for the levels of these indoor allergens to drop significantly. Dust mite allergen exposure can be reduced by (1) encasing bedding and pillows in allergen-impermeable covers; (2) washing bedding weekly in hot water (> 130°F); (3) removing wall-to-wall carpeting and upholstered furniture; and (4) reducing and maintaining indoor humidity <50%.

Tobacco, wood and coal smoke, dusts, strong odors, and noxious air pollutants (e.g., nitrogen dioxide from inadequately vented gas stoves and furnaces) can aggravate asthma. These airway irritants should be eliminated from or reduced in the homes, schools/daycare centers, and automobiles/school transportation used by children with asthma. Annual influenza vaccination continues to be recommended for all children with asthma to reduce the risk of severe complications, although influenza is not responsible for the large majority of virus-induced asthma exacerbations experienced by children.

Treating Comorbid Conditions

Rhinitis, sinusitis, and GER often accompany asthma and worsen disease severity. They can also mimic asthma symptoms and lead to misclassification of asthma severity and control. Indeed, these conditions, along with asthma are the most common causes of chronic cough. Effective management of these comorbid conditions may improve asthma symptoms and disease severity, such that less asthma medication is needed to achieve good asthma control.

Gastroesophageal reflux is common in children with persistent asthma (see Chapter 349). GER may worsen asthma through 2 postulated mechanisms: (1) aspiration of refluxed gastric contents (micro- or macro-aspiration); and (2) vagally mediated reflex bronchospasm. Occult GER should be suspected in individuals with difficult-to-control asthma, especially patients who have prominent nocturnal asthma symptoms or who prop themselves up in bed to reduce nocturnal symptoms. GER can be demonstrated by reflux of barium into the esophagus during a barium swallow procedure or by esophageal probe monitoring. Because radiographic studies lack sufficient sensitivity and specificity, extended esophageal monitoring is the method of choice for diagnosing GER. If significant GER is noted, reflux precautions should be instituted (no food 2 hr before bedtime, head of bed elevated 6 inches, avoidance of caffeinated beverages), and medications such as proton pump inhibitors (omeprazole, lansoprazole) or H_2 -receptor antagonists (cimetidine, ranitidine) administered for 8-12 wk. Of note, proton pump inhibition did not improve asthma control in a study of children with persistent, poorly controlled asthma and GER.

Rhinitis is usually comorbid with asthma, detected in about 90% of children with asthma. Rhinitis can be seasonal and/or perennial, with allergic and nonallergic components. Rhinitis complicates and worsens asthma via numerous direct and indirect mechanisms. Nasal breathing may improve asthma and reduce exercise-induced bronchospasm by humidifying and warming inspired air and filtering out allergens and irritants that can trigger asthma and worsen airway inflammation. Reduction of nasal congestion and obstruction can help the nose to perform these humidifying, warming, and filtering functions. In asthmatic patients, improvement in rhinitis is also associated with modest reductions in AHR, airways inflammation, asthma symptoms, and asthma medication use. Optimal rhinitis management in children is similar to asthma management in regard to the importance of interventions to reduce nasal inflammation (see Chapter 168).

Radiographic evidence for **sinus disease** is common in patients with asthma. There is usually significant improvement in asthma control in patients diagnosed and treated for sinus disease. A coronal, “screening” or “limited” CT scan of the sinuses is the gold standard test for sinus disease and can be helpful if recurrent sinusitis has been suspected and repeatedly treated without such evidence. In comparison, sinus radiographs are inaccurate and should be avoided. If the patient with asthma has clinical and radiographic evidence for sinusitis, topical therapy to include nasal saline irrigations, intranasal corticosteroids, and a 2-3 wk course of antibiotics should be considered.

Component 4: Principles of Asthma Pharmacotherapy

The current version of NIH asthma guidelines (2007) provides treatment recommendations that vary by level of asthma severity and age-groups (Table 169.11). There are 6 treatment steps. Patients at **Treatment Step 1** have intermittent asthma. Children with mild persistent asthma are at **Treatment Step 2** . Children with moderate persistent asthma can be at **Treatment Step 3 or 4** .

Children with severe persistent asthma are at **Treatment Steps 5 and 6** . The goals of therapy are to achieve a well-controlled state by reducing the components of both impairment (e.g., preventing or minimizing symptoms, infrequently needing quick-reliever medications, maintaining “normal” lung function and normal activity levels) and risk (e.g., preventing recurrent exacerbations, reduced lung growth, and medication adverse effects). The recommendations for initial therapy are based on assessment of asthma severity, while level of control determines any modifications of treatment in children who are already using controller therapy. A major objective of this approach is to identify and treat all “persistent” and inadequately controlled asthma with antiinflammatory controller medication. Management of Treatment Step 1 (intermittent asthma) is simply the use of a SABA as needed for symptoms and for pretreatment in those with exercise-induced bronchospasm (see Table 169.11).

Table 169.11

Stepwise Approach for Managing Asthma in Children*

AGE	THERAPY †	INTERMITTENT ASTHMA	PERSISTENT ASTHMA: DAILY MEDICATION				
		 STEP DOWN if possible (and asthma is well controlled at least 3 months) ASSESS CONTROL STEP UP if needed (first check inhaler technique, adherence, environmental control, and comorbid condition)					
		Step 1	**Step 2**	**Step 3**	**Step 4**	**Step 5**	**S**
0-4 yr	Preferred	SABA prn	Low-dose ICS	Medium-dose ICS	Medium-dose ICS + *either* LABA *or* LTRA	High-dose ICS + *either* LABA *or* LTRA	
	Alternative		Cromolyn or montelukast				
5-11 yr	Preferred	SABA prn	Low-dose ICS	*Either* low-dose ICS ± LABA, LTRA, or theophylline *or*	Medium-dose ICS + LABA	High-dose ICS + LABA	

				Medium-dose ICS			
	Alternative		Cromolyn, LTRA, nedocromil, or theophylline		Medium-dose ICS + *either* LTRA *or* Theophylline	High-dose ICS + *either* LTRA *or* Theophylline	
≥12 yr	Preferred	SABA prn	Low-dose ICS	Low-dose ICS + LABA *or* Medium-dose ICS	Medium-dose ICS + LABA	High-dose ICS + LABA *and* Consider omalizumab for patients with allergies	
	Alternative		Cromolyn, LTRA, nedocromil, or theophylline	Low-dose ICS + LTRA, theophylline, or zileuton	Medium-dose ICS + LTRA, theophylline, or zileuton		
	Each step: Patient education, environmental control, and management of comorbidities. Age ≥5 yr: Steps 2-4: Consider subcutaneous allergen immunotherapy for patients who have allergic ast						
	QUICK-RELIEF MEDICATION FOR ALL PATIENTS						
	SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatm intervals as needed. Short course of oral systemic corticosteroids may be needed. *Caution:* Use of SABA >2 days/wk for symptom relief (not prevention of exercise-induced bronchospas indicates inadequate control and the need to step up treatment. For ages 0-4 yr: With viral respiratory infection: SABA q4-6h up to 24 hr (longer with physician consul short course of systemic corticosteroids if exacerbation is severe or patient has history of previous sever exacerbations.						

[*] Notes:

[†] Alphabetical order is used when more than 1 treatment option is listed within *either* preferred or alternative therapy.

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4-6 wk and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children age 0-4 yr are limited.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

- Theophylline is a less desirable alternative because of the need to monitor serum concentration levels. The 2016 GINA guidelines do not recommend the use of theophylline as a controller medication and in IV forms to treat status asthmaticus due to its severe adverse effects profile.
- Zileuton is less desirable alternative because of limited studies as adjunctive therapy and the need to monitor liver function.

ICS, Inhaled corticosteroid; LABA, inhaled long-acting β_2 -agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroid; prn, as needed; SABA, inhaled short-acting β_2 -agonist.

Adapted from the National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3): Guidelines for the diagnosis and management of asthma—summary report 2007, *J Allergy Clin Immunol* 120(Suppl):S94–S138, 2007.

The preferred treatment for all patients with persistent asthma is ICS therapy, as monotherapy or in combination with adjunctive therapy. The type(s) and amount(s) of daily controller medications to be used are determined by the asthma severity and control rating.

Low-dose ICS therapy is the treatment of choice for all children at Treatment Step 2 (mild persistent asthma). Alternative medications include a leukotriene-modifying agent (montelukast), nonsteroidal antiinflammatory drugs (cromolyn, nedocromil), and theophylline. There are 4 co-equal choices for the treatment of school-aged children at Treatment Step 3 (moderate persistent asthma): medium-dose ICS, combination low-dose ICS and **inhaled long-acting β_2 -agonist (LABA)** , a **leukotriene receptor antagonist (LTRA)** , or theophylline. In a study of children with uncontrolled asthma receiving low-dose ICS, the addition of LABA provided greater improvement than either adding an **LTRA** or increasing ICS dosage. However, some children had a good response to medium-dose ICS or the addition of an LTRA, justifying them as step-up controller therapy options. The preferred therapy for children at Treatment Step 4 (also moderate persistent asthma) is medium-dose ICS/LABA combination. Alternatives include medium-dose ICS with either theophylline or an LTRA. For young children (≤4 yr) at Treatment Step 3, medium-dose ICS is recommended, while medium-dose ICS plus either an LABA or an LTRA are recommended for preschool-age children at Treatment Step 4.

Children with severe persistent asthma (Treatment Steps 5 and 6) should receive combination high-dose ICS plus LABA. Long-term administration of oral corticosteroids as controller therapy is effective but is rarely required. In addition, omalizumab can be used in children ≥6 yr old with severe allergic asthma, while mepolizumab is approved for children ≥12 yr with severe asthma eosinophilic asthma. A rescue course of systemic corticosteroids may be necessary at any step for very poorly controlled asthma. For children age ≥5 yr with allergic asthma requiring Treatment Steps 2-4 care, allergen immunotherapy can also be considered.

“Step-Up, Step-Down” Approach

The NIH guidelines emphasize initiating higher-level controller therapy at the outset to establish prompt control, with measures to “step-down” therapy once good asthma control is achieved. Initially, airflow limitation and the pathology of asthma may limit the delivery and efficacy of ICS such that stepping up to higher doses and/or combination therapy may be needed to gain asthma control. Furthermore, ICS requires weeks to months of daily administration for optimal efficacy to occur. Combination pharmacotherapy can achieve relatively immediate improvement while also providing daily ICS to improve long-term control and reduce exacerbation risk.

Asthma therapy can be stepped down after good asthma control has been achieved and maintained for at least 3 mo. By determining the lowest number or dose of daily controller medications that can maintain good control, the potential for medication adverse effects is reduced. Regular follow-up is still emphasized because the variability of asthma's course is well recognized. When asthma is not well controlled, therapy should be escalated by increasing controller treatment step by 1 level and closely monitoring for clinical improvement. For a child with very poorly controlled asthma, the recommendations are to consider a short course of prednisone, or to increase therapy by 2 steps, with reevaluation in 2 wk. If step-up therapy is being considered, it is important to check inhaler technique and adherence, implement environmental control measures, and identify and treat comorbid conditions.

Referral to Asthma Specialist

Referral to an asthma specialist for consultation or co-management is recommended if there are difficulties in achieving or maintaining good asthma control. For children <4 yr, referral is recommended if the patient requires at least Treatment Step 3 care, and should be considered if the patient requires Treatment Step 2 care. For children ≥5 yr, consultation with a specialist is recommended if the patient requires Treatment Step 4 care or higher, and should be considered if Treatment Step 3 is required. Referral is also recommended if allergen immunotherapy or biologic therapy is being considered.

Long-Term Controller Medications

All levels of persistent asthma should be treated with ICS therapy to reduce airway inflammation and improve long-term control (see Table 169.11). Other long-term controller medications include LABAs, leukotriene modifiers, cromolyn, sustained-release theophylline, and tiotropium in adolescents. Omalizumab (Xolair) and mepolizumab (Nucala) are approved by the U.S. Food and Drug Administration (FDA) for use as an add-on therapy in children ≥6 yr and ≥12 yr who have severe allergic asthma or eosinophilic asthma, respectively, that remains difficult to control. Corticosteroids are the most potent and most effective medications used to treat both the acute (administered systemically) and the chronic (administered by inhalation) manifestations of asthma. They are available in inhaled, oral, and parenteral forms (Tables 169.12 and 169.13).

Table 169.12

Usual Dosages for Long-Term Control Medications

MEDICATION	**AGE**		
	0-4 yr	**5-11 yr**	**≥12 yr**
INHALED CORTICOSTEROIDS (see Table 169.13)			
Methylprednisolone: 2, 4, 8, 16, 32 mg tablets Prednisolone: 5 mg tablets; 5 mg/5 mL, 15 mg/5 mL Prednisone: 1, 2.5, 5, 10, 20, 50 mg tablets; 5 mg/mL, 5 mg/5 mL	0.25-2 mg/kg daily in single dose in AM or qod as needed for control Short-course “burst”: 1-2 mg/kg/day; maximum 30 mg/day for 3-10 days	0.25-2 mg/kg daily in single dose in AM or qod as needed for control Short-course “burst”: 1-2 mg/kg/day; maximum 60 mg/day for 3-10 days	7.5-60 mg daily in a single dose in AM or qod as needed for control Short-course “burst” to achieve control: 40-60 mg/day as single or 2 divided doses for 3-10 days
Fluticasone/salmeterol (Advair):	N/A		
DPI: 100, 250, or 500 µg/50 µg		1 inhalation bid; dose depends on level of severity or control (the 100/50 dosage is indicated in children ≥4 yr)	1 inhalation bid; dose depends on level of severity or control
HFA: 45 µg/21 µg, 115 µg/21 µg, 230 µg/21 µg			2 inhalations bid; dose depends on level of severity or control
Budesonide/formoterol (Symbicort): HFA: 80 µg/4.5 µg, 160 µg/4.5 µg	N/A		2 inhalations bid; dose depends on level of severity or control
Mometasone/formoterol (Dulera):			2 inhalations bid; dose depends on level of severity

HFA: 100 µg/5 µg, 200 µg/5 µg			or control
Leukotriene receptor antagonists:			
Montelukast (Singulair): 4 or 5 mg chewable tablet 4 mg granule packets 10 mg tablet	4 mg qhs (1-5 yr of age)	5 mg qhs (6-14 yr)	10 mg qhs (indicated in children ≥15 yr)
Zafirlukast (Accolate): 10 or 20 mg tablet	N/A	10 mg bid (7-11 yr)	40 mg daily (20 mg tablet bid)
5-Lipoxygenase inhibitor: (Zileuton CR): 600 mg tablet	N/A	N/A	1,200 mg bid (give 2 tablets bid)
Immunomodulators:			
Omalizumab (anti-IgE; Xolair): SC injection, 150 mg/1.2 mL after reconstitution with 1.4 mL sterile water for injection	N/A	N/A	150-375 mg SC q 2-4 wk, depending on body weight and pretreatment serum IgE level
Mepolizumab (anti–IL-5; Nucala): SC injection, 100 mg after reconstitution with 1.2 mL sterile water for injection	N/A	N/A	100 mg SC q 4 wk

bid, 2 times daily; DPI, dry powder inhaler; HFA, hydrofluoroalkane; MDI, metered-dose inhaler; q, every; qhs, every night; qid, 4 times daily; qod, every other day; SC, subcutaneous(ly).

Table 169.13

Estimated Comparative Inhaled Corticosteroid Doses

GLUCOCORTICOID	**LOW DAILY DOSE**	**MEDIUM DAILY DOSE**	**HIGH DAILY DOSE**
Beclomethasone (Qvar) MDI: 40 or 80 µg (Approved for children ≥5 yr)	80-160 µg	160-320 µg	>320 µg
Budesonide (Pulmicort Flexhaler) DPI: 90, 180 µg (Approved for children ≥6 yr)	200 µg	200-400 µg	>400 µg
Budesonide suspension for nebulization (Generic and Pulmicort Respules) 0.25 mg, 0.5 mg, 1 mg (Approved for children 1-8 yr)	0.5 mg	1.0 mg	2.0 mg
Ciclesonide (Alvesco) MDI: 80, 160 µg	80 µg	80-160 µg	160 µg

(Approved for children ≥12 yr)			
Flunisolide (Aerospan) MDI: 80 µg/puff (Approved for children ≥6 yr)	80 µg	80-160 µg	160 µg
Fluticasone propionate (Flovent, Flovent Diskus) MDI: 44, 110, 220 µg DPI: 50, 100, 250 µg (44 and 50 µg approved for children ≥4 yr)	88-176 µg 100-200 µg	176-440 µg 200-500 µg	>440 µg >500 µg
Fluticasone furoate (Arnuity Ellipta) DPI: 100, 200 µg (Approved for children ≥12 yr)	100 µg	100-200 µg	200 µg
Mometasone Furoate (Asmanex, Asmanex Twisthaler) MDI: 100, 200 µg DPI: 110, 220 µg (Approved for children ≥4 yr)	110 µg 100 µg	110 µg 100 µg	110 µg 100 µg

DPI, Dry powder inhaler; MDI, metered-dose inhaler.

Adapted from National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3): Guidelines for the diagnosis and management of asthma—summary report 2007, *J Allergy Clin Immunol* 120(Suppl):S94–S138, 2007.

Inhaled Corticosteroids

ICS therapy improves lung function; reduces asthma symptoms, AHR, and use of "rescue" medications; improves quality of life; and most importantly reduces the need for prednisone, urgent care visits, and hospitalizations by approximately 50%. Epidemiologic studies have also shown that ICS therapy substantially lowers the risk of death attributable to asthma if used regularly. Because ICS therapy can achieve all the goals of asthma management, it is viewed as first-line treatment for persistent asthma.

Seven ICSs are FDA approved for use in children. The NIH and GINA guidelines provide equivalence classifications (see Table 169.13), although direct comparisons of efficacy and safety outcomes are lacking. ICSs are available in metered-dose inhalers (MDIs) using hydrofluoroalkane (HFA) as their propellant, in dry powder inhalers (DPIs), or in suspension for nebulization. Fluticasone propionate, fluticasone furoate, mometasone furoate, ciclesonide, and to a lesser extent budesonide are considered "second-generation" ICSs, in that they have greater antiinflammatory potency and less *systemic* bioavailability (and thus potential for systemic adverse effects) because of their extensive first-pass hepatic metabolism. The selection of the initial ICS dose is based on the determination of disease severity.

Even though ICSs can be very effective, there has been some reluctance to treat children with ICSs due to parental and occasionally physician concerns regarding their potential for adverse effects with chronic use. The adverse effects that occur with long-term systemic corticosteroid therapy have not been seen or have only rarely been reported in children receiving ICSs in recommended doses. The risk of adverse effects from ICS therapy is related to the dose and frequency of administration (Table 169.14). High doses (≥1,000 µg/day in children) and frequent administration (4 times/day) are more likely to have both local and systemic adverse effects. Children who receive maintenance therapy with higher ICS doses are also likely to require frequent systemic corticosteroid courses for asthma exacerbations, further increasing their risk of corticosteroid adverse effects.

Table 169.14

Risk Assessment for Corticosteroid Adverse Effects

	CONDITIONS	RECOMMENDATIONS
Low risk	(≤1 risk factor*) Low- to medium-dose ICS (see Table 169.13)	Monitor blood pressure and weight with each physician visit. Measure height annually (stadiometry); monitor periodically for declining growth rate and pubertal developmental delay. Encourage regular physical exercise. Ensure adequate dietary calcium and vitamin D with additional supplements for daily calcium if needed. Avoid smoking and alcohol. Ensure TSH status if patient has history of thyroid abnormality.
Medium risk	(If >1 risk factor,* consider evaluating as high risk) High-dose ICS (see Table 169.13) At least 4 courses of OCS/yr	As above, *plus* : Yearly ophthalmologic evaluations to monitor for cataracts or glaucoma Baseline bone densitometry (DEXA scan) Consider patient at increased risk for adrenal insufficiency, especially with physiologic stressors (e.g., surgery, accident, significant illness).
High risk	Chronic systemic corticosteroids (>7.5 mg daily or equivalent for >1 mo) ≥7 OCS burst treatments/year Very-high-dose ICS (e.g., fluticasone propionate ≥800 µg/day)	As above, *plus* : DEXA scan: if DEXA z score ≤1.0, recommend close monitoring (every 12 mo) Consider referral to a bone or endocrine specialist. Bone age assessment Complete blood count Serum calcium, phosphorus, and alkaline phosphatase determinations Urine calcium and creatinine measurements Measurements of testosterone in males, estradiol in amenorrheic premenopausal women, vitamin D (25-OH and 1,25-OH vitamin D), parathyroid hormone, and osteocalcin Urine telopeptides for those receiving long-term systemic or frequent OCS treatment Assume adrenal insufficiency for physiologic stressors (e.g., surgery, accident, significant illness).

[*] Risk factors for osteoporosis: presence of other chronic illness(es), medications (corticosteroids, anticonvulsants, heparin, diuretics), low body weight, family history of osteoporosis, significant fracture history disproportionate to trauma, recurrent falls, impaired vision, low dietary calcium and vitamin D intake, and lifestyle factors (decreased physical activity, smoking, alcohol intake).

DEXA, Dual-energy x-ray absorptiometry; ICS, inhaled corticosteroid; OCS, oral corticosteroid; TSH, thyroid-stimulating hormone.

The most commonly encountered ICS adverse effects are local: oral **candidiasis** (thrush) and **dysphonia** (hoarse voice). Thrush results from propellant-induced mucosal irritation and local immunosuppression, and dysphonia is the result of vocal cord myopathy. These effects are dose dependent and are most common in individuals receiving high-dose ICS or oral corticosteroid therapy. The incidence of these local effects can be greatly minimized by using a spacer with an MDI with the ICS, because spacers reduce oropharyngeal deposition of the drug and propellant. Mouth rinsing using a "swish and spit" technique after ICS use is also recommended.

The potential for growth suppression and osteoporosis with long-term ICS use had been an unanswered concern. However, a long-term, prospective NIH-sponsored study (CAMP) followed the growth and bone mineral density (BMD) of >1,000 children (age 6-12 yr at entry) with mild to moderate asthma until they reached adulthood and found slight growth suppression and osteopenia in some children who received long-term ICS therapy. A small (1.1 cm), limited (1 year) growth suppressive effect was noted in children receiving budesonide, 200 µg twice daily, after 5 yr of therapy. Height was then followed until all children had reached adulthood (mean age 25 yr). Those who received ICS therapy remained approximately 1 cm shorter than those who received placebo. Thus, children treated with long-term ICS therapy are likely to be about 1 cm shorter than expected as an adult, which is of little clinical significance. BMD was no different in those receiving budesonide vs placebo during the duration of the study, while a follow-up study after a mean of 7 years found a slight dose-dependent effect of ICS therapy on bone mineral accretion only among males. A much greater effect on BMD was observed with increasing numbers of oral corticosteroid bursts for acute asthma, as well as an increase in risk for osteopenia, which was again limited to males. These findings were with use of low-dose budesonide; higher ICS doses, especially of agents with increased potency, have a greater potential for adverse effects. Thus, corticosteroid adverse effects screening and osteoporosis prevention measures are recommended for patients receiving higher ICS doses, since these patients are also likely to require systemic courses for exacerbations (see Table 169.14).

Systemic Corticosteroids

The development of second-generation ICSs, especially when used in combination with a LABA in a single device, have allowed the vast majority of children with asthma to achieve and maintain good control without need for maintenance oral corticosteroid (OCS) therapy. Thus, OCSs are used primarily to treat asthma exacerbations and, rarely, in children with very severe disease. In these patients, every attempt should be made to exclude comorbid conditions and to keep the OCS dose at ≤20 mg every other day. Doses exceeding this amount are associated with numerous adverse effects (see Chapter 593). To determine the need for continued OCS therapy, tapering of the OCS dose over several weeks should be attempted, with close monitoring of the patient's symptoms and lung function.

Prednisone, prednisolone, and methylprednisolone are rapidly and completely absorbed, with peak plasma concentrations occurring within 1-2 hr. Prednisone is an inactive prodrug that requires biotransformation via first-pass hepatic metabolism to prednisolone, its active form. Corticosteroids are metabolized in the liver into inactive compounds, with the rate of metabolism influenced by drug interactions and disease states. Anticonvulsants (phenytoin, phenobarbital, carbamazepine) increase the metabolism of prednisolone, methylprednisolone, and dexamethasone, with methylprednisolone most significantly affected. Rifampin also enhances the clearance of corticosteroids and can result in diminished therapeutic effect. Other medications (ketoconazole, oral contraceptives) can significantly delay corticosteroid metabolism. Some macrolide antibiotics, such as erythromycin and clarithromycin, delay the clearance of only methylprednisolone.

Long-term OCS therapy can result in a number of adverse effects over time (see Chapter 595). Some occur immediately (metabolic effects), whereas others can develop insidiously over several months to years (growth suppression, osteoporosis, cataracts). Most adverse effects occur in a cumulative dose- and duration-dependent manner. Children who require routine or frequent short courses of OCSs, especially with concurrent high-dose ICSs, should receive corticosteroid adverse effects screening (see Table 169.14) and osteoporosis preventive measures (see Chapter 726).

Long-Acting Inhaled β-Agonists

Although considered daily controller medications, *LABAs (salmeterol,* *formoterol) are not intended for use as monotherapy for persistent asthma because they can increase the risk for serious asthma exacerbations (ICU admission, endotracheal intubation) and asthma-related deaths when used without an ICS.* The likely mechanism involves the ability of LABAs to “mask” worsening asthma inflammation and asthma severity, leading to a delay in seeking urgent care and increased risk of a life-threatening exacerbation. Although both salmeterol and formoterol have a prolonged duration of effect (≥12 hr), salmeterol has a prolonged onset of effect (60 min), while formoterol's onset of effect is rapid (5-10 min) after administration. Given their long duration of action, LABAs are well suited for patients with nocturnal asthma and for individuals who require frequent use of SABA inhalations during the day to prevent exercise-induced bronchospasm (EIB), but only in combination with ICSs. Of note, the FDA requires all LABA-containing medications to be labeled with a warning of an increase in severe asthma episodes associated with these agents. In addition, the FDA recommends that once a patient is well controlled on combination ICS/LABA therapy, the LABA component should be discontinued while continuing treatment with the ICS.

Combination ICS/LABA Therapy

Combination ICS/LABA therapy is recommended for patients who are suboptimally controlled with ICS therapy alone and those with moderate or severe persistent asthma. In those inadequately controlled with ICS alone, combination ICS/LABA therapy is superior to add-on therapy with either an LTRA or theophylline or doubling the ICS dose. Benefits include improvement in baseline lung function, less need for rescue SABA therapy, improved quality of life, and fewer asthma exacerbations. A large study by the NIH-sponsored CARE Network found that in children inadequately controlled with low-dose ICS therapy, combination low-dose fluticasone/salmeterol (100 µg/21 µg) twice daily was almost twice as effective as other step-up regimens, including fluticasone (250 µg) twice daily or low-dose fluticasone (100 µg twice daily) plus montelukast once daily, with the greatest improvement in reducing exacerbations requiring prednisone and study withdrawals due to poorly controlled asthma. In addition, combination fluticasone/salmeterol was as effective as medium-dose fluticasone and was superior to combination fluticasone/montelukast therapy in black children, arguing against the notion that black children are more prone to serious asthma exacerbations than white children when treated with combination ICS/LABA therapy.

Despite their efficacy and widespread use, the long-term safety of LABAs, even when used in combination with ICS in a single inhaler, has been questioned. To address this concern of rare, severe asthma-related events with LABA/ICS use, large randomized controlled trials (RCTs) compared the safety of combination ICS/LABA vs ICS monotherapy. Two studies of >23,000 adults and adolescents ≥12 yr old with various levels of asthma severity were randomized to receive ICS (low or medium dose) monotherapy vs equivalent ICS/LABA (fluticasone vs fluticasone/salmeterol; budesonide vs budesonide/formoterol) over 26 weeks to determine if small but significant differences might occur in asthma hospitalization, intubation, or death attributable to ICS/LABA. No intubations or asthma deaths occurred during the study, and no differences in asthma hospitalizations between treatment groups were observed. The similar pediatric study enrolled >6,000 children age 4-11 yr with various levels of asthma severity to receive either fluticasone (low or medium dose) or equivalent fluticasone/salmeterol dose over 26 weeks, with similar findings of no significant differences in severe asthma-related events between treatment groups. *These results strongly suggest that the use of combination ICS/LABA products in children and adults with moderate to severe persistent asthma is both effective and safe.*

Leukotriene-Modifying Agents

Leukotrienes are potent proinflammatory mediators that can induce bronchospasm, mucus secretion, and airways edema. Two classes of leukotriene modifiers have been developed: inhibitors of leukotriene synthesis and leukotriene receptor antagonists (LTRAs). Zileuton, the only synthesis inhibitor, is not approved for use in children <12 yr. Because zileuton can result in elevated liver function enzyme values in 2–4% of patients, and interacts with medications metabolized via the cytochrome P450 system, it is rarely prescribed for children with asthma.

LTRAs have bronchodilator and targeted antiinflammatory properties and reduce exercise-, aspirin-, and allergen-induced bronchoconstriction. LTRAs are recommended as an alternative treatment for mild persistent asthma and as an add-on medication with ICS for moderate persistent asthma. Two LTRAs with FDA-approved use in children are montelukast and zafirlukast. Both medications improve asthma symptoms, decrease the need for rescue β-agonist use, and modestly improve lung function. **Montelukast** is approved for use in children ≥1 yr of age and is administered once daily, whereas **zafirlukast** is approved in children ≥5 yr and is given twice daily. LTRAs are less effective than ICSs in patients with mild persistent asthma (e.g., ICSs improve baseline lung function 5–15%, whereas LTRAs improve lung function 2.5–7.5%). LTRAs have few, if any, significant adverse effects, although case reports have described mood changes and suicidality in adolescents soon after instituting montelukast. When initially prescribing montelukast, a precaution is to inform the child and family that, if mood changes are noted after starting montelukast, they should discontinue its use and contact their physician.

Nonsteroidal Antiinflammatory Agents

Cromolyn and **nedocromil** are considered nonsteroidal antiinflammatory drugs (NSAIDs), although they have little efficacy as a long-term controller for asthma. They can block EIB and bronchospasm caused by allergen challenge. Although both drugs are considered alternative controller agents for children with mild persistent asthma, *the 2016 GINA guidelines no longer recommend cromolyn or nedocromil*. Because they inhibit EIB and allergen-triggered responses, cromolyn (nedocromil is no longer available in the United States) can be used as an alternative or add-on to SABAs for these specific circumstances.

Theophylline is a phosphodiesterase inhibitor with bronchodilator and antiinflammatory effects that can reduce asthma symptoms and rescue SABA use. Although the National Heart, Lung, and Blood Institute (NHLBI) guidelines continue to include theophylline as an add-on agent to ICS in school-age children at Treatment Step 3 and beyond, it is rarely used in children today because of its potential toxicity. Theophylline has a narrow therapeutic window, with overdosage associated with headaches, vomiting, cardiac arrhythmias, seizures, and death. Therefore, when used, serum theophylline levels need to be carefully and routinely monitored, especially if the patient has a viral illness associated with a fever or is concomitantly taking a medication known to delay theophylline clearance. As a result, *the 2016 GINA guidelines no longer recommend theophylline* at any level of asthma severity or control.

Long-Acting Inhaled Anticholinergics

Tiotropium is a long-acting anticholinergic agent (24-hr duration of action) that is FDA approved for use in children with asthma ≥12 yr old. Studies in adults and adolescents have found tiotropium to be equivalent to a LABA when used in combination with an ICS. It has also been found to reduce exacerbations and improve lung function in patients with inadequately controlled asthma despite treatment with combination ICS/LABA products.

Allergen Immunotherapy

Allergen immunotherapy (**AIT**) involves administering gradually increasing doses of allergens to a person with allergic disease to reduce or eliminate the patient's allergic response to those allergens, including allergic rhinoconjunctivitis and asthma. When properly administered to an appropriate candidate, AIT is a safe, effective therapy capable not only of reducing or preventing symptoms, but also of potentially altering the natural history of the disease by minimizing disease duration and preventing disease progression. Conventional AIT is given subcutaneously (subcutaneous immunotherapy, **SCIT**) under the direction of an experienced allergist. Sublingual immunotherapy (**SLIT**) is less potent but can still be effective, and has less potential for severe allergic adverse reactions.

The goal of SCIT or SLIT is to increase the dose of allergen extract administered in order to reach a therapeutic maintenance dose of each major allergen, in a manner that minimizes the likelihood of systemic allergic reactions. For SCIT, allergen extracts are formulated for each patient based on documented allergen sensitizations and problematic exposures. Maintenance doses are generally given monthly for SCIT or daily for SLIT, to complete a 3-5 yr course. Most of the controlled trials examining AIT efficacy on seasonal or perennial allergic asthma are favorable. A meta-analysis of 20 trials examining the effects of SCIT on allergic asthma revealed significant improvement with fewer symptoms, improved lung function, less need for medication, and AHR reduction.

Although AIT is regarded as safe, the potential for **anaphylaxis** always exists when patients receive extracts containing allergens to which they are sensitized. Local transient allergic reactions are common (SCIT: injection site allergic reaction; SLIT: mild oral itching). Systemic allergic reactions have been very rarely reported with SLIT, such that it is typically administered at home. In comparison, systemic allergic reactions occur more often with SCIT, with fatal anaphylaxis occurring in approximately 1 per 2 million injections. Because of the risks of systemic allergic reactions to SCIT, standard precautions include administering SCIT in medical settings where a physician with access to emergency equipment and medications required for the treatment of anaphylaxis is available (see Chapter 174). Patients should be observed in the office for 30 min after each injection because most systemic reactions to SCIT begin within this time frame. *SCIT should never be given at home or by untrained personnel.* Because of the complexities and risks of administration, SCIT should only be administered by an experienced allergist.

AIT should be discontinued in patients who have not shown improvement after 1 yr of receiving maintenance doses of an appropriate allergen extract(s), or who have a serious systemic allergic or adverse reaction.

Biologic Therapies

Biologic therapies are genetically engineered proteins derived from human genes and designed to inhibit specific immune mediators of disease. Several are FDA approved as add-on controller therapies (i.e., in addition to conventional controller therapies) for severe asthma in adults and children.

Omalizumab (Anti-IgE Antibody).

Omalizumab is a humanized monoclonal antibody (mAb) that binds IgE and prevents its binding to the high-affinity IgE receptor, thereby blocking IgE-mediated allergic responses and inflammation. It is FDA approved for patients >6 yr old with severe allergic asthma who continue to have inadequate disease control despite treatment with high-dose ICS and/or OCS. Omalizumab is given every 2-4 wk subcutaneously, with the dosage based on body weight and serum IgE levels. Omalizumab can improve asthma control while allowing ICS and/or OCS dose reduction. Omalizumab has been studied in inner-city children with exacerbation-prone asthma. When added to guideline-based controller management, omalizumab reduced exacerbations (50%) that peak in the spring and fall seasons. A follow-up prospective preseasonal treatment study confirmed the effect on fall seasonal exacerbations and demonstrated how omalizumab restores antiviral (IFN-α) immune responses to rhinovirus (the most common infectious trigger of exacerbations) that are impaired by IgE-mediated mechanisms. Omalizumab is well tolerated, although local injection site reactions can occur. Hypersensitivity reactions (including anaphylaxis) have been reported following approximately 0.1% of injections. As a result, omalizumab has an FDA black box warning of potentially serious and life-threatening anaphylactic adverse reactions.

Mepolizumab (Anti–IL-5 Antibody).

Mepolizumab, an anti–IL-5 antibody that blocks IL-5-mediated eosinophilopoiesis, reduces severe asthma exacerbations and lowers sputum and blood eosinophils while allowing for a significant reduction in OCS dose in adults with severe exacerbation-prone eosinophilic asthma. It is administered subcutaneously every 4 wk and is FDA approved for severe eosinophilic asthmatic children ≥12 yr old. **Reslizumab** , another anti–IL-5 antibody therapeutic, is administered intravenously and is FDA approved for severe asthmatics ≥18 yr old (i.e., not currently approved for use in children).

Dupilumab (Anti–IL-4 Receptor α Antibody).

Dupilumab, an anti–IL-4 receptor antibody that inhibits both IL-4 and IL-13 production (both cytokines share the same IL-4 receptor) and atopic immune responses, reduces exacerbations and symptoms and improves lung function in moderate to severe asthmatic patients with persistent eosinophilia. Although not yet FDA approved, studies are ongoing in both children and adults.

Quick-Reliever Medications

Quick-reliever or “rescue” medications (SABAs, inhaled anticholinergics, and short-course systemic corticosteroids) are used in the management of acute asthma symptoms (Table 169.15).

Table 169.15

Management of Asthma Exacerbation (Status Asthmaticus)

RISK ASSESSMENT ON ADMISSION		
Focused history	Onset of current exacerbation Frequency and severity of daytime and nighttime symptoms and activity limitation Frequency of rescue bronchodilator use Current medications and allergies Potential triggers History of systemic steroid courses, emergency department visits, hospitalization, intubation, or life-threatening episodes	
Clinical assessment	Physical examination findings: vital signs, breathlessness, air movement, use of accessory muscles, retractions, anxiety level, alteration in mental status Pulse oximetry Lung function (defer in patients with moderate to severe distress or history of labile disease)	
Risk factors for asthma morbidity and death	See Table 169.16 .	
TREATMENT		
Drug and Trade Name	**Mechanisms of Action and Dosing**	**Cautions and Adverse Effects**

Oxygen (mask or nasal cannula)	Treats hypoxia	Monitor pulse oximetry to maintain O_2 saturation >92% Cardiorespiratory monitoring
Inhaled short-acting β-agonists:	Bronchodilator	During exacerbations, frequent or continuous doses can cause pulmonary vasodilation, V̇/Q̇ mismatch, and hypoxemia. Adverse effects: palpitations, tachycardia, arrhythmias, tremor, hypoxemia
Albuterol nebulizer solution (5 mg/mL concentrate; 2.5 mg/3 mL, 1.25 mg/3 mL, 0.63 mg/3 mL)	Nebulizer: 0.15 mg/kg (minimum 2.5 mg) as often as every 20 min for 3 doses as needed, then 0.15-0.3 mg/kg up to 10 mg every 1-4 hr as needed, or up to 0.5 mg/kg/hr by continuous nebulization	Nebulizer: when giving concentrated forms, dilute with saline to 3 mL total nebulized volume.
Albuterol MDI (90 µg/puff)	2-8 puffs up to every 20 min for 3 doses as needed, then every 1-4 hr as needed	For MDI: use spacer/holding chamber
Levalbuterol (Xopenex) nebulizer solution (1.25 mg/0.5 mL concentrate; 0.31 mg/3 mL, 0.63 mg/3 mL, 1.25 mg/3 mL)	0.075 mg/kg (minimum 1.25 mg) every 20 min for 3 doses, then 0.075-0.15 mg/kg up to 5 mg every 1-4 hr as needed, or 0.25 mg/kg/hr by continuous nebulization	Levalbuterol 0.63 mg is equivalent to 1.25 mg of standard albuterol for both efficacy and side effects.
Systemic corticosteroids:	Antiinflammatory	If patient has been exposed to chickenpox or measles, consider passive immunoglobulin prophylaxis; also, risk of complications with herpes simplex and tuberculosis. For daily dosing, 8 AM administration minimizes adrenal suppression. Children may benefit from dosage tapering if course exceeds 7 days. Adverse effects monitoring: frequent therapy bursts risk numerous corticosteroid adverse effects (see Chapter 595); see Table 169.14 for adverse effects screening recommendations.
Prednisone: 1, 2.5, 5, 10, 20, 50 mg tablets Methylprednisolone (Medrol): 2, 4, 8, 16, 24, 32 mg tablets Prednisolone: 5 mg tablets; 5 mg/5 mL and 15 mg/5 mL solution	0.5-1 mg/kg every 6-12 hr for 48 hr, then 1-2 mg/kg/day bid (maximum 60 mg/day)	
Depo-Medrol (IM);	Short-course “burst” for exacerbation: 1-2	

Solu-Medrol (IV)	mg/kg/day qd or bid for 3-7 days	
Dexamethasone	See text	See text
Anticholinergics:	Mucolytic/bronchodilator	Should not be used as first-line therapy; added to β_2 -agonist therapy
Ipratropium:		
Atrovent (nebulizer solution 0.5 mg/2.5 mL; MDI 18 µg/inhalation)	Nebulizer: 0.5 mg q6-8h (tid-qid) as needed MDI: 2 puffs qid	
Ipratropium with albuterol:		
DuoNeb nebulizer solution (0.5 mg ipratropium + 2.5 mg albuterol/3 mL vial)	1 vial by nebulizer qid	Nebulizer: may mix ipratropium with albuterol
Injectable sympathomimetic epinephrine:	Bronchodilator	For extreme circumstances (e.g., impending respiratory failure despite high-dose inhaled SABA, respiratory failure)
Adrenalin 1 mg/mL (1 : 1000) EpiPen autoinjection device (0.3 mg; EpiPen Jr 0.15 mg)	SC or IM: 0.01 mg/kg (max dose 0.5 mg); may repeat after 15-30 min	
Terbutaline:		Terbutaline is β-agonist–selective relative to epinephrine. Monitoring with continuous infusion: cardiorespiratory monitor, pulse oximetry, blood pressure, serum potassium Adverse effects: tremor, tachycardia, palpitations, arrhythmia, hypertension, headaches, nervousness, nausea, vomiting, hypoxemia
Brethine 1 mg/mL	Continuous IV infusion (terbutaline only): 2-10 µg/kg loading dose, followed by 0.1-0.4 µg/kg/min Titrate in 0.1-0.2 µg/kg/min increments every 30 min, depending on clinical response.	
RISK ASSESSMENT FOR DISCHARGE		
Medical stability	Discharge home if there has been sustained improvement in symptoms and bronchodilator treatments are at least 3 hr apart, physical findings are normal, PEF >70% of predicted or personal best, and oxygen saturation >92% when breathing room air.	
Home supervision	Capability to administer intervention and to observe and respond appropriately to clinical deterioration	
Asthma education	See Table 169.8 .	

IM, Intramuscular; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting β-agonist; SC, subcutaneous; V/Q̇, ventilation/perfusion; bid, 2 times daily; tid, 3 times daily; qid; 4 times daily; qd, every day.

Short-Acting Inhaled β-Agonists

Given their rapid onset of action, effectiveness, and 4-6 hr duration of action, SABAs (albuterol, levalbuterol, terbutaline, pirbuterol) are the drugs of choice for acute asthma symptoms (“rescue” medication) and for preventing EIB. β-Adrenergic agonists cause bronchodilation by inducing airway smooth muscle relaxation, reducing vascular permeability and airways edema, and improving mucociliary clearance. Levalbuterol, the R-isomer of albuterol, is associated with less tachycardia and tremor, which can be bothersome to some asthmatic patients. Overuse of β-agonists is associated with an increased risk of death or near-death episodes from asthma. This is a major concern for some patients with asthma who rely on the frequent use of SABAs as a “quick fix” for their asthma, rather than using controller medications in a preventive manner. It is helpful to monitor the frequency of SABA use, in that use of at least 1 MDI/mo or at least 3 MDIs/year (200 inhalations/MDI) indicates inadequate asthma control and necessitates improving other aspects of asthma therapy and management.

Anticholinergic Agents

As bronchodilators, the anticholinergic agents (e.g., ipratropium bromide) are less potent than the β-agonists. Inhaled ipratropium is used primarily in the treatment of acute severe asthma. When used in combination with albuterol, ipratropium can improve lung function and reduce the rate of hospitalization in children who present to the ED with acute asthma. Ipratropium has few central nervous system adverse effects and is available in both MDI and nebulizer formulations. Although widely used in all children with asthma exacerbations, it is FDA approved for use in children >12 yr old. A combination ipratropium/albuterol product is also available in both nebulized (generic and Duoneb) and mist formulations (Combivent Respimat).

Delivery Devices and Inhalation Technique

Inhaled medications are delivered in aerosolized form in a MDI, as a DPI formulation, or in a suspension form delivered via a nebulizer. **Spacer devices** , recommended for the administration of all MDI medications, are simple and inexpensive tools that (1) decrease the coordination required to use MDIs, especially in young children; (2) improve the delivery of inhaled drug to the lower airways; and (3) minimize the risk of drug and propellant-mediated oropharyngeal adverse effects (dysphonia and thrush). Optimal inhalation technique for each puff of MDI-delivered medication is a slow (5 sec) inhalation, then a 5-10 sec breathhold. No waiting time is required between puffs of medication. Preschool-age children cannot perform this inhalation technique. As a result, MDI medications in this age-group are delivered with a spacer and mask, using a different technique: Each puff is administered with regular breathing for about 30 sec or 5-10 breaths; a tight seal must be maintained; and talking, coughing, or crying will blow the medication out of the spacer. This technique will not deliver as much medication per puff as the optimal MDI technique used by older children and adults.

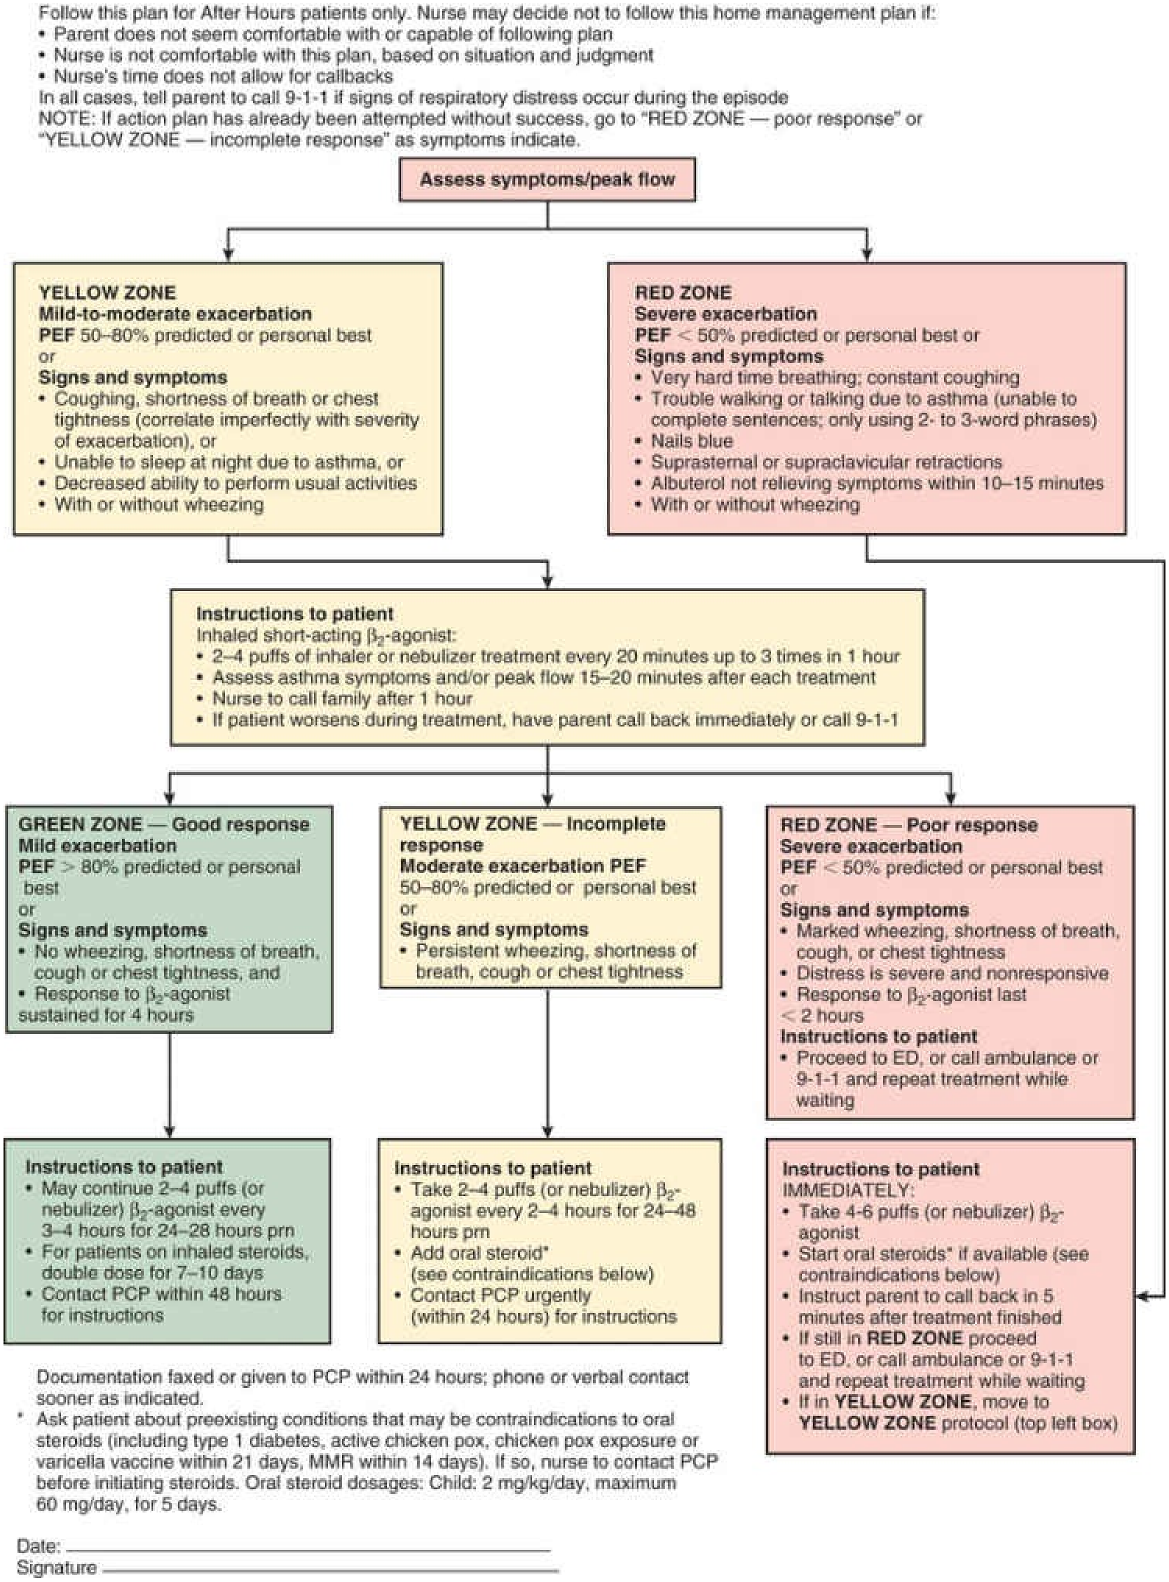
Dry powder inhaler devices (e.g., Diskus, Flexhaler, Autohaler, Twisthaler, Aerolizer, Ellipta) are popular because of their simplicity of use, although adequate inspiratory flow is needed. DPIs are breath-actuated devices (the drug comes out only as it is breathed in), and spacers are not needed. Mouth rinsing is recommended after ICS use to remove ICS deposited on the oral mucosa and reduce the swallowed ICS and the risk of thrush.

Nebulizers are the mainstay of aerosol treatment for infants and young children. An advantage of using nebulizers is the simple technique required of relaxed breathing. The preferential nasal breathing, small airways, low tidal volume, and high respiratory rate of infants greatly increase the difficulty of inhaled drug therapy targeting the lung airways. Disadvantages of nebulizers include need for a power source, inconvenience in that treatments take about 5 min, expense, and potential for bacterial contamination.

Asthma Exacerbations and Their Management

Asthma exacerbations are acute or subacute episodes of progressively worsening symptoms and airflow obstruction. Airflow obstruction during exacerbations can become extensive, resulting in life-threatening respiratory insufficiency. Often, asthma exacerbations worsen during sleep (between midnight and 8 AM), when airways inflammation and hyperresponsiveness are at their peak. Importantly, SABAs, which are first-line therapy for asthma symptoms and exacerbations, increase pulmonary blood flow through obstructed, unoxygenated areas of the lungs with increasing dosage and frequency. When airways obstruction is not resolved with SABA use, ventilation/perfusion mismatching can cause hypoxemia, which can perpetuate bronchoconstriction and further worsen the condition. Severe, progressive asthma exacerbations need to be managed in a medical setting, with administration of supplemental oxygen as first-line therapy and close monitoring for potential worsening. Complications that can occur during severe exacerbations include atelectasis (common) and air leaks in the chest (pneumomediastinum, pneumothorax; rare).

A severe exacerbation of asthma that does not improve with standard therapy is termed **status asthmaticus** . Immediate management of an asthma exacerbation involves a rapid evaluation of the severity of obstruction and assessment of risk for further clinical deterioration (Fig. 169.8 ; see Tables 169.14 and 169.15). For most patients, exacerbations improve with frequent bronchodilator treatments and a course of systemic (oral or intravenous) corticosteroid. However, the optimal management of a child with an asthma exacerbation should include a more comprehensive assessment of the events leading up to the exacerbation and the underlying disease severity. Indeed, the frequency and severity of asthma exacerbations help define the severity of a patient's asthma. Whereas most children who experience life-threatening asthma episodes have moderate to severe asthma by other criteria, some children with asthma appear to have mild disease except when they have severe, even near-fatal exacerbations. The biologic, environmental, economic, and psychosocial risk factors associated with asthma morbidity and death can further guide this assessment (Table 169.16).



Follow this plan for After Hours patients only. Nurse may decide not to follow this home management plan if:
- Parent does not seem comfortable with or capable of following plan
- Nurse is not comfortable with this plan, based on situation and judgment
- Nurse's time does not allow for callbacks

In all cases, tell parent to call 9-1-1 if signs of respiratory distress occur during the episode
NOTE: If action plan has already been attempted without success, go to "RED ZONE — poor response" or "YELLOW ZONE — incomplete response" as symptoms indicate.

Assess symptoms/peak flow

YELLOW ZONE
Mild-to-moderate exacerbation
PEF 50–80% predicted or personal best
or
Signs and symptoms
- Coughing, shortness of breath or chest tightness (correlate imperfectly with severity of exacerbation), or
- Unable to sleep at night due to asthma, or
- Decreased ability to perform usual activities
- With or without wheezing

RED ZONE
Severe exacerbation
PEF < 50% predicted or personal best or
Signs and symptoms
- Very hard time breathing; constant coughing
- Trouble walking or talking due to asthma (unable to complete sentences; only using 2- to 3-word phrases)
- Nails blue
- Suprasternal or supraclavicular retractions
- Albuterol not relieving symptoms within 10–15 minutes
- With or without wheezing

Instructions to patient
Inhaled short-acting β_2-agonist:
- 2–4 puffs of inhaler or nebulizer treatment every 20 minutes up to 3 times in 1 hour
- Assess asthma symptoms and/or peak flow 15–20 minutes after each treatment
- Nurse to call family after 1 hour
- If patient worsens during treatment, have parent call back immediately or call 9-1-1

GREEN ZONE — Good response
Mild exacerbation
PEF > 80% predicted or personal best
or
Signs and symptoms
- No wheezing, shortness of breath, cough or chest tightness, and
- Response to β_2-agonist sustained for 4 hours

YELLOW ZONE — Incomplete response
Moderate exacerbation PEF
50–80% predicted or personal best
or
Signs and symptoms
- Persistent wheezing, shortness of breath, cough or chest tightness

RED ZONE — Poor response
Severe exacerbation
PEF < 50% predicted or personal best
or
Signs and symptoms
- Marked wheezing, shortness of breath, cough, or chest tightness
- Distress is severe and nonresponsive
- Response to β_2-agonist last < 2 hours

Instructions to patient
- Proceed to ED, or call ambulance or 9-1-1 and repeat treatment while waiting

Instructions to patient
- May continue 2–4 puffs (or nebulizer) β_2-agonist every 3–4 hours for 24–28 hours prn
- For patients on inhaled steroids, double dose for 7–10 days
- Contact PCP within 48 hours for instructions

Instructions to patient
- Take 2–4 puffs (or nebulizer) β_2-agonist every 2–4 hours for 24–48 hours prn
- Add oral steroid*
(see contraindications below)
- Contact PCP urgently
(within 24 hours) for instructions

Instructions to patient
IMMEDIATELY:
- Take 4-6 puffs (or nebulizer) β_2-agonist
- Start oral steroids* if available (see contraindications below)
- Instruct parent to call back in 5 minutes after treatment finished
- If still in **RED ZONE** proceed to ED, or call ambulance or 9-1-1 and repeat treatment while waiting
- If in **YELLOW ZONE**, move to **YELLOW ZONE** protocol (top left box)

Documentation faxed or given to PCP within 24 hours; phone or verbal contact sooner as indicated.

* Ask patient about preexisting conditions that may be contraindications to oral steroids (including type 1 diabetes, active chicken pox, chicken pox exposure or varicella vaccine within 21 days, MMR within 14 days). If so, nurse to contact PCP before initiating steroids. Oral steroid dosages: Child: 2 mg/kg/day, maximum 60 mg/day, for 5 days.

FIG. 169.8 Algorithm for treatment of acute asthma symptoms. PEF, Peak expiratory flow; ED, emergency department; PCP, primary care physician.

(Courtesy of BJC Healthcare/Washington University School of Medicine, Community Asthma Program, January 2000.)

Table 169.16

Risk Factors for Asthma Morbidity and Mortality

Biologic

Previous severe asthma exacerbation (intensive care unit admission, intubation for asthma)
Sudden asphyxia episodes (respiratory failure, arrest)
Two or more hospitalizations for asthma in past year
Three or more emergency department visits for asthma in past year
Increasing and large diurnal variation in peak flows
Use of >2 canisters of short-acting β-agonists per month
Poor response to systemic corticosteroid therapy
Male gender
Low birthweight
Nonwhite (especially black) ethnicity
Sensitivity to *Alternaria*

Environmental

Allergen exposure
Environmental tobacco smoke exposure
Air pollution exposure
Urban environment

Economic and Psychosocial

Poverty
Crowding
Mother <20 yr old
Mother with less than high school education
Inadequate medical care:

    - Inaccessible
    - Unaffordable
    - No regular medical care (only emergency)
    - Lack of written Asthma Action Plan
    - No care sought for chronic asthma symptoms
    - Delay in care of asthma exacerbations
    - Inadequate hospital care for asthma exacerbation
- Psychopathology in the parent or child
- Poor perception of asthma symptoms or severity
- Alcohol or substance abuse

Asthma exacerbations characteristically vary among individuals but tend to be similar in the same patient. Severe asthma exacerbations, resulting in respiratory distress, hypoxia, hospitalization, and respiratory failure, are the best predictors of future life-threatening exacerbations or a fatal asthma episode. In addition to distinguishing such high-risk children, some experience exacerbations that develop over days, with airflow obstruction resulting from progressive inflammation, epithelial sloughing, and cast impaction of small airways. When such a process is extreme, respiratory failure as a result of fatigue can ensue, necessitating mechanical ventilation for numerous days. In contrast, some children experience abrupt-onset exacerbations that may result from extreme AHR and physiologic susceptibility to airways closure. Such exacerbations, when extreme, are asphyxial in nature, often occur outside medical settings, are initially associated with very high arterial partial pressure of carbon dioxide (P_{CO_2}) levels, and tend to require only brief periods of supportive ventilation. Recognizing the characteristic differences in asthma exacerbations is important for optimizing their early management.

Home Management of Asthma Exacerbations

Families of all children with asthma should have a **written Asthma Action Plan** (see Fig. 169.7) to guide their recognition and management of exacerbations, along with the necessary medications and tools to manage them. Early recognition of asthma exacerbations in order to intensify treatment early can often prevent further worsening and keep exacerbations from becoming severe. A written home action plan can reduce the risk of asthma death by 70%. The NIH guidelines recommend immediate treatment with “rescue” medication (inhaled SABA, up to 3 treatments in 1 hr). A good response is characterized by resolution of symptoms within 1 hr, no further symptoms over the next 4 hr, and improvement in PEF value to at least 80% of personal best. The child's physician should be contacted for follow-up, especially if bronchodilators are required repeatedly over the next 24-48 hr. If the child has an incomplete response to initial treatment with rescue medication (persistent symptoms and/or PEF <80% of personal best), a short course of OCS therapy (prednisone, 1-2 mg/kg/day [not to exceed 60 mg/day] for 4 days) should be instituted, in addition to inhaled β-agonist therapy. The physician should also be contacted for further instructions. Immediate medical attention should be sought for severe exacerbations, persistent signs of respiratory distress, lack of expected response or sustained improvement after initial treatment, further deterioration, or high-risk factors for asthma morbidity or mortality (e.g., previous history of severe exacerbations). For patients with severe asthma and/or a history of life-threatening episodes, especially if abrupt in onset, an epinephrine autoinjector and perhaps portable oxygen at home can be considered. Use of either of these extreme measures for home management of asthma exacerbations would be an indication to call 911 for emergency support services.

Emergency Department Management of Asthma Exacerbations

In the ED, the primary goals of asthma management include correction of hypoxemia, rapid improvement of airflow obstruction, and prevention of progression or recurrence of symptoms. Interventions are based on clinical severity on arrival, response to initial therapy, and presence of risk factors associated with asthma morbidity and mortality (see Table 169.16). Indications of a severe exacerbation include breathlessness, dyspnea, retractions, accessory muscle use, tachypnea or labored breathing, cyanosis, mental status changes, a silent chest with poor air exchange, and severe airflow limitation (PEF or FEV_1 value <50% of personal best or predicted values). Initial treatment includes supplemental oxygen, inhaled β-agonist therapy every 20 min for 1 hr, and, if necessary, oral or intravenous (IV) systemic corticosteroids (see Table 169.15 and Fig. 169.8). In the ED, single oral, intravenous, or intramuscular (IM) dose dexamethasone (0.6 mg/kg, maximum 16 mg) has been found to be an effective alternative to prednisone and with a lower incidence of emesis. In addition, a second dose of dexamethasone should be given the next day whether discharged or admitted to the hospital. Inhaled ipratropium may be added to the β-agonist treatment if no significant response is seen with the 1st inhaled β-agonist treatment. An IM injection of epinephrine or other β-agonist may be administered in severe cases. Oxygen should be administered and continued for at least 20 min after SABA administration to compensate for possible ventilation/perfusion abnormalities caused by SABAs.

Close monitoring of clinical status, hydration, and oxygenation are essential elements of immediate management. A poor response to intensified treatment in the 1st hr suggests that the exacerbation will not remit quickly. The patient may be discharged home if there is sustained improvement in symptoms, normal physical findings, PEF >70% of predicted or personal best, and oxygen saturation >92% while the patient is breathing room air for 4 hr. Discharge medications include administration of an inhaled β-agonist up to every 3-4 hr plus a 3-7 day course of an OCS. Optimizing controller therapy before discharge is also recommended. The addition of ICS to a course of OCS in the ED setting reduces the risk of exacerbation recurrence over the subsequent month.

Hospital Management of Asthma Exacerbations

For patients with severe exacerbations that do not adequately improve within 1-2 hr of intensive treatment, observation and/or admission to the hospital, at least overnight, is likely to be needed. Other indications for hospital admission include high-risk features for asthma morbidity or death (see Table 169.16). Admission to an intensive care unit (ICU) is indicated for patients with severe respiratory distress, poor response to therapy, and concern for potential respiratory failure and arrest.

Supplemental oxygen, frequent or continuous administration of an inhaled bronchodilator, and systemic corticosteroid therapy are the conventional interventions for children admitted to the hospital for status asthmaticus (see Table 169.15). Supplemental oxygen is administered because many children hospitalized with acute asthma have or eventually have hypoxemia, especially at night and with increasing SABA administration. SABAs can be delivered frequently (every 20 min to 1 hr) or continuously (at 5-15 mg/hr). When administered continuously, significant systemic absorption of β-agonist occurs, and thus continuous nebulization can obviate the need for IV β-agonist therapy. Adverse effects of frequently administered β-agonist therapy include tremor, irritability, tachycardia, and hypokalemia; lactic acidosis is an uncommon complication. Patients requiring frequent or continuous nebulized β-agonist therapy should have ongoing cardiac monitoring. Because frequent β-agonist therapy can cause ventilation/perfusion mismatch and hypoxemia, oximetry is also indicated. Inhaled ipratropium is often added to albuterol every 6 hr if patients do not show a remarkable improvement, although there is little evidence to support its use in hospitalized children receiving aggressive inhaled β-agonist therapy and systemic corticosteroids. In addition to its potential to provide a synergistic effect with a β-agonist agent in relieving severe bronchospasm, ipratropium may be beneficial in patients who have mucus hypersecretion or who are receiving β-blockers.

Short-course systemic corticosteroid therapy is recommended for use in moderate to severe asthma exacerbations to hasten recovery and prevent recurrence of symptoms. Corticosteroids are effective as single doses administered in the ED, short courses in the clinic setting, and both oral and IV formulations in hospitalized children. Studies in children hospitalized with acute asthma have found corticosteroids administered orally to be as effective as IV corticosteroids. Accordingly, OCS therapy can often be used, although children with sustained respiratory distress and those unable to tolerate oral preparations or liquids are obvious candidates for IV corticosteroid therapy.

Patients with persistent severe dyspnea and high-flow oxygen requirements require additional evaluation, such as complete blood count, arterial blood gases, serum electrolytes, and chest radiograph, to monitor for respiratory insufficiency, comorbidities, infection, and dehydration. Hydration status monitoring is especially important in infants and young children, whose increased respiratory rate (insensible losses) and decreased oral intake put them at higher risk for dehydration. Further complicating this situation is the association of increased antidiuretic hormone secretion with status asthmaticus. Administration of fluids at or slightly below maintenance fluid requirements is recommended. Chest physical therapy, incentive spirometry, and mucolytics are not recommended during the early acute period of asthma exacerbations because they can trigger severe bronchoconstriction.

Despite intensive therapy, some asthmatic children remain critically ill and at risk for respiratory failure, intubation, and mechanical ventilation. Complications (e.g., air leaks) related to asthma exacerbations increase with intubation and assisted ventilation, so every effort should be made to relieve bronchospasm and prevent respiratory failure. Several therapies, including parenteral β-agonists, magnesium sulfate (25-75 mg/kg, maximum dose 2.5 g, given intravenously over 20 min), and inhaled heliox (helium and oxygen mixture) have demonstrated some benefit as adjunctive therapies in patients with severe status asthmaticus. Administration of magnesium sulfate requires monitoring of serum levels and cardiovascular status. Parenteral (SC, IM, or IV) epinephrine or terbutaline sulfate may be effective in patients with life-threatening obstruction that is not responding to high doses of inhaled β-agonists, because inhaled medication may not reach the lower airway in such patients.

Rarely, a severe asthma exacerbation in a child results in respiratory failure, and intubation and mechanical ventilation become necessary. **Mechanical ventilation** in severe asthma exacerbations requires the careful balance of enough pressure to overcome airways obstruction while reducing hyperinflation, air trapping, and the likelihood of barotrauma (pneumothorax, pneumomediastinum) (see Chapter 439). To minimize the likelihood of such complications, mechanical ventilation should be anticipated, and asthmatic children at risk for the development of respiratory failure should be managed in a pediatric ICU. Elective tracheal intubation with rapid-induction sedatives and paralytic agents is safer than emergency intubation. Mechanical ventilation aims to achieve adequate oxygenation while tolerating mild to moderate hypercapnia (P_{CO_2} 50-70 mm Hg) to minimize barotrauma. Volume-cycled ventilators, using short inspiratory and long expiratory times, 10-15 mL/kg tidal volume, 8-15 breaths/min, peak pressures <60 cm H_2O, and without positive end-expiratory pressure are starting mechanical ventilation parameters that can achieve these goals. As measures to relieve mucus plugs, chest percussion and airways lavage are not recommended because they can induce further bronchospasm. One must consider the nature of asthma exacerbations leading to respiratory failure; those of rapid or abrupt onset tend to resolve quickly (hours to 2 days), whereas those that progress gradually to respiratory failure can require days to weeks of mechanical ventilation. Such prolonged cases are further complicated by corticosteroid-induced myopathy, which can lead to severe muscle weakness requiring prolonged rehabilitation.

In children, management of severe exacerbations in medical centers is usually successful, even when extreme measures are required. Consequently, asthma deaths in children rarely occur in medical centers; most occur at home or in community settings before lifesaving medical care can be administered. This point highlights the importance of home and community management of asthma exacerbations, early intervention measures to keep exacerbations from becoming severe, and steps to reduce asthma severity. A follow-up appointment within 1-2 wk of a child's discharge from the hospital after resolution of an asthma exacerbation should be used to monitor clinical improvement and to reinforce key educational elements, including action plans and controller medications.

Special Management Circumstances

Management of Infants and Young Children

Recurrent wheezing episodes in preschool-age children are common, occurring in as much as one third of this population. Of these, most improve and even become asymptomatic during the prepubescent school-age years, whereas others have lifelong persistent asthma. All require management of their recurrent wheezing problems (see Tables 169.5 , 169.6 , and 169.11). The NIH guidelines recommend risk assessment to identify preschool-age children who are likely to have persistent asthma. One implication of this recommendation is that these at-risk children may be candidates for conventional asthma management, including daily controller therapy and early intervention with exacerbations (see Tables 169.7 , 169.8 , and 169.11). For young children with a history of moderate to severe exacerbations, nebulized budesonide is FDA approved, and its use as a controller medication could prevent subsequent exacerbations.

Using aerosol therapy in infants and young children with asthma presents unique challenges. There are 2 delivery systems for inhaled medications for this age-group: the nebulizer and the MDI with spacer/holding chamber and face mask. Multiple studies demonstrate the effectiveness of both nebulized albuterol in acute episodes and nebulized budesonide in the treatment of recurrent wheezing in infants and young children. In such young children, inhaled medications administered via MDI with spacer and face mask may be acceptable, although perhaps not preferred because of limited published information and lack of FDA approval for children <4 yr of age.

Asthma Management During Surgery

Patients with asthma are at risk from disease-related complications from surgery, such as bronchoconstriction and asthma exacerbation, atelectasis, impaired coughing, respiratory infection, and latex exposure, which may induce asthma complications in patients with latex allergy. All patients with asthma should be evaluated before surgery, and those who are inadequately controlled should allow time for intensified treatment to improve asthma stability before surgery, if possible. A systemic corticosteroid course may be indicated for the patient who is having symptoms and/or FEV_1 or PEF values <80% of the patient's personal best. In addition, patients who have received >2 wk of systemic corticosteroid and/or moderate- to high-dose ICS therapy may be at risk for intraoperative adrenal insufficiency. For these patients, anesthesia services should be alerted to provide “stress” replacement doses of systemic corticosteroid for the surgical procedure and possibly the postoperative period.

Prognosis

Recurrent coughing and wheezing occurs in 35% of preschool-age children. Of these, approximately one third continue to have persistent asthma into later childhood, and approximately two thirds improve on their own through their teen years. Asthma severity by ages 7-10 yr is predictive of asthma persistence in adulthood. Children with moderate to severe asthma and with lower lung function measures are likely to have persistent asthma as adults. Children with milder asthma and normal lung function are likely to improve over time, with some becoming periodically asthmatic (disease-free for months to years); however, complete remission for 5 yr in childhood is uncommon.

Prevention

Although chronic airways inflammation may result in pathologic remodeling of lung airways, conventional antiinflammatory interventions—the cornerstone of asthma control—do not help children outgrow their asthma. Although controller medications reduce asthma morbidities, most children with moderate to severe asthma continue to have symptoms into young adulthood. Investigations into the environmental and lifestyle factors responsible for the lower prevalence of childhood asthma in rural areas and farming communities suggest that early immunomodulatory intervention might prevent asthma development. A *hygiene hypothesis* purports that naturally occurring microbial exposures in early life might drive early immune development away from allergic sensitization, persistent airways inflammation, and remodeling through early microbiome and innate immune development. If these natural microbial exposures truly have an asthma-protective effect, without significant adverse health consequences, these findings may foster new strategies for asthma prevention.

Several nonpharmacotherapeutic measures with numerous positive health attributes—avoidance of environmental tobacco smoke (beginning prenatally), prolonged breastfeeding (>4 mo), an active lifestyle, and a healthy diet—might reduce the likelihood of asthma development. Immunizations are currently not considered to increase the likelihood of development of asthma; therefore all standard childhood immunizations are recommended for children with asthma, including varicella and annual influenza vaccines.

CHAPTER 170

Atopic Dermatitis (Atopic Eczema)

Donald Y.M. Leung, Scott H. Sicherer

Atopic dermatitis (AD) , or eczema, is the most common chronic relapsing skin disease seen in infancy and childhood. It affects 10–30% of children worldwide and frequently occurs in families with other atopic diseases. Infants with AD are predisposed to development of food allergy, allergic rhinitis, and asthma later in childhood, a process called *the atopic march* .

Etiology

AD is a complex genetic disorder that results in a defective skin barrier, reduced skin innate immune responses, and polarized adaptive immune responses to environmental allergens and microbes that lead to chronic skin inflammation.

Pathology

Acute AD skin lesions are characterized by **spongiosis** , or marked intercellular edema, of the epidermis. In AD, dendritic antigen-presenting cells (APCs) in the epidermis, such as Langerhans cells, exhibit surface-bound IgE molecules with cell processes that reach into upper epidermis to sense allergens and pathogens. These APCs play an important role in cutaneous responses to type 2 immune responses (see Chapter 166). There is marked perivenular T-cell and inflammatory monocyte-macrophage infiltration in acute AD lesions. Chronic, lichenified AD is characterized by a hyperplastic epidermis with hyperkeratosis and minimal spongiosis. There are predominantly IgE-bearing Langerhans cells in the epidermis, and macrophages in the dermal mononuclear cell infiltrate. Mast cell and eosinophil numbers are increased, contributing to skin inflammation.

Pathogenesis

AD is associated with multiple phenotypes and endotypes that have overlapping clinical presentations. **Atopic eczema** is associated with IgE-mediated sensitization (at onset or during the course of eczema) and occurs in 70–80% of patients with AD. **Nonatopic eczema** is not associated with IgE-mediated sensitization and is seen in 20–30% of patients with AD. Both forms of AD are associated with eosinophilia. In atopic eczema, circulating T cells expressing the skin homing receptor **cutaneous lymphocyte-associated antigen** produce increased levels of T-helper type 2 (Th2) cytokines, including interleukin (IL)-4 and IL-13, which induce isotype switching to IgE synthesis. Another cytokine, IL-5, plays an important role in eosinophil development and survival. Nonatopic eczema is associated with lower IL-4 and IL-13 but increased IL-17 and IL-23 production than in atopic eczema. Age and race have also been found to affect the immune profile in AD.

Compared with the skin of healthy individuals, both unaffected skin and acute skin lesions of patients with AD have an increased number of cells expressing IL-4 and IL-13. Chronic AD skin lesions, by contrast, have fewer cells that express IL-4 and IL-13, but increased numbers of cells that express IL-5, granulocyte-macrophage colony-stimulating factor, IL-12, and interferon (IFN)-γ than acute AD lesions. Despite increased type 1 and type 17 immune responses in chronic AD, IL-4 and IL-13 as well as other type 2 cytokines (e.g. TSLP, IL-31, IL-33) predominate and reflect increased numbers of Type 2 innate lymphoid cells and Th2 cells. The infiltration of IL-22–expressing T cells correlates with severity of AD, blocks keratinocyte differentiation, and induces epidermal hyperplasia. The importance of IL-4 and IL-13 in driving severe persistent AD has been validated by multiple clinical trials now demonstrating that biologics blocking IL-4 and IL-13 action lead to clinical improvement in moderate to severe AD.

In healthy people the skin acts as a protective barrier against external irritants, moisture loss, and infection. Proper function of the skin depends on adequate moisture and lipid content, functional immune responses, and structural integrity. *Severely dry skin is a hallmark of AD.* This results from compromise of the epidermal barrier, which leads to excess transepidermal water loss, allergen penetration, and microbial colonization. **Filaggrin** , a structural protein in the epidermis, and its breakdown products are critical to skin barrier function, including moisturization of the skin. Genetic mutations in the filaggrin gene *(FLG)* family have been identified in patients with ichthyosis vulgaris (dry skin, palmar hyperlinearity) and in up to 50% of patients with severe AD. *FLG* mutation is strongly associated with development of food allergy and eczema herpeticum. Nonetheless, up to 60% of carriers of a *FLG* mutation do not develop atopic diseases. Cytokines found in allergic inflammation, such as IL-4, IL-13, IL-22, IL-25, and tumor necrosis factor, can also reduce filaggrin and other epidermal proteins and lipids. AD patients are at increased risk of bacterial, viral, and fungal infection related to impairment of innate immunity, disturbances in the microbiome, skin epithelial dysfunction, and overexpression of polarized immune pathways, which dampen host antimicrobial responses.

Clinical Manifestations

AD typically begins in infancy. Approximately 50% of patients experience symptoms in the 1st yr of life, and an additional 30% are diagnosed between 1 and 5 yr of age. Intense **pruritus** , especially at night, and **cutaneous reactivity** are the cardinal features of AD. Scratching and excoriation cause increased skin inflammation that contributes to the development of more pronounced eczematous skin lesions. Foods (cow's milk, egg, peanut, tree nuts, soy, wheat, fish, shellfish), aeroallergens (pollen, grass, animal dander, dust mites), infection (*Staphylococcus aureus* , herpes simplex, coxsackievirus, molluscum), reduced humidity, excessive sweating, and irritants (wool, acrylic, soaps, toiletries, fragrances, detergents) can trigger pruritus and scratching.

Acute AD skin lesions are intensely pruritic with erythematous papules (Figs. 170.1 and 170.2). Subacute dermatitis manifests as erythematous, excoriated, scaling papules. In contrast, chronic AD is characterized by **lichenification** (Fig. 170.3), or thickening of the skin with accentuated surface markings, and **fibrotic papules** . In chronic AD, all 3 types of skin reactions may coexist in the same individual. Most patients with AD have dry, lackluster skin regardless of their stage of illness. Skin reaction pattern and distribution vary with the patient's age and disease activity. AD is generally more acute in infancy and involves the face, scalp, and extensor surfaces of the extremities. The diaper area is usually spared. Older children and children with chronic AD have lichenification and localization of the rash to the flexural folds of the extremities. AD can go into remission as the patient grows older, however, many children with AD have persistent eczema as an adult (Fig. 170.1*C*).

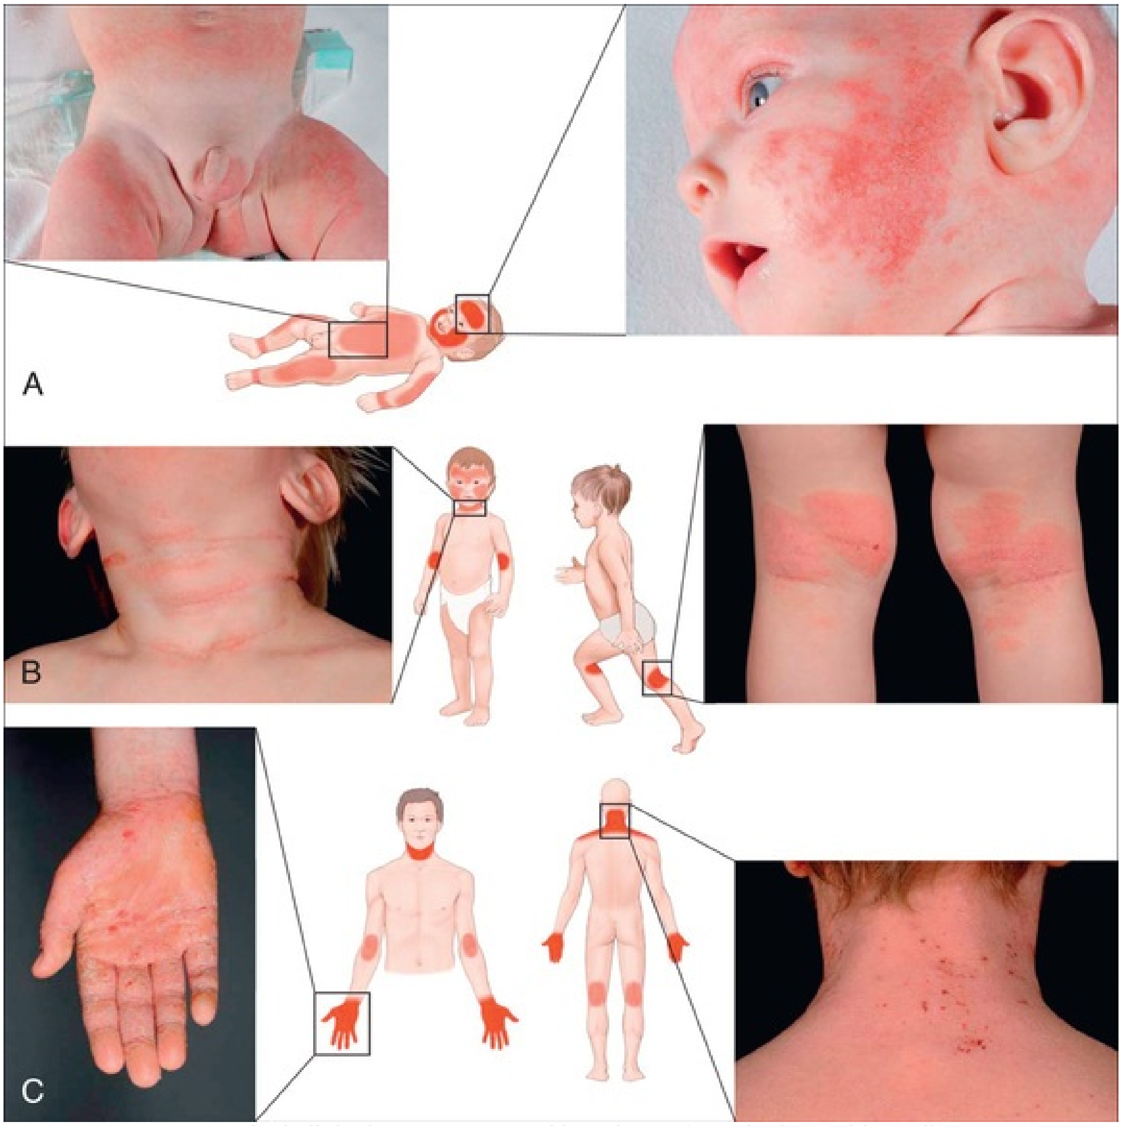

FIG. 170.1 Typical clinical appearance and locations of atopic dermatitis at different ages. Top row, In infants, atopic dermatitis is generally acute, with lesions mainly on the face and the extensor surfaces of the limbs. The trunk might be affected, but the napkin area is typically spared. Middle row, From age 1-2 yr onward, polymorphous manifestations with different types of skin lesions are seen, particularly in flexural folds. Bottom row, Adolescents and adults often present lichenified and excoriated plaques at flexures, wrists, ankles, and eyelids; in the head and neck type, the upper trunk, shoulders, and scalp are involved. Adults might have only chronic hand eczema or present with prurigo-like lesions. (From Weidinger S, Novak N: Atopic dermatitis, *Lancet* 387:1111, 2016.)

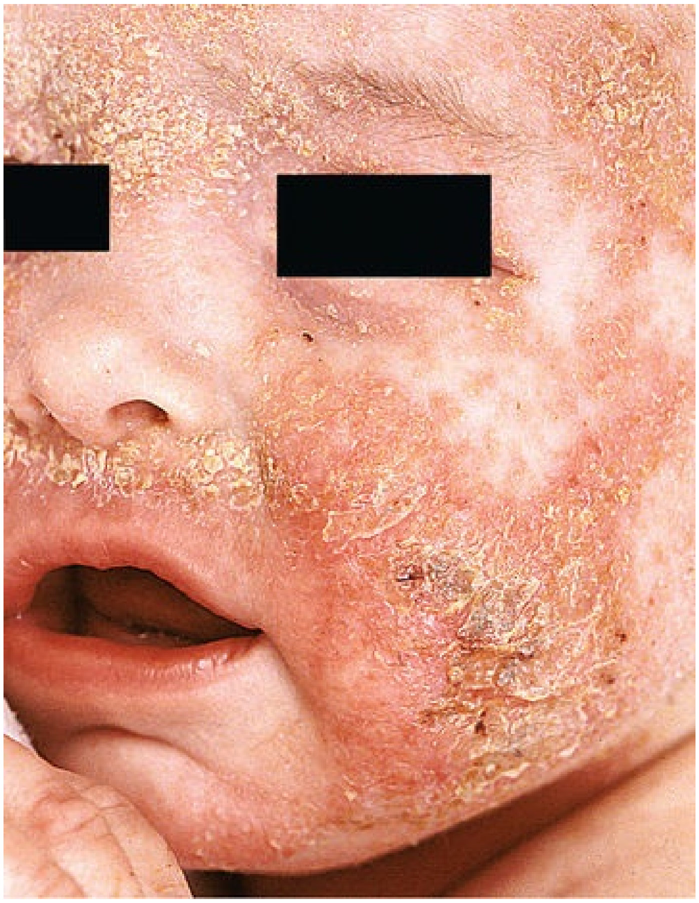

FIG. 170.2 Crusted lesions of atopic dermatitis on the face. (From Eichenfield LF, Friedan IJ, Esterly NB: *Textbook of neonatal dermatology,* Philadelphia, 2001, Saunders, p 242.)

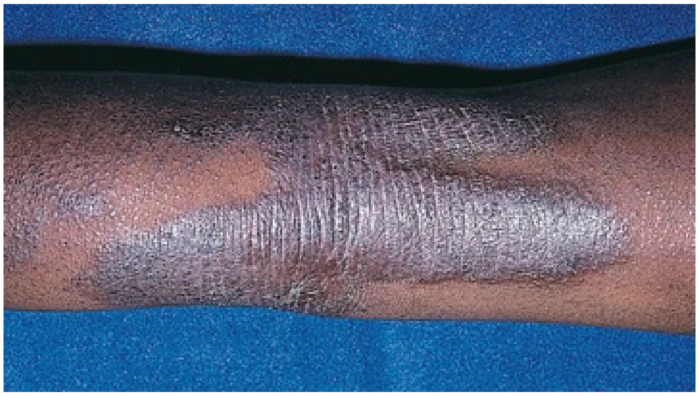

FIG. 170.3 Lichenification of the popliteal fossa from chronic rubbing of the skin in atopic dermatitis. (From Weston WL, Lane AT, Morelli JG: *Color textbook of pediatric dermatology,* ed 2, St Louis, 1996, Mosby, p 33.)

Laboratory Findings

There are no specific laboratory tests to diagnose AD. Many patients have peripheral blood eosinophilia and increased serum IgE levels. Serum IgE measurement or skin-prick testing can identify the allergens (foods, inhalant/microbial allergens) to which patients are sensitized. The diagnosis of clinical allergy to these allergens requires confirmation by history and environmental challenges.

Diagnosis and Differential Diagnosis

AD is diagnosed on the basis of 3 major features: pruritus, an eczematous dermatitis that fits into a typical pattern of skin inflammation, and a chronic or chronically relapsing course (Table 170.1). Associated features, such as a family history of asthma, hay fever, elevated IgE, and immediate skin test reactivity, reinforce the diagnosis of AD.

Table 170.1

Clinical Features of Atopic Dermatitis

Major Features

- Pruritus
- Facial and extensor eczema in infants and children
- Flexural eczema in adolescents
- Chronic or relapsing dermatitis
- Personal or family history of atopic disease

Associated Features

- Xerosis
- Cutaneous infections (*Staphylococcus aureus*, group A streptococcus, herpes simplex, coxsackievirus, vaccinia, molluscum, warts)
- Nonspecific dermatitis of the hands or feet
- Ichthyosis, palmar hyperlinearity, keratosis pilaris
- Nipple eczema

White dermatographism and delayed blanch response
Anterior subcapsular cataracts, keratoconus
Elevated serum IgE levels
Positive results of immediate-type allergy skin tests
Early age at onset
Dennie lines (Dennie-Morgan infraorbital folds)
Facial erythema or pallor
Course influenced by environmental and/or emotional factors

Many inflammatory skin diseases, immunodeficiencies, skin malignancies, genetic disorders, infectious diseases, and infestations share symptoms with AD and should be considered and excluded before a diagnosis of AD is established (Tables 170.2 and 170.3). Severe combined immunodeficiency (see Chapter 152.1) should be considered for infants presenting in the first yr of life with diarrhea, failure to thrive, generalized scaling rash, and recurrent cutaneous and/or systemic infection. Histiocytosis should be excluded in any infant with AD and failure to thrive (see Chapter 534). Wiskott-Aldrich syndrome, an X-linked recessive disorder associated with thrombocytopenia, immune defects, and recurrent severe bacterial infections, is characterized by a rash almost indistinguishable from that in AD (see Chapter 152.2). One of the hyper-IgE syndromes is characterized by markedly elevated serum IgE values, recurrent deep-seated bacterial infections, chronic dermatitis, and refractory dermatophytosis. Many of these patients have disease as a result of autosomal dominant *STAT3* mutations. In contrast, some patients with hyper-IgE syndrome present with increased susceptibility to viral infections and an autosomal recessive pattern of disease inheritance. These patients may have a *DOCK8* (dedicator of cytokinesis 8 gene) mutation. This diagnosis should be considered in young children with severe eczema, food allergy, and disseminated skin viral infections.

Table 170.2

Differential Diagnosis of Atopic Dermatitis (AD)

	MAIN AGE GROUP AFFECTED	FREQUENCY*	CHARACTERISTICS AND CLINICAL FEATURES
OTHER TYPES OF DERMATITIS			
Seborrheic	Infants	Common	Salmon-red greasy scaly lesions, often on the scalp (cradle

dermatitis			cap) and napkin area; generally presents in the 1st 6 wk of life; typically clears within weeks
Seborrheic dermatitis	Adults	Common	Erythematous patches with yellow, white, or grayish scales in seborrheic areas, particularly the scalp, central face, and anterior chest
Nummular dermatitis	Children and adults	Common	Coin-shaped scaly patches, mostly on legs and buttocks; usually no itch
Irritant contact dermatitis	Children and adults	Common	Acute to chronic eczematous lesions, mostly confined to the site of exposure; history of locally applied irritants is a risk factor; might coexist with AD
Allergic contact dermatitis	Children and adults	Common	Eczematous rash with maximum expression at sites of direct exposure but might spread; history of locally applied irritants is a risk factor; might coexist with AD
Lichen simplex chronicus	Adults	Uncommon	One or more localized, circumscribed, lichenified plaques that result from repetitive scratching or rubbing because of intense itch
Asteatotic eczema	Adults	Common	Scaly, fissured patches of dermatitis overlying dry skin, most often on lower legs
INFECTIOUS SKIN DISEASES			
Dermatophyte infection	Children and adults	Common	One or more demarcated scaly plaques with central clearing and slightly raised reddened edge; variable itch
Impetigo	Children	Common	Demarcated erythematous patches with blisters or honey-yellow crusting
Scabies	Children	Common †	Itchy superficial burrows and pustules on palms and soles, between fingers, and on genitalia; might produce secondary eczematous changes
HIV	Children and adults	Uncommon	Seborrhea-like rash
CONGENITAL IMMUNODEFICIENCIES (see Table 170.3)			
Keratinization Disorders			
Ichthyosis vulgaris	Infants and adults	Uncommon	Dry skin with fine scaling, particularly on the lower abdomen and extensor areas; perifollicular skin roughening; palmar hyperlinearity; full form (i.e., 2 *FLG* mutations) is uncommon; often coexists with AD
NUTRITIONAL DEFICIENCY–METABOLIC DISORDERS			
Zinc deficiency (acrodermatitis enteropathica)	Children	Uncommon	Erythematous scaly patches and plaques, most often around the mouth and anus; rare congenital form accompanied by diarrhea and alopecia
Biotin deficiency (nutritional or biotinidase deficiency)	Infants	Uncommon	Scaly periorofacial dermatitis, alopecia, conjunctivitis, lethargy, hypotonia
Pellagra (niacin deficiency)	All ages	Uncommon	Scaly crusted epidermis, desquamation, sun-exposed areas, diarrhea
Kwashiorkor	Infants and children	Geographic dependent	Flaky scaly dermatitis, swollen limbs with cracked peeling patches
Phenylketonuria	Infants	Uncommon	Eczematous rash, hypopigmentation, blonde hair, developmental delay
NEOPLASTIC DISEASE			
Cutaneous T-cell lymphoma	Adults	Uncommon	Erythematous pink-brown macules and plaques with a fine scale; poorly responsive to topical corticosteroids; variable itch (in early stages)
Langerhans cell histiocytosis	Infants	Uncommon	Scaly and purpuric dermatosis, hepatosplenomegaly, cytopenias

[*] Common = approximately 1 in 10 to 1 in 100; uncommon = 1 in 100 to 1 in 1000; rare = 1 in 1000 to 1 in 10,000; very rare = <1 in 10,000.

[†] Especially in developing countries.

FLG, filaggrin gene.

Table 170.3

Features of Primary Immunodeficiencies Associated With Eczematous Dermatitis

DISEASE	GENE	INHERITANCE	CLINICAL FEATURES	LAB ABNORMALITIES
AD-HIES	*STAT3*	AD, less commonly sporadic	Cold abscesses Recurrent sinopulmonary infections Mucocutaneous candidiasis Coarse facies Minimal trauma fractures Scoliosis Joint hyperextensibility Retained primary teeth Coronary artery tortuosity or dilation Lymphoma	High IgE (>2000 IU/µL) Eosinophilia
DOCK8 deficiency	*DOCK8*	AR	Severe mucocutaneous viral infections Mucocutaneous candidiasis Atopic features (asthma, allergies) Squamous cell carcinoma Lymphoma	High IgE Eosinophilia With or without decreased IgM
PGM3 deficiency	*PGM3*	AR	Neurologic abnormalities Leukocytoclastic vasculitis Atopic features (asthma, allergies) Sinopulmonary infections Mucocutaneous viral infections	High IgE Eosinophilia
WAS	*WASP*	XLR	Hepatosplenomegaly Lymphadenopathy Atopic diathesis Autoimmune conditions (especially hemolytic anemia) Lymphoreticular malignancies	Thrombocytopenia (<80,000/µL) Low mean platelet volume Eosinophilia is common Lymphopenia Low IgM, variable IgG
SCID	Variable, depends on type	XLR and AR most common	Recurrent, severe infections Failure to thrive Persistent diarrhea Recalcitrant oral candidiasis Omenn syndrome: lymphadenopathy, hepatosplenomegaly,	Lymphopenia common Variable patterns of reduced lymphocyte subsets (T, B, natural killer cells) Omenn syndrome: high lymphocytes, eosinophilia, high IgE

			erythroderma	
IPEX	*FOXP3*	XLR	Severe diarrhea (autoimmune enteropathy) Various autoimmune endocrinopathies (especially diabetes mellitus, thyroiditis) Food allergies	High IgE Eosinophilia Various autoantibodies
Netherton syndrome	*SPINK5*	AR	Hair shaft abnormalities Erythroderma Ichthyosis linearis circumflexa Food allergies Recurrent gastroenteritis Neonatal hypernatremic dehydration Upper and lower respiratory infections	High IgE Eosinophilia

AD, Autosomal dominant; AD-HIES, autosomal-dominant hyper-IgE syndrome; AR, autosomal recessive; *DOCK8* , dedicator of cytokinesis 8 gene; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome; PGM3, phosphoglucomutase 3; SCID, severe combined immunodeficiency; WAS, Wiskott-Aldrich syndrome.

From Kliegman RM, Bordini BJ, editors: *Undiagnosed and Rare Diseases in Children* 64(1):41–42, 2017.

Adolescents who present with an eczematous dermatitis but no history of childhood eczema, respiratory allergy, or atopic family history may have allergic **contact dermatitis** (see Chapter 674.1). A contact allergen may be the problem in any patient whose AD does not respond to appropriate therapy. Sensitizing chemicals, such as parabens and lanolin, can be irritants for patients with AD and are commonly found as vehicles in therapeutic topical agents. Topical glucocorticoid contact allergy has been reported in patients with chronic dermatitis receiving topical corticosteroid therapy. Eczematous dermatitis has also been reported with HIV infection as well as with a variety of infestations such as scabies. Other conditions that can be confused with AD include psoriasis, ichthyosis, and seborrheic dermatitis.

Treatment

The treatment of AD requires a systematic, multifaceted approach that incorporates skin moisturization, topical antiinflammatory therapy, identification and elimination of flare factors (Table 170.4), and, if necessary, systemic therapy. Assessment of the severity also helps direct therapy (Table 170.5).

Table 170.4

Counseling and Aggravating Factors for Patients With Atopic Dermatitis (AD)

Maintain cool temperature in bedroom, and avoid too many bed covers.
Increase emollient use with cold weather.
Avoid exposure to herpes sores; urgent visit if flare of unusual aspect.
Clothing: Avoid skin contact with irritating fibers (wool, large-fiber textiles).
- Do not use tight and too-warm clothing, to avoid excessive sweating.
- New, nonirritating clothing designed for AD children is being evaluated.

Tobacco: Avoid exposure.
Vaccines: Normal schedule in noninvolved skin, including egg-allergic patients (see text).
Sun exposure: No specific restriction.
- Usually helpful because of improvement of epidermal barrier.
- Encourage summer holidays in altitude or at beach resorts.

Physical exercise, sports: no restriction.
- If sweating induces flares of AD, progressive adaptation to exercise.
- Shower and emollients after swimming pool.

Food allergens:
- Maintain breastfeeding exclusively to 4-6 mo if possible.
- Consider evaluation for early introduction of allergens (see Chapter 176).
- Otherwise normal diet, unless an allergy workup has proved the need to exclude a specific food.

Indoor aeroallergens: House dust mites
- Use adequate ventilation of housing; keep the rooms well aerated even in winter.
- Avoid wall-to-wall carpeting.
- Remove dust with a wet sponge.
- Vacuum floors and upholstery with an adequately filtered cleaner once a week.
- Avoid soft toys in bed (cradle), except washable ones.

  - Wash bedsheets at a temperature higher than 55°C (131°F) every 10 days.
  - Use bed and pillow encasings made of Gore-Tex or similar material.

Furred pets: Advise to avoid. If allergy is demonstrated, be firm on avoidance measures, such as pet removal.

Pollen: Close windows during peak pollen season on warm and dry weather days, and restrict, if possible, time outdoors.

  - Windows may be open at night and early in the morning or during rainy weather.
  - Avoid exposure to risk situations (lawn mowing).
  - Use pollen filters in motor vehicles.
  - Clothes and pets can vectorize aeroallergens, including pollen.

Adapted from Darsow U, Wollenberg A, Simon D, et al: ETFAD/EADV Eczema Task Force 2009 position paper on diagnosis and treatment of atopic dermatitis, *J Eur Acad Dermatol Venereol* 24:321, 2010.

Table 170.5

Categorization of Physical Severity of Atopic Eczema

Clear —Normal skin, with no evidence of atopic eczema

Mild —Areas of dry skin, infrequent itching (with or without small areas of redness)

Moderate —Areas of dry skin, frequent itching, redness (with or without excoriation and localized skin thickening)

Severe —Widespread areas of dry skin, incessant itching, redness (with or without excoriation, extensive skin thickening, bleeding, oozing, cracking, and alteration of pigmentation)

From Lewis-Jones S, Mugglestone MA; Guideline Development Group: Management of atopic eczema in children aged up to 12 years: summary of NICE guidance, *BMJ* 335:1263–1264, 2007.

Cutaneous Hydration

Because patients with AD have impaired skin barrier function from reduced filaggrin and skin lipid levels, they present with diffuse, abnormally dry skin, or **xerosis** . *Moisturizers are first-line therapy.* Lukewarm soaking baths or showers for 15-20 min followed by the application of an occlusive emollient to retain moisture provide symptomatic relief. Hydrophilic ointments of varying degrees of viscosity can be used according to the patient's preference. Occlusive ointments are sometimes not well tolerated because of interference with the function of the eccrine sweat ducts and may induce the development of folliculitis. In these patients, less occlusive agents should be used. Several prescription (classified as a medical device) “therapeutic moisturizers” or “barrier creams” are available, containing components such as ceramides and filaggrin acid metabolites intended to improve skin barrier function. There are minimal data demonstrating their efficacy over standard emollients.

Hydration by baths or wet dressings promotes transepidermal penetration of topical glucocorticoids. Dressings may also serve as effective barriers against persistent scratching, in turn promoting healing of excoriated lesions. Wet dressings are recommended for use on severely affected or chronically involved areas of dermatitis refractory to skin care. It is critical that wet dressing therapy be followed by topical emollient application to avoid potential drying and fissuring from the therapy. Wet dressing therapy can be complicated by maceration and secondary infection and should be closely monitored by a physician.

Topical Corticosteroids

Topical corticosteroids are the cornerstone of antiinflammatory treatment for acute exacerbations of AD. Patients should be carefully instructed on their use of topical glucocorticoids to avoid potential adverse effects. There are 7 classes of topical glucocorticoids, ranked according to their potency, as determined by vasoconstrictor assays (Table 170.6). Because of their potential adverse effects, the ultrahigh-potency glucocorticoids should not be used on the face or intertriginous areas and should be used only for very short periods on the trunk and extremities. Mid-potency glucocorticoids can be used for longer periods to treat chronic AD involving the trunk and extremities. Long-term control can be maintained with twice-weekly applications of topical fluticasone or mometasone to areas that have healed but are prone to relapse, once control of AD is achieved after a daily regimen of topical corticosteroids. Compared with creams, ointments have a greater potential to occlude the epidermis, resulting in enhanced systemic absorption.

Table 170.6

Selected Topical Corticosteroid Preparations*

Group 1

Clobetasol propionate (Temovate) 0.05% ointment/cream
Betamethasone dipropionate (Diprolene) 0.05% ointment/lotion/gel
Fluocinonide (Vanos) 0.1% cream

Group 2

Mometasone furoate (Elocon) 0.1% ointment
Halcinonide (Halog) 0.1% cream
Fluocinonide (Lidex) 0.05% ointment/cream
Desoximetasone (Topicort) 0.25% ointment/cream
Betamethasone dipropionate (Diprolene) 0.05% cream

Group 3

Fluticasone propionate (Cutivate) 0.005% ointment
Halcinonide (Halog) 0.1% ointment
Betamethasone valerate (Valisone) 0.1% ointment

Group 4

Mometasone furoate (Elocon) 0.1% cream
Triamcinolone acetonide (Kenalog) 0.1% ointment/cream
Fluocinolone acetonide (Synalar) 0.025% ointment

Group 5

Fluocinolone acetonide (Synalar) 0.025% cream

Hydrocortisone valerate (Westcort) 0.2% ointment

Group 6

Desonide (DesOwen) 05% ointment/cream/lotion
Alclometasone dipropionate (Aclovate) 0.05% ointment/cream

Group 7

Hydrocortisone (Hytone) 2.5%, 1%, 0.5% ointment/cream/lotion

---

[*] Representative corticosteroids are listed by group from 1 (superpotent) through 7 (least potent).

Adapted from Stoughton RB: Vasoconstrictor assay-specific applications. In Malbach HI, Surber C, editors: *Topical corticosteroids,* Basel, Switzerland, 1992, Karger, pp 42–53.

Adverse effects of topical glucocorticoids can be divided into local adverse effects and systemic adverse effects, the latter resulting from suppression of the hypothalamic-pituitary-adrenal axis. *Local* adverse effects include the development of striae and skin atrophy. *Systemic* adverse effects are related to the potency of the topical corticosteroid, site of application, occlusiveness of the preparation, percentage of the body surface area covered, and length of use. The potential for adrenal suppression from potent topical corticosteroids is greatest in infants and young children with severe AD requiring intensive therapy.

Topical Calcineurin Inhibitors

The nonsteroidal topical calcineurin inhibitors are effective in reducing AD skin inflammation. Pimecrolimus cream 1% (Elidel) is indicated for mild to moderate AD. Tacrolimus ointment 0.1% and 0.03% (Protopic) is indicated for moderate to severe AD. Both are approved for short-term or intermittent long-term treatment of AD in patients ≥2 yr whose disease is unresponsive to or who are intolerant of other conventional therapies or for whom these therapies are inadvisable because of potential risks. Topical calcineurin inhibitors may be better than topical corticosteroids in the treatment of patients whose AD is poorly responsive to topical steroids, patients with steroid phobia, and those with face and neck dermatitis, in whom ineffective, low-potency topical corticosteroids are typically used because of fears of steroid-induced skin atrophy.

Phosphodiesterase Inhibitor

Crisaborole (Eucrisa) is an approved nonsteroidal topical antiinflammatory phosphodiesterase-4 (PDE-4) inhibitor indicated for the treatment of mild to moderate AD down to age 2 yr. It may be used as an alternative to topical corticosteroids or calcineurin inhibitors.

Tar Preparations

Coal tar preparations have antipruritic and antiinflammatory effects on the skin; however, their antiinflammatory effects are usually not as pronounced as those of topical glucocorticoids or calcineurin inhibitors. Therefore, topical tar preparations are not a preferred approach for management of AD. Tar shampoos can be particularly beneficial for scalp dermatitis. Adverse effects associated with tar preparations include skin irritation, folliculitis, and photosensitivity.

Antihistamines

Systemic antihistamines act primarily by blocking the histamine H_1 receptors in the dermis, thereby reducing histamine-induced pruritus. Histamine is only one of many mediators that induce pruritus of the skin, so patients may derive minimal benefit from antihistaminic therapy. Because pruritus is usually worse at night, sedating antihistamines (hydroxyzine, diphenhydramine) may offer an advantage with their soporific side effects when used at bedtime. Doxepin hydrochloride has both tricyclic antidepressant and H_1 - and H_2 -receptor blocking effects. Short-term use of a sedative to allow adequate rest may be appropriate in cases of severe nocturnal pruritus. Studies of newer, nonsedating antihistamines have shown variable effectiveness in controlling pruritus in AD, although they may be useful in the small subset of patients with AD and concomitant urticaria. For children, melatonin may be effective in promoting sleep because production is deficient in AD.

Systemic Corticosteroids

Systemic corticosteroids are rarely indicated in the treatment of chronic AD. The dramatic clinical improvement that may occur with systemic corticosteroids is frequently associated with a severe rebound flare of AD after therapy discontinuation. Short courses of oral corticosteroids may be appropriate for an acute exacerbation of AD while other treatment measures are being instituted in parallel. If a short course of oral corticosteroids is given, as during an asthma exacerbation, it is important to taper the dosage and begin intensified skin care, particularly with topical corticosteroids, and frequent bathing, followed by application of emollients or proactive topical corticosteroids, to prevent rebound flaring of AD.

Cyclosporine

Cyclosporine is a potent immunosuppressive drug that acts primarily on T cells by suppressing cytokine gene transcription and has been shown to be effective in the control of severe AD. Cyclosporin forms a complex with an intracellular protein, cyclophilin, and this complex in turn inhibits calcineurin, a phosphatase required for activation of NFAT (nuclear factor of activated T cells), a transcription factor necessary for cytokine gene transcription. Cyclosporine (5 mg/kg/day) for short-term and long-term (1 yr) use has been beneficial for children with severe, refractory AD. Possible adverse effects include renal impairment and hypertension.

Dupilumab

A monoclonal antibody that binds to the IL-4 receptor α subunit, dupilumab (Dupixent) inhibits the signaling of IL-4 and IL-13, cytokines associated with AD. In adults with moderate to severe AD not controlled by standard topical therapy, dupilumab reduces pruritus and improves skin clearing.

Antimetabolites

Mycophenolate mofetil is a purine biosynthesis inhibitor used as an immunosuppressant in organ transplantation that has been used for treatment of refractory AD. Aside from immunosuppression, herpes simplex retinitis and dose-related bone marrow suppression have been reported with its use. Of note, not all patients benefit from treatment. Therefore, mycophenolate mofetil should be discontinued if the disease does not respond within 4-8 wk.

Methotrexate is an antimetabolite with potent inhibitory effects on inflammatory cytokine synthesis and cell chemotaxis. Methotrexate has been used for patients with recalcitrant AD. In AD, dosing is more frequent than the weekly dosing used for psoriasis.

Azathioprine is a purine analog with antiinflammatory and antiproliferative effects that has been used for severe AD. Myelosuppression is a significant adverse effect, and thiopurine methyltransferase levels may identify individuals at risk.

Before any of these drugs is used, patients should be referred to an AD specialist who is familiar with treatment of severe AD to weigh relative benefits of alternative therapies.

Phototherapy

Natural sunlight is often beneficial to patients with AD as long as sunburn and excessive sweating are avoided. Many phototherapy modalities are effective for AD, including ultraviolet A-1, ultraviolet B, narrow-band ultraviolet B, and psoralen plus ultraviolet A. Phototherapy is generally reserved for patients in whom standard treatments fail. Maintenance treatments are usually required for phototherapy to be effective. Short-term adverse effects with phototherapy include erythema, skin pain, pruritus, and pigmentation. Long-term adverse effects include predisposition to cutaneous malignancies.

Unproven Therapies

Other therapies may be considered in patients with refractory AD.

Interferon-γ

IFN-γ is known to suppress Th2-cell function. Several studies, including a multicenter, double-blind, placebo-controlled trial and several open trials, have demonstrated that treatment with recombinant human IFN-γ results in clinical improvement of AD. Reduction in clinical severity of AD correlated with the ability of IFN-γ to decrease total circulating eosinophil counts. Influenza-like symptoms are common side effects during the treatment course.

Omalizumab

Treatment of patients who have severe AD and elevated serum IgE values with monoclonal anti-IgE may be considered in those with allergen-induced flares of AD. However, there have been no published double-blind, placebo-controlled trials of omalizumab's use. Most reports have been case studies and show inconsistent responses to anti-IgE.

Allergen Immunotherapy

In contrast to its acceptance for treatment of allergic rhinitis and extrinsic asthma, immunotherapy with aeroallergens in the treatment of AD is controversial. There are reports of both disease exacerbation and improvement. Studies suggest that specific immunotherapy in patients with AD sensitized to dust mite allergen showed improvement in severity of skin disease, as well as reduction in topical corticosteroid use.

Probiotics

Perinatal administration of the probiotic *Lactobacillus rhamnosus* strain GG has been shown to reduce the incidence of AD in at-risk children during the 1st 2 yr of life. The treatment response has been found to be more pronounced in patients with positive skin-prick test results and elevated IgE values. Other studies have not demonstrated a benefit.

Chinese Herbal Medications

Several placebo-controlled clinical trials have suggested that patients with severe AD may benefit from treatment with traditional Chinese herbal therapy. The patients had significantly reduced skin disease and decreased pruritus. The beneficial response of Chinese herbal therapy is often temporary, and effectiveness may wear off despite continued treatment. The possibility of hepatic toxicity, cardiac side effects, or idiosyncratic reactions remains a concern. The specific ingredients of the herbs also remain to be elucidated, and some preparations have been found to be contaminated with corticosteroids. At present, Chinese herbal therapy for AD is considered investigational.

Vitamin D

Vitamin D deficiency often accompanies severe AD. Vitamin D enhances skin barrier function, reduces corticosteroid requirements to control inflammation, and augments skin antimicrobial function. Several small clinical studies suggest vitamin D can enhance antimicrobial peptide expression in the skin and reduce severity of skin disease, especially in patients with low baseline vitamin D, as during winter, when exacerbation of AD often occurs. Patients with AD might benefit from supplementation with vitamin D, particularly if they have a documented low level or low vitamin D intake.

Avoiding Triggers

It is essential to identify and eliminate triggering factors for AD, both during the period of acute symptoms and on a long-term basis to prevent recurrences (see Table 170.4).

Irritants

Patients with AD have a low threshold response to irritants that trigger their itch-scratch cycle. Soaps or detergents, chemicals, smoke, abrasive clothing, and exposure to extremes of temperature and humidity are common triggers. *Patients with AD should use soaps with minimal defatting properties and a neutral pH.* New clothing should be laundered before wearing to decrease levels of formaldehyde and other chemicals. Residual laundry detergent in clothing may trigger the itch-scratch cycle; using a liquid rather than powder detergent and adding a 2nd rinse cycle facilitates removal of the detergent.

Every attempt should be made to allow children with AD to be as normally active as possible. A sport such as swimming may be better tolerated than others that involve intense perspiration, physical contact, or heavy clothing and equipment. Rinsing off chlorine immediately and lubricating the skin after swimming are important. Although ultraviolet light may be beneficial to some patients with AD, high–sun protection factor (SPF) sunscreens should be used to avoid sunburn.

Foods

Food allergy is comorbid in approximately 40% of infants and young children with moderate to severe AD (see Chapter 176). Undiagnosed food allergies in patients with AD may induce eczematous dermatitis in some patients and urticarial reactions, wheezing, or nasal congestion in others. Increased severity of AD symptoms and younger age correlate directly with the presence of food allergy. Removal of food allergens from the diet leads to significant clinical improvement but requires much education, because most common allergens (egg, milk, peanut, wheat, soy) contaminate many foods and are difficult to avoid.

Potential allergens can be identified by a careful history and performing selective skin-prick tests or in vitro blood testing for allergen-specific IgE. Negative skin and blood test results for allergen-specific IgE have a high predictive value for excluding suspected allergens. Positive results of skin or blood tests using foods often do not correlate with clinical symptoms and should be confirmed with controlled food challenges and elimination diets. Extensive elimination diets, which can be nutritionally deficient, are rarely required. Even with multiple positive skin test results, the majority of patients react to fewer than 3 foods under controlled challenge conditions.

Aeroallergens

In older children, AD flares can occur after intranasal or epicutaneous exposure to aeroallergens such as fungi, animal dander, grass, and ragweed pollen. Avoiding aeroallergens, particularly dust mites, can result in clinical improvement of AD. Avoidance measures for dust mite–allergic patients include using dust mite–proof encasings on pillows, mattresses, and box springs; washing bedding in hot water weekly; removing bedroom carpeting; and decreasing indoor humidity levels with air conditioning.

Infections

Patients with AD have increased susceptibility to bacterial, viral, and fungal skin infections. Antistaphylococcal antibiotics are very helpful for treating patients who are heavily colonized or infected with *Staphylococcus aureus.* Erythromycin and azithromycin are usually beneficial for patients who are not colonized with a resistant *S. aureus* strain; a first-generation cephalosporin (cephalexin) is recommended for macrolide-resistant *S. aureus* . Topical mupirocin is useful in the treatment of localized impetiginous lesions, with systemic clindamycin or trimethoprim/sulfamethoxazole needed for methicillin-resistant *S. aureus* (MRSA). Cytokine-mediated skin inflammation contributes to skin colonization with *S. aureus* . This finding supports the importance of combining effective antiinflammatory therapy with antibiotics for treating moderate to severe AD to avoid the need for repeated courses of antibiotics, which can lead to the emergence of antibiotic-resistant strains of *S. aureus*. Dilute bleach baths (½ cup of bleach in 40 gallons of water) twice weekly may be also considered to reduce *S. aureus* colonization. In one randomized trial, the group who received the bleach baths plus intranasal mupirocin (5 days/mo) had significantly decreased severity of AD at 1 and 3 mo compared with placebo. Patients rinse off after the soaking. Bleach baths may not only reduce *S. aureus* abundance on the skin but also have antiinflammatory effects.

Herpes simplex virus (HSV) can provoke recurrent dermatitis and may be misdiagnosed as *S. aureus* infection (Fig. 170.4). The presence of punched-out erosions, vesicles, and infected skin lesions that fail to respond to oral antibiotics suggests HSV infection, which can be diagnosed by a Giemsa-stained Tzanck smear of cells scraped from the vesicle base or by viral polymerase chain reaction or culture. Topical corticosteroids should be temporarily discontinued if HSV infection is suspected. Reports of life-threatening dissemination of HSV infections in patients with AD who have widespread disease mandate antiviral treatment. Persons with AD are also susceptible to **eczema vaccinatum** , which is similar in appearance to eczema herpeticum and historically follows smallpox (vaccinia virus) vaccination.

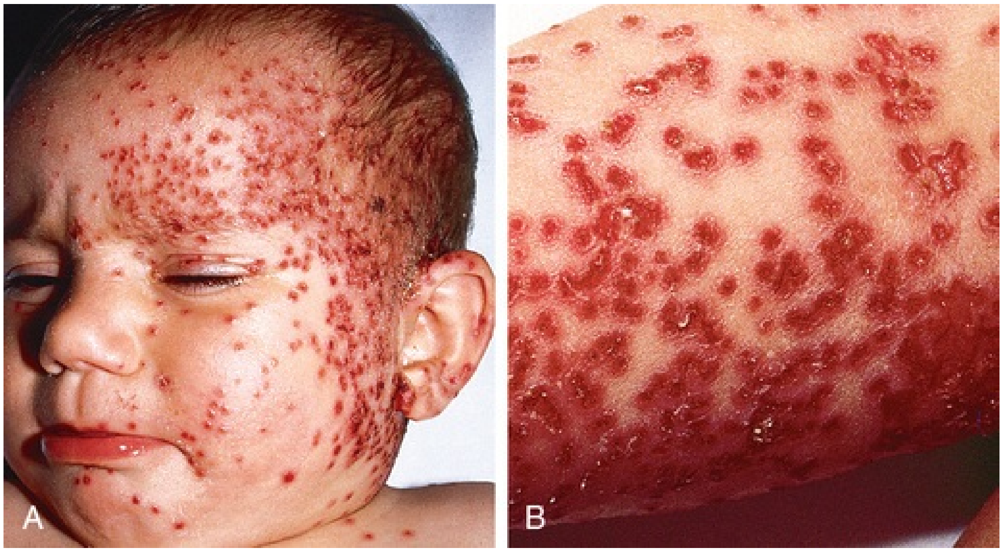

FIG. 170.4 Eczema herpeticum infection in a patient with atopic dermatitis. Numerous

punched-out vesicles and erosions involving the face (A) and extremities (B). (From Papulosquamous eruptions. In Cohen BA, editor: *Pediatric dermatology,* Philadelphia,2013, Saunders, pp 68–103.)

Cutaneous warts, coxsackievirus, and molluscum contagiosum are additional viral infections affecting children with AD.

Dermatophyte infections can also contribute to exacerbation of AD. Patients with AD have been found to have a greater susceptibility to *Trichophyton rubrum* fungal infections than nonatopic controls. There has been particular interest in the role of *Malassezia furfur* (formerly known as *Pityrosporum ovale*) in AD because it is a lipophilic yeast commonly present in the seborrheic areas of the skin. IgE antibodies against *M. furfur* have been found in patients with head and neck dermatitis. A reduction of AD severity has been observed in these patients after treatment with antifungal agents.

Complications

Exfoliative dermatitis may develop in patients with extensive skin involvement. It is associated with generalized redness, scaling, weeping, crusting, systemic toxicity, lymphadenopathy, and fever and is usually caused by superinfection (e.g., with toxin-producing *S. aureus* or HSV infection) or inappropriate therapy. In some cases the withdrawal of systemic glucocorticoids used to control severe AD precipitates exfoliative erythroderma.

Eyelid dermatitis and chronic blepharitis may result in visual impairment from corneal scarring. **Atopic keratoconjunctivitis** is usually bilateral and can have disabling symptoms that include itching, burning, tearing, and copious mucoid discharge. Vernal conjunctivitis is associated with papillary hypertrophy or cobblestoning of the upper eyelid conjunctiva. It typically occurs in younger patients and has a marked seasonal incidence with spring exacerbations. **Keratoconus** is a conical deformity of the cornea believed to result from chronic rubbing of the eyes in patients with AD. Cataracts may be a primary manifestation of AD or from extensive use of systemic and topical glucocorticoids, particularly around the eyes.

Prognosis

AD generally tends to be more severe and persistent in young children, particularly if they have null mutations in their filaggrin genes. Periods of remission occur more frequently as patients grow older. Spontaneous resolution of AD has been reported to occur after age 5 yr in 40–60% of patients affected during infancy, particularly for mild disease. Earlier studies suggested that approximately 84% of children outgrow their AD by adolescence; however, later studies reported that AD resolves in approximately 20% of children monitored from infancy until adolescence and becomes less severe in 65%. Of those adolescents treated for mild dermatitis, >50% may experience a relapse of disease as adults, which frequently manifests as *hand dermatitis*, especially if daily activities require repeated hand wetting. Predictive factors of a poor prognosis for AD include widespread AD in childhood, *FLG* null mutations, concomitant allergic rhinitis and asthma, family history of AD in parents or siblings, early age at onset of AD, being an only child, and very high serum IgE levels.

Prevention

Breastfeeding may be beneficial. Probiotics and prebiotics may also reduce the incidence or severity of AD, but this approach is unproven. If an infant with AD is diagnosed with food allergy, the breastfeeding mother may need to eliminate the implicated food allergen from her diet. For infants with severe eczema, introduction of infant-safe forms of peanut as early as 4-6 mo, after other solids are tolerated, is recommended after consultation with the child's pediatrician and/or allergist for allergy testing. This approach may prevent peanut allergy (see Chapter 176). Identification and elimination of triggering factors are the mainstay for prevention of flares as well as for the long-term treatment of AD.

Emollient therapy applied to the whole body for the 1st few mo of life may enhance the cutaneous barrier and reduce the risk of eczema.

CHAPTER 171

Insect Allergy

Julie Wang, Scott H. Sicherer

Allergic responses to stinging or, more rarely, biting insects vary from localized cutaneous reactions to systemic anaphylaxis. **Allergic reactions** caused by inhalation of airborne particles of insect origin result in acute and chronic respiratory symptoms of seasonal or perennial rhinitis, conjunctivitis, and asthma.

Etiology

Most reactions to stinging and biting insects, such as those induced by wasps, mosquitoes, flies, and fleas, are limited to a primary lesion isolated to the area of the sting or bite and do not represent an allergic response. Occasionally, insect stings or bites induce pronounced localized reactions or systemic reactions that may be based on immediate or delayed hypersensitivity reactions. Systemic allergic responses to insects are usually attributed to IgE antibody–mediated responses, which are caused primarily by stings from venomous insects of the order **Hymenoptera** and more rarely from ticks, spiders, scorpions, and *Triatoma* (kissing bug). Members of the order Hymenoptera include *apids* (honeybee, bumblebee), *vespids* (yellow jacket, wasp, hornet), and *formicids* (fire and harvester ants) (Fig. 171.1). Among winged stinging insects, yellow jackets are the most notorious for stinging because they are aggressive and ground dwelling, and they linger near activities involving food. Hornets nest in trees, whereas wasps build honeycomb nests in dark areas such as under porches; both are aggressive if disturbed. Honeybees are less aggressive and nest in tree hollows; unlike the stings of other flying Hymenoptera, honeybee stings almost always leave a barbed stinger with venom sac.

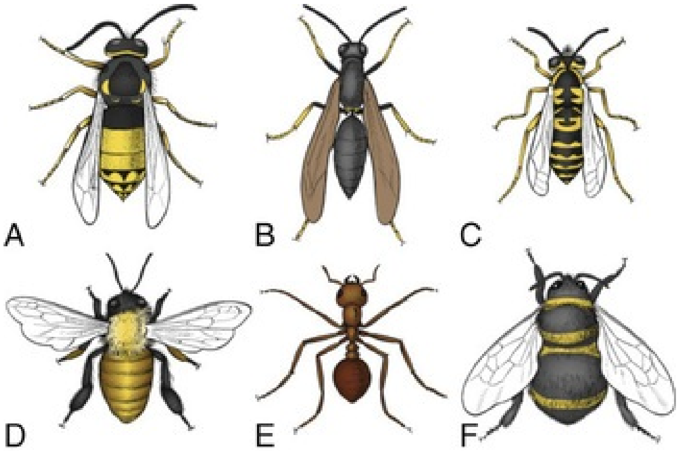

FIG. 171.1 Representative venomous Hymenoptera. A, Hornet *(Vespula maculata)* . B, Wasp *(Chlorion ichneumerea)* . C, Yellowjacket *(Vespula maculiforma)* . D, Honeybee *(Apis mellifera)* . E, Fire ant *(Solenopsis invicta)* . F, Bumblebee *(Bombus species)* . (From Erickson TB, Marquez A: Arthropod envenomation and parasitism. In Auerbach PS, Cushing TA, Harris NS (eds): Auerbach's wilderness medicine, ed 7, Philadelphia, 2017, Elsevier, Fig 41-1, p 937.)

In the United States, fire ants are found increasingly in the Southeast, living in large mounds of soil. When disturbed, the ants attack in large numbers, anchor themselves to the skin by their mandibles, and sting multiple times in a circular pattern. Sterile pseudopustules form at the sting sites. Systemic reactions to stinging insects occur in 0.4–0.8% of children and 3% of adults and account for approximately 40 deaths each year in the United States.

Although reactions to insect bites are common, IgE-mediated reactions are infrequently reported and anaphylaxis is rare. The *Triatoma* (kissing bug) bite causes an erythematous plaque that is painless. Mosquito bites generally result in local reactions that are pruritic. Large, local reactions to mosquito bites can occur in some young children; this is known as **skeeter syndrome** and is often misdiagnosed as cellulitis. The *tabanid* species (horsefly, deerfly), typically found in rural and suburban areas, are large flies that induce painful bites.

IgE antibody–mediated allergic responses to airborne particulate matter carrying insect emanations contribute to seasonal and perennial symptoms affecting the upper and lower airways. Seasonal allergy is attributed to exposures to a variety of insects, particularly aquatic insects such as the caddis fly and midge, or lake fly, at a time when larvae pupate and adult flies are airborne. **Perennial allergy** is attributed to sensitization to insects such as cockroaches and ladybugs, as well as house dust mite, which is phylogenetically related to spiders rather than insects and has 8 rather than 6 legs.

Pathogenesis

Hymenoptera venoms contain numerous components with toxic and pharmacologic activity and with allergenic potential. These constituents include vasoactive substances such as histamine, acetylcholine, and kinins; enzymes such as phospholipase and hyaluronidase; apamin; melittin; and formic acid. The majority of patients who experience systemic reactions after Hymenoptera stings have IgE-mediated sensitivity to antigenic substances in the venom. Some venom allergens are homologous among members of the Hymenoptera order; others are family specific. There is substantial cross-reactivity among vespid venoms, but these venom allergies are distinct from honeybee venom allergies.

Localized skin responses to biting insects are caused primarily by vasoactive or irritant materials derived from insect saliva; they rarely occur from IgE-associated responses. Systemic IgE-mediated allergic reactions to salivary proteins of biting insects such as mosquitoes are reported but uncommon.

A variety of proteins derived from insects can become airborne and induce IgE-mediated respiratory responses, causing inhalant allergies. The primary allergen from the caddis fly is a hemocyanin-like protein, and that from the midge fly is derived from hemoglobin. Allergens from the cockroach are the best studied and are derived from cockroach saliva, secretions, fecal material, and debris from skin casts.

Clinical Manifestations

Clinical reactions to stinging venomous insects are categorized as local, large local, generalized cutaneous, systemic, toxic, and delayed/late. Simple **local reactions** involve limited swelling and pain and generally last <24 hr. **Large local reactions** develop over hours and days, involve swelling of extensive areas (>10 cm) that are contiguous with the sting site, and may last for days. **Generalized cutaneous reactions** typically progress within minutes and include cutaneous symptoms of urticaria, angioedema, and pruritus beyond the site of the sting. **Systemic reactions** are identical to anaphylaxis from other triggers and may include symptoms of generalized urticaria, laryngeal edema, bronchospasm, and hypotension. Stings from a large number of insects at once may result in **toxic reactions** of fever, malaise, emesis, and nausea because of the chemical properties of the venom in large doses. Serum sickness, nephrotic syndrome, vasculitis, neuritis, or encephalopathy may occur as **delayed/late**

reactions to stinging insects.

Insect bites are usually urticarial but may be papular or vesicular. **Papular urticaria** affecting the lower extremities in children is usually caused by multiple bites. Occasionally, individuals have large, local reactions. IgE antibody–associated immediate- and late-phase allergic responses to mosquito bites sometimes mimic cellulitis.

Inhalant allergy caused by insects results in clinical disease similar to that induced by other inhalant allergens such as pollens. Depending on individual sensitivity and exposure, reactions may result in seasonal or perennial rhinitis, conjunctivitis, or asthma.

Diagnosis

The diagnosis of allergy from stinging and biting insects is generally evident from the history of exposure, typical symptoms, and physical findings. The diagnosis of Hymenoptera allergy rests in part on the identification of venom-specific IgE by skin-prick testing or in vitro testing. The primary reasons to pursue testing are to confirm reactivity when venom immunotherapy (**VIT**) is being considered or when it is clinically necessary to confirm venom hypersensitivity as a cause of a reaction. Venoms of 5 Hymenoptera (honeybee, yellow jacket, yellow hornet, white-faced hornet, and wasp), as well as the jack jumper ant in Australia and whole body extract of fire ant, are available for skin testing. Although skin tests are considered to be the most sensitive modality for detection of venom-specific IgE, additional evaluation with an in vitro serum assay for venom-specific IgE is recommended if skin test results are negative in the presence of a convincing history of a severe systemic reaction. In vitro tests have a 20% incidence of both false-positive and false-negative results, so it is not appropriate to exclude venom hypersensitivity based on this test alone. If initial skin-prick and in vitro test results are negative in the context of a convincing history of a severe reaction, repeat testing is recommended before concluding that allergy is unlikely. Skin tests are usually accurate within 1 wk of a sting reaction, but occasionally a refractory period is observed that warrants retesting after 4-6 wk if the initial results are negative.

An elevated **basal tryptase** level is associated with more severe reactions to venom stings. Therefore, basal tryptase should be measured if there is a history of severe reaction to a sting, hypotensive reaction, lack of urticaria in a systemic sting reaction, or negative venom IgE in a patient who has a history of systemic reaction to a sting. As many as 40% of skin test–positive patients may not experience anaphylaxis on sting challenge, so testing without an appropriate clinical history is potentially misleading.

The diagnosis of inhalant insect allergy may be evident from a history of typical symptoms. A chronic respiratory symptom during long-term exposure, as may occur with cockroach allergy, is less amenable to identification by history alone. Skin-prick or in vitro immunoassay tests for specific IgE to the insect are used to confirm inhalant insect allergy. Allergy tests may be particularly warranted for potential cockroach allergy in patients with persistent asthma and known cockroach exposure.

Treatment

For local cutaneous reactions caused by insect stings and bites, treatment with cold compresses, topical medications to relieve itching, and occasionally a systemic antihistamine and oral analgesic are appropriate. Stingers should be removed promptly by scraping, with caution not to squeeze the venom sac because doing so could inject more venom. Sting sites rarely become infected, possibly because of the antibacterial actions of venom constituents. Vesicles left by fire ant stings that are scratched open should be cleansed to prevent secondary infection.

Anaphylactic reactions after a Hymenoptera sting are treated the same as anaphylaxis from any cause; *epinephrine is the drug of choice.* Adjunctive treatment includes antihistamines, corticosteroids, intravenous fluids, oxygen, and transport to the emergency department (see Chapter 174). Referral to an allergist-immunologist should be considered for patients who have experienced a generalized cutaneous or systemic reaction to an insect sting, who need education about avoidance and emergency treatment, who may be candidates for VIT, or who have a condition that may complicate management of anaphylaxis (e.g., use of β-blockers).

Venom Immunotherapy

Hymenoptera VIT is highly effective (95–97%) in decreasing the risk for **severe anaphylaxis** . The selection of patients for VIT depends on several factors (Table 171.1). Individuals with local reactions, regardless of age, are not at increased risk for severe systemic reactions on a subsequent sting and are not candidates for VIT. The risk of a systemic reaction for those who experienced a large, local reaction is approximately 7%; testing or VIT is usually not recommended, and prescription of self-injectable epinephrine is considered optional but usually not necessary. There is growing evidence that VIT can reduce the size and duration of large, local reactions, and therefore VIT may be considered for those with frequent or unavoidable large, local reactions. *Those who experience severe systemic reactions, such as airway involvement or hypotension, and who have specific IgE to venom allergens should receive immunotherapy.* Immunotherapy against winged Hymenoptera is generally not required when stings have caused only generalized urticaria or angioedema, because the risk for a systemic reaction after a subsequent sting is approximately 10% and the chance of a more severe reaction is <3%. VIT may be considered if there are potential high-risk cofactors such as comorbid cardiovascular disease or use of specific cardiovascular medications (e.g., ACE inhibitors, β-blockers), elevated basal tryptase level, or high likelihood of future stings. VIT is usually not indicated if there is no evidence of IgE to venom.

Table 171.1

Indications for Venom Immunotherapy (VIT) Against Winged Hymenoptera

SYMPTOMS	SKIN TEST/IN VITRO TEST	RISK OF SYSTEMIC REACTION IF UNTREATED*	VIT RECOMMENDED
Large local reaction	Usually not indicated	~7%	Usually not indicated
Generalized cutaneous reaction	Usually not indicated	10%	Usually not indicated
Systemic reaction	Positive result	Child: 40% Adult: 30–60%	Yes
	Negative result	—	Usually not indicated

[*] Risks generally decrease after 10 yr.

The incidence of adverse effects in the course of treatment is not trivial in adults; 50% experience large, local reactions, and about 10% experience systemic reactions. The incidence of both local and systemic reactions is much lower in children. Patients treated with honeybee venom are at higher risk for systemic reactions to VIT than those receiving treatment with vespid venom. Individuals with mast cell disorders are at increased risk for severe anaphylaxis and more frequent systemic reactions with VIT; thus some experts recommend basal tryptase level for risk assessment purposes.

It is uncertain how long immunotherapy with Hymenoptera venom should continue. In general, treatment duration of 3-5 yr is recommended because >80% of adults who have received 5 yr of therapy tolerate challenge stings without systemic reactions for 5-10 yr after completion of treatment. Long-term responses to treatment are even better for children. Follow-up over a mean of 18 yr of children with moderate to severe insect sting reactions who received VIT for a mean of 3-5 yr and were stung again showed a reaction rate of only 5%; untreated children experienced a reaction rate of 32%. Whereas duration of therapy with VIT may be individualized, it is clear that a significant number of untreated children retain their allergy. Extended or lifelong treatment may be considered for those who have had life-threatening anaphylaxis with insect stings, those with honeybee allergy, and those with occupational exposures to Hymenoptera. Lifelong VIT should also be considered for patients with mast cell disorders because they have a higher rate of failure of VIT and relapse when VIT is discontinued.

Less is known about the natural history of fire ant hypersensitivity and efficacy of immunotherapy for this allergy. The criteria for starting immunotherapy are similar to those for hypersensitivities to other Hymenoptera, but there is stronger consideration to treat patients who have only cutaneous systemic reactions with VIT. Only whole body fire ant extract is commercially available for diagnostic skin testing and immunotherapy.

Inhalant Allergy

The symptoms of inhalant allergy caused by insects are managed as for other causes of seasonal or perennial rhinitis (see Chapter 168), conjunctivitis (Chapter 172), and asthma (Chapter 169).

Prevention

Avoidance of stings and bites is essential. To reduce the risk of stings, sensitized individuals should have known or suspected nests near the home removed by trained professionals, should wear gloves when gardening, should wear long pants and shoes with socks when walking in the grass or through fields, and should avoid or be cautious about eating or drinking outdoors. Typical insect repellents do not guard against Hymenoptera.

Individuals who are at high risk for future severe reactions to Hymenoptera stings should have immediate access to self-injectable epinephrine. High-risk individuals include those who have a history of severe reactions, are prescribed angiotensin-converting enzyme (ACE) inhibitors or β-adrenergic blockers, or have elevated basal tryptase level. Adults responsible for allergic children and older patients who can self-treat must be carefully taught the indications and technique of administration for this medication. Particular attention is necessary for children in out-of-home daycare centers, at school, or attending camps, to ensure that an emergency action plan is in place. The individual at risk for anaphylaxis from an insect sting should also wear an identification bracelet indicating the allergy.

Avoidance of the insect is the preferred management of inhalant allergy. This can prove difficult, particularly for those living in apartments, where eradication of cockroaches may be problematic. Immunotherapy for dust mites is effective and should be considered in conjunction with avoidance measures. In contrast, there is limited data regarding the efficacy of cockroach immunotherapy.

CHAPTER 172

Ocular Allergies

Christine B. Cho, Mark Boguniewicz, Scott H. Sicherer

The **eye** is a common target of allergic disorders because of its marked vascularity and direct contact with allergens in the environment. The **conjunctiva** is the most immunologically active tissue of the external eye. Ocular allergies can occur as isolated target organ disease or more often in conjunction with nasal allergies. Ocular symptoms can significantly affect quality of life.

Clinical Manifestations

There are a few distinct entities that constitute allergic eye disease, all of which have bilateral involvement. Sensitization is necessary for all these except giant papillary conjunctivitis. Vernal and atopic keratoconjunctivitis are potentially sight threatening (see Chapter 652).

Allergic Conjunctivitis

Allergic conjunctivitis is the most common hypersensitivity response of the eye, affecting approximately 25% of the general population and 30% of children with atopy. It is caused by direct exposure of the mucosal surfaces of the eye to environmental allergens. Patients complain of variable ocular itching, rather than pain, with increased tearing. Clinical signs include bilateral injected conjunctivae with vascular congestion that may progress to *chemosis*, or conjunctival swelling, and a watery discharge (Fig. 172.1).

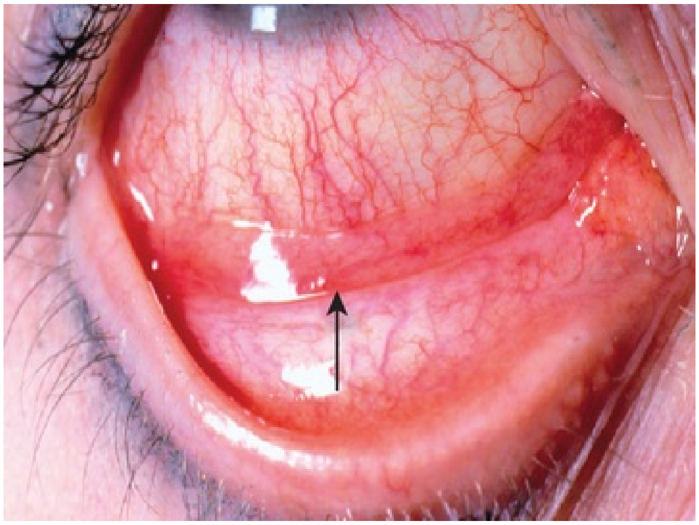

FIG. 172.1 Allergic conjunctivitis. *Arrow* indicates area of chemosis in the conjunctivitis. (From Adkinson NF Jr, Bochner BS, Burks AW, et al, editors: *Middleton's allergy: principles & practice,* ed 8, vol 1, St Louis, Mosby/Elsevier, 2014, p 619.)

Allergic conjunctivitis occurs in a seasonal or, less frequently, perennial form. **Seasonal allergic conjunctivitis** is typically associated with allergic rhinitis (see Chapter 168) and is most commonly triggered by pollens. Major pollen groups in the temperate zones include trees (late winter to early spring), grasses (late spring to early summer), and weeds (late summer to early fall), but seasons can vary significantly in different parts of the United States. Mold spores can also cause seasonal allergy symptoms, principally in the summer and fall. Seasonal allergy symptoms may be aggravated by coincident exposure to perennial allergens. **Perennial allergic conjunctivitis** is triggered by allergens such as animal danders or dust mites that are present throughout the year. Symptoms are usually less severe than with seasonal allergic conjunctivitis. Because pollens and soil molds may be present intermittently by season, and exposure to allergens such as furred animals may be perennial, classification as intermittent (symptoms present <4 days/wk or for <4 wk) and persistent (symptoms present >4 days/wk and for >4 wk) has been proposed.

Vernal Keratoconjunctivitis

Vernal keratoconjunctivitis is a severe bilateral chronic inflammatory process of the upper tarsal conjunctival surface that occurs in a limbal or palpebral form. It may threaten eyesight if there is corneal involvement. Although vernal keratoconjunctivitis is not IgE mediated, it occurs most frequently in children with seasonal allergies, asthma, or atopic dermatitis. Vernal keratoconjunctivitis affects boys twice as often as girls and is more common in persons of Asian and African descent. It affects primarily children in temperate areas, with exacerbations in the spring and summer, but can occur throughout the year. Symptoms include severe ocular itching exacerbated by exposure to irritants, light, or perspiration. In addition, patients may complain of severe photophobia, foreign body sensation, and lacrimation. Giant papillae occur predominantly on the upper tarsal plate and are typically described as *cobblestoning* (Fig. 172.2). Other signs include a stringy or thick, ropey discharge, cobblestone papillae, transient yellow-white points in the limbus *(Trantas dots)* and conjunctiva *(Horner points)* , corneal “shield” ulcers, and Dennie lines (Dennie-Morgan folds), which are prominent symmetric skin folds that extend in an arc from the inner canthus beneath and parallel to the lower lid margin. Children with vernal keratoconjunctivitis have measurably longer eyelashes, which may represent a reaction to ocular inflammation.

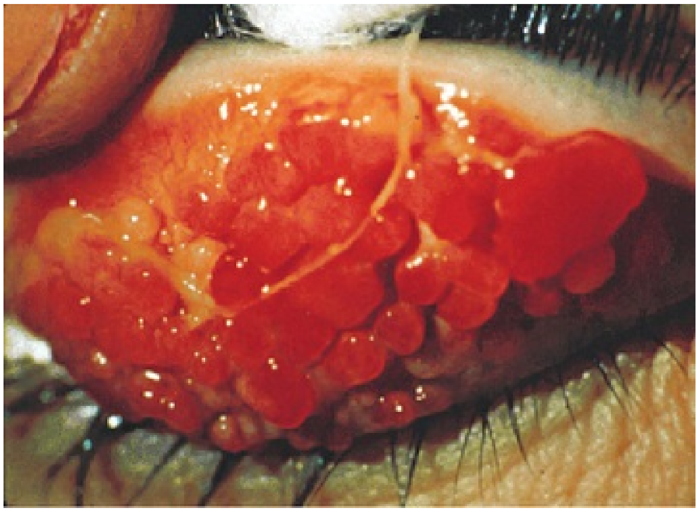

FIG. 172.2 **Vernal keratoconjunctivitis. Cobblestone papillae and ropey discharge are seen on the underside (tarsal conjunctiva) of the upper eyelid. (From Adkinson NF Jr, Bochner BS, Burks AW, et al, editors: *Middleton's allergy: principles & practice,* ed 8, vol 1, St Louis, Mosby/Elsevier, 2014, p 627.)**

Atopic Keratoconjunctivitis

Atopic keratoconjunctivitis is a chronic inflammatory ocular disorder most often involving the lower tarsal conjunctiva. It may threaten eyesight if there is corneal involvement. Almost all patients have atopic dermatitis, and a significant number have asthma. Atopic keratoconjunctivitis rarely presents before late adolescence. Symptoms include severe bilateral ocular itching, burning, photophobia, and tearing with a mucoid discharge that are much more severe than in allergic conjunctivitis and persist throughout the year. The bulbar conjunctiva is injected and chemotic; cataracts may occur. Trantas dots or giant papillae may also be present. Eyelid eczema can extend to the periorbital skin and cheeks with erythema and thick, dry scaling. Secondary staphylococcal blepharitis is common because of eyelid induration and maceration. Chronic eye rubbing associated with vernal and atopic keratoconjunctivitis can lead to **keratoconus** , a noninflammatory cone-shaped corneal ectasia. This may lead to corneal thinning and perforation.

Giant Papillary Conjunctivitis

Giant papillary conjunctivitis has been linked to chronic exposure to foreign bodies, such as contact lenses, both hard and soft, ocular prostheses, and sutures. Symptoms and signs include mild bilateral ocular itching, tearing, a foreign body sensation, and excessive ocular discomfort with mild mucoid discharge with white or clear exudate on awakening, which may become thick and stringy. Trantas dots, limbal infiltration, bulbar conjunctival hyperemia, and edema may develop.

Contact Allergy

Contact allergy typically involves the eyelids but can also involve the conjunctivae. It is being recognized more frequently in association with increased exposure to topical medications, contact lens solutions, and preservatives.

Diagnosis

Nonallergic conjunctivitis can be viral, bacterial, or chlamydial in origin. It is typically unilateral but can be bilateral with symptoms initially developing in 1 eye (see Chapter 644). Symptoms include stinging or burning rather than itching and often a foreign body sensation. Ocular discharge can be watery, mucoid, or purulent. Masqueraders of ocular allergy also include nasolacrimal duct obstruction, foreign body, blepharoconjunctivitis, dry eye, uveitis, and trauma.

Treatment

Primary treatment of ocular allergies includes avoidance of allergens, cold compresses, and lubrication. **Secondary treatment** regimens include the use of oral or topical antihistamines and, if necessary, topical decongestants, mast cell stabilizers, and antiinflammatory agents (Table 172.1). Drugs with dual antihistamine and mast cell–blocking activities provide the most advantageous approach in treating allergic conjunctivitis, with both fast-acting symptomatic relief and disease-modifying action. Children often complain of stinging or burning with use of topical ophthalmic preparations and usually prefer oral antihistamines for allergic conjunctivitis. It is important not to contaminate topical ocular medications by allowing the applicator tip to contact the eye or eyelid. Using refrigerated medications may decrease some of the discomfort associated with their use. Topical decongestants act as vasoconstrictors, reducing erythema, vascular congestion, and eyelid edema, but do not diminish the allergic response. Adverse effects of topical vasoconstrictors include burning or stinging and rebound hyperemia or conjunctivitis medicamentosa with chronic use. Combined use of an antihistamine and a vasoconstrictor is more effective than use of either agent alone. Use of topical nasal corticosteroids for allergic rhinoconjunctivitis decreases ocular symptoms, presumably through a nasoocular reflex.

Table 172.1

Topical Ophthalmic Medications for Allergic Conjunctivitis

DRUG AND TRADE NAMES	MECHANISM OF ACTION AND DOSING	CAUTIONS AND ADVERSE EVENTS
Azelastine hydrochloride 0.05% Optivar	Antihistamine Children ≥3 yr: 1 gtt bid	Not for treatment of contact lens–related irritation; the preservative may be absorbed by soft contact lenses. Wait at least 10 min after administration before inserting soft contact lenses.
Emedastine difumarate 0.05% Emadine	Antihistamine Children ≥3 yr: 1 gtt qid	Soft contact lenses should not be worn if the eye is red. Wait at least 10 min after administration before inserting soft contact lenses.
Levocabastine hydrochloride 0.05% Livostin	Antihistamine Children ≥12 yr: 1 gtt bid-qid up to 2 wk	Not for use in patients wearing soft contact lenses during treatment.
Pheniramine maleate	Antihistamine/vasoconstrictor	Avoid prolonged use (>3-4 days) to avoid rebound symptoms. Not for use with contact lenses.
0.3% Naphazoline	Children >6 yr: 1-2 gtt qid	

hydrochloride		
0.025%		
Naphcon-A, Opcon-A		
Cromolyn sodium 4% Crolom, Opticrom	Mast cell stabilizer Children >4 yr: 1-2 gtt q4-6h	Can be used to treat giant papillary conjunctivitis and vernal keratitis. Not for use with contact lenses.
Lodoxamide tromethamine 0.1% Alomide	Mast cell stabilizer Children ≥2 yr: 1-2 gtt qid up to 3 mo	Can be used to treat vernal keratoconjunctivitis. Not for use in patients wearing soft contact lenses during treatment.
Nedocromil sodium 2% Alocril	Mast cell stabilizer Children ≥3 yr: 1-2 gtt bid	Avoid wearing contact lenses while exhibiting the signs and symptoms of allergic conjunctivitis.
Pemirolast potassium 0.1% Alamast	Mast cell stabilizer Children >3 yr: 1-2 gtt qid	Not for treatment of contact lens–related irritation; the preservative may be absorbed by soft contact lenses. Wait at least 10 min after administration before inserting soft contact lenses.
Epinastine hydrochloride 0.05% Elestat	Antihistamine/mast cell stabilizer Children ≥3 yr: 1 gtt bid	Contact lenses should be removed before use. Wait at least 15 min after administration before inserting soft contact lenses. Not for the treatment of contact lens irritation.
Ketotifen fumarate 0.025% Zaditor	Antihistamine/mast cell stabilizer Children ≥3 yr: 1 gtt bid q8-12h	Not for treatment of contact lens–related irritation; the preservative may be absorbed by soft contact lenses. Wait at least 10 min after administration before inserting soft contact lenses.
Olopatadine hydrochloride 0.1%, 0.2%, 0.7% Patanol Pataday Pazeo	Antihistamine/mast cell stabilizer Children ≥3 yr: 1 gtt bid (8 hr apart) Children≥2 yr: 1 gtt qd	Not for treatment of contact lens–related irritation; the preservative may be absorbed by soft contact lenses. Wait at least 10 min after administration before inserting soft contact lenses.
Alcaftadine, 0.25% Lastacaft	Antihistamine/mast cell stabilizer Children > 2 yr: 1 gtt bid q8-12h	Contact lenses should be removed before application; may be inserted after 10 min. Not for the treatment of contact lens irritation.
Bepotastine besilate 1.5% Bepreve	Antihistamine/mast cell stabilizer Children >2 yr: 1 gtt bid q8-12h	Contact lenses should be removed before application, may be inserted after 10 min. Not for the treatment of contact lens irritation.
Ketorolac tromethamine 0.5% Acular	NSAID Children ≥3 yr: 1 gtt qid	Avoid with aspirin or NSAID sensitivity. Use ocular product with caution in patients with complicated ocular surgeries, corneal denervation or epithelial defects, ocular surface diseases (e.g., dry eye syndrome), repeated ocular surgeries within a short period, diabetes mellitus, or rheumatoid arthritis; these patients may be at risk for corneal adverse events that may be sight threatening. *Do not use while wearing contact lenses.*
Fluorometholone 0.1%, 0.25% suspension (0.1%, 0.25%) and ointment	Fluorinated corticosteroid Children ≥2 yr, 1 gtt into conjunctival sac of affected eye(s) bid-qid. During initial 24-48 hr, dosage may be	If improvement does not occur after 2 days, patient should be reevaluated. Patient should remove soft contact lenses before administering (contains benzalkonium chloride) and delay reinsertion of lenses for ≥15 min after administration. Close monitoring for

(0.1%) FML, FML Forte, Flarex	increased to 1 gtt q4h. Ointment (~1.3 cm in length) into conjunctival sac of affected eye(s) 1-3 times daily. May be applied q4h during initial 24-48 hr of therapy.	development of glaucoma and cataracts.

NSAID, Nonsteroidal antiinflammatory drug; bid, 2 times daily; gtt, drops; qid, 4 times daily; q4-6h; every 4-6 hr; qd, every day.

Tertiary treatment of ocular allergy includes topical (or rarely oral) corticosteroids and should be conducted in conjunction with an ophthalmologist. Local administration of topical corticosteroids may be associated with increased intraocular pressure, viral infections, and cataract formation. Other immunomodulatory medications, such as topical tacrolimus or topical cyclosporine, are used as steroid-sparing agents by ophthalmologists. Allergen immunotherapy can be very effective in seasonal and perennial allergic conjunctivitis, especially when associated with rhinitis, and can decrease the need for oral or topical medications to control allergy symptoms.

Because vernal and atopic keratoconjunctivitis can be associated with visual morbidity, if these diagnoses are suspected, the patient should be referred to an ophthalmologist. *Symptoms that should prompt referral to an ophthalmologist include unilateral red eye with pain, photophobia, change in vision, refractory dry eyes, or corneal abnormality.*

CHAPTER 173

Urticaria (Hives) and Angioedema

Amy P. Stallings, Stephen C. Dreskin, Michael M. Frank, Scott H. Sicherer

Urticaria and angioedema affect 20% of individuals at some point in their life. Episodes of hives that last for <6 wk are considered *acute*, whereas those that occur on most days of the week for >6 wk are designated *chronic*. The distinction is important, because the causes and mechanisms of urticaria formation and the therapeutic approaches are different in each instance.

Etiology and Pathogenesis

Acute urticaria and angioedema are often caused by an allergic IgE–mediated reaction (Table 173.1). This form of urticaria is a self-limited process that occurs when an allergen activates mast cells in the skin. Common causes of acute generalized urticaria include foods, drugs (particularly antibiotics), and stinging-insect venoms. If an allergen (latex, animal dander) penetrates the skin locally, hives often can develop at the site of exposure. Acute urticaria can also result from non–IgE-mediated stimulation of mast cells, caused by radiocontrast agents, viral agents (including hepatitis B and Epstein-Barr virus), opiates, and nonsteroidal antiinflammatory drugs (NSAIDs). The diagnosis of **chronic urticaria** is established when lesions occur on most days of the week for >6 wk and are not physical urticaria or recurrent acute urticaria with repeated exposures to a specific agent (Tables 173.2 and 173.3). In about half the cases, chronic urticaria is accompanied by angioedema. Rarely, angioedema occurs without urticaria. Angioedema without urticaria is often a result of allergy, but recurrent angioedema suggests other diagnoses.

Table 173.1

Etiology of Acute Urticaria

Etiology of Acute Urticaria

Foods	Egg, milk, wheat, peanuts, tree nuts, soy, shellfish, fish, (direct mast cell degranulation)
Medications	Suspect all medications, even nonprescription or homeopathic
Insect stings	Hymenoptera (honeybee, yellow jacket, hornets, wasp, fire ants), biting insects (papular urticaria)
Infections	**Bacterial** (streptococcal pharyngitis, *Mycoplasma* , sinusitis); viral (hepatitis, mononucleosis [Epstein-Barr virus], coxsackieviruses A and B); **Parasitic** *(Ascaris, Ancylostoma, Echinococcus, Fasciola, Filaria, Schistosoma, Strongyloides, Toxocara, Trichinella);* **Fungal** (dermatophytes, *Candida*)
Contact allergy	Latex, pollen, animal saliva, nettle plants, caterpillars
Transfusion reactions	Blood, blood products, or IV immune globulin administration

From Youseff MJ, Chiu YE: Eczema and urticaria as manifestations of undiagnosed and rare diseases, *Pediatr Clin North Am* 64:39–56, 2017 (Table 2, pp 49–50).

A typical **hive** is an erythematous, pruritic, raised wheal that blanches with pressure, is transient, and resolves without residual lesions, unless the area was intensely scratched. In contrast, urticaria associated with serum sickness reactions, systemic lupus erythematosus (SLE), or other vasculitides in which a skin biopsy reveals a small-vessel vasculitis, often have distinguishing clinical features. Lesions that burn more than itch, last >24 hr, do not blanch, blister, heal with scarring, or that are associated with bleeding into the skin (purpura) suggest urticarial vasculitis. Atypical aspects of the gross appearance of the hives or associated symptoms should heighten concern that the urticaria or angioedema may be the manifestation of a systemic disease process (Table 173.4).

Table 173.4

Distinguishing Features Between Urticaria and Systemic Urticarial Syndromes

COMMON URTICARIA	URTICARIAL SYNDROMES (≥1 of following)
Only typical wheals: Erythematous edematous lesions Transient (<24-36 hr) Asymmetric distribution Resolution without signs No associated different elementary lesions (papules, vesicles, purpura, crustae)	Atypical “wheals”: Infiltrated plaques Persistent (>24-36 hr) Symmetric distribution Resolution with signs (hypo/hyperpigmentation, bruising, or scarring) Associated different elementary lesions (papules, vesicles, purpura, scaling, crustae)

Pruritic (rarely stinging/burning) Possibly associated with angioedema No associated systemic symptoms	Not pruritic; rather painful or burning Usually no associated angioedema Often associated with systemic symptoms (fever, malaise, arthralgia, abdominal pain, weight loss, acral circulatory abnormalities, neurologic signs

From Peroni A, Colato C, Zanoni G, Girolomoni G: Urticarial lesions: if not urticaria, what else? The differential diagnosis of urticaria, *J Am Acad Dermatol* 62(4):559, 2009.

Physical Urticaria

Physically induced urticaria and angioedema share the common property of being induced by an environmental stimulus, such as a change in temperature or direct stimulation of the skin with pressure, stroking, vibration, or light (see Table 173.2).

Cold-Dependent Disorders

Cold urticaria is characterized by the development of localized pruritus, erythema, and urticaria/angioedema after exposure to a cold stimulus. Total body exposure, as seen with swimming in cold water, can cause massive release of vasoactive mediators, resulting in hypotension, loss of consciousness, and even death if not promptly treated. The diagnosis is confirmed by challenge testing for an *isomorphic cold reaction* by holding an ice cube in place on the patient's skin for 5 min. In patients with cold urticaria, an urticarial lesion develops about 10 min after removal of the ice cube and on rewarming of the chilled skin. Cold urticaria can be associated with the presence of **cryoproteins** such as cold agglutinins, cryoglobulins, cryofibrinogen, and the Donath-Landsteiner antibody seen in secondary syphilis (paroxysmal cold hemoglobinuria). In patients with cryoglobulins the isolated proteins appear to transfer cold sensitivity and activate the complement cascade on in vitro incubation with normal plasma. The term **idiopathic cold urticaria** generally applies to patients without abnormal circulating plasma proteins such as cryoglobulins. Cold urticaria has also been reported after viral infections. Cold urticaria must be distinguished from the **familial cold autoinflammatory syndrome** (see later, Diagnosis) (Table 173.5 ; see also Table 173.3 and Chapter 188).

Table 173.5

Hereditary Diseases With Cold-Induced Urticaria

		EPISODIC SYMPTOMS	SUSTAINED/PROGRESSIVE SYMPTOMS
CAPS	FCAS	Urticarial rash, arthralgia, myalgia, chills, fever, swelling of extremities	Renal amyloidosis
	MWS	Urticarial rash, arthralgia, chills, fever	Sensorineural deafness, renal amyloidosis
	CINCA	Fever	Rash, arthritis, chronic meningitis, visual defect, deafness, growth retardation, renal amyloidosis
NAPS12 (FCAS2)		Fever, arthralgia, myalgia, urticaria, abdominal pain, aphthous ulcers, lymphadenopathy	Sensorineural deafness
PLAID (FCAS3)		Urticaria induced by evaporative cooling, sinopulmonary infections	Serum low IgM and IgA levels; high IgE levels; decreased B and NK cells; granulomata; antinuclear antibodies

CAPS, Cryopyrin-associated periodic syndromes; FCAS, familial cold-induced autoinflammatory syndrome; MWS, Muckle-Wells syndrome; CINCA, chronic infantile neurologic cutaneous articular syndrome; NAPS, NLRP-12–associated periodic syndrome; PLAID, PLCG2-associated antibody deficiency and immune dysregulation.

From Kanazawa N: Hereditary disorders presenting with urticaria, *Immunol Allergy Clin NORTH Am* 34:169–179, 2014 (Table 4, p 176).

Cholinergic Urticaria

Cholinergic urticaria is characterized by the onset of small, punctate pruritic wheals surrounded by a prominent erythematous flare and associated with exercise, hot showers, and sweating. Once the patient cools down, the rash usually subsides in 30-60 min. Occasionally, symptoms of more generalized cholinergic stimulation, such as lacrimation, wheezing, salivation, and syncope, are observed. These symptoms are mediated by cholinergic nerve fibers that innervate the musculature via parasympathetic neurons and innervate the sweat glands by cholinergic fibers that travel with the sympathetic nerves. Elevated plasma histamine values parallel the onset of urticaria triggered by changes in body temperature.

Dermatographism

The ability to write on skin, dermatographism (also called *dermographism* or *urticaria factitia*) may occur as an isolated disorder or may accompany chronic urticaria or other physical urticaria. It can be diagnosed by observing the skin after stroking it with a tongue depressor. In patients with dermatographism, a linear response occurs secondary to reflex vasoconstriction, followed by pruritus, erythema, and a linear flare caused by secondary dilation of the vessel and extravasation of plasma.

Pressure-Induced Urticaria and Angioedema

Pressure-induced urticaria differs from most types of urticaria or angioedema in that symptoms typically occur 4-6 hr after pressure has been applied. The disorder is clinically heterogeneous. Some patients may complain of swelling, with or without pruritus, secondary to pressure, with normal-appearing skin (no urticaria), so the term *angioedema* is more appropriate. Other lesions are predominantly urticarial and may or may not be associated with significant swelling. When urticaria is present, an infiltrative skin lesion is seen, characterized by a perivascular mononuclear cell infiltrate and dermal edema similar to that seen in chronic idiopathic urticaria. Symptoms occur at sites of tight clothing; foot swelling is common after walking; and buttock swelling may be prominent after sitting for a few hours. This condition can coexist with chronic idiopathic urticaria or can occur separately. The diagnosis is confirmed by challenge testing in which pressure is applied perpendicular to the skin. This is often done with a sling attached to a 10 lb weight that is placed over the patient's arm for 20 min.

Solar Urticaria

Solar urticaria is a rare disorder in which urticaria develops within minutes of direct sun exposure. Typically, pruritus occurs first, in approximately 30 sec, followed by edema confined to the light-exposed area and surrounded by a prominent erythematous zone. The lesions usually disappear within 1-3 hr after cessation of sun exposure. When large areas of the body are exposed, systemic symptoms may occur, including hypotension and wheezing. Solar urticaria has been classified into 6 types, depending on the wavelength of light that induces skin lesions and the ability or inability to transfer the disorder passively with serum IgE. The rare inborn error of metabolism **erythropoietic protoporphyria** can be confused with solar urticaria because of the development of itching and burning of exposed skin immediately after sun exposure. In erythropoietic protoporphyria, fluorescence of ultraviolet-irradiated red blood cells can be demonstrated, and protoporphyrins are found in the urine.

Aquagenic Urticaria

Patients with aquagenic urticaria demonstrate small wheals after contact with water, regardless of its temperature, and are thereby distinguishable from patients with cold urticaria or cholinergic urticaria. Direct application of a compress of water to the skin is used to test for the presence of aquagenic urticaria. Rarely, chlorine or other trace contaminants may be responsible for the reaction.

Chronic Idiopathic Urticaria and Angioedema

A common disorder of unknown origin, chronic idiopathic urticaria and angioedema is often associated with normal routine laboratory values and no evidence of systemic disease. Chronic urticaria does not appear to result from an allergic reaction. It differs from allergen-induced skin reactions and from physically induced urticaria in that histologic studies reveal cellular infiltrate predominantly around small venules. Skin examination reveals infiltrative hives with palpably elevated borders, sometimes varying greatly in size and shape but generally being rounded.

Biopsy of a typical lesion reveals nonnecrotizing, perivascular, mononuclear cellular infiltration. Varying histopathologic processes can occur in the skin and manifest as urticaria. Patients with **hypocomplementemia** and **cutaneous vasculitis** can have urticaria and/or angioedema. Biopsy of these lesions in patients with urticaria, arthralgias, myalgias, and an elevated erythrocyte sedimentation rate (ESR) as manifestations of necrotizing venulitis can reveal fibrinoid necrosis with a predominantly neutrophilic infiltrate. However, the urticarial lesions may be clinically indistinguishable from those seen in the more typical, nonvasculitic cases.

Chronic urticaria is increasingly associated with the presence of antithyroid antibodies. Affected patients generally have antibodies to thyroglobulin or a microsomally derived antigen (peroxidase), even if they are euthyroid. The incidence of elevated thyroid antibodies in patients with chronic urticaria is approximately 12%, compared with 3–6% in the general population. Although some patients show clinical reduction of the urticaria with thyroid replacement therapy, others do not. The role of thyroid autoantibodies in chronic urticaria is uncertain; their presence may reflect a tendency of the patient to develop autoantibodies, but they may not play a direct role in chronic urticaria. Of patients with chronic urticaria, 35–40% have a positive **autologous serum skin test** result: If serum from these patients is intradermally injected into their skin, a significant wheal and flare reaction develops. Such patients frequently have a complement-activating IgG antibody directed against the α subunit of the IgE receptor that can cross-link the IgE receptor (α subunit) and degranulate mast cells and basophils. An additional 5–10% of patients with chronic urticaria have anti-IgE antibodies rather than an anti–IgE receptor antibody.

Diagnosis

The diagnosis of both acute and chronic urticaria is primarily clinical and requires that the physician be aware of the various forms of urticaria.

Urticaria is transient, pruritic, erythematous, raised wheals that may become tense and painful. The lesions may coalesce and form polymorphous, serpiginous, or annular lesions (Figs. 173.1 and 173.2). Individual lesions usually last 20 min to 3 hr and rarely more than 24 hr. The lesions often disappear, only to reappear at another site. **Angioedema** involves the deeper subcutaneous tissues in locations such as the eyelids, lips, tongue, genitals, dorsum of the hands or feet, or wall of the gastrointestinal (GI) tract.

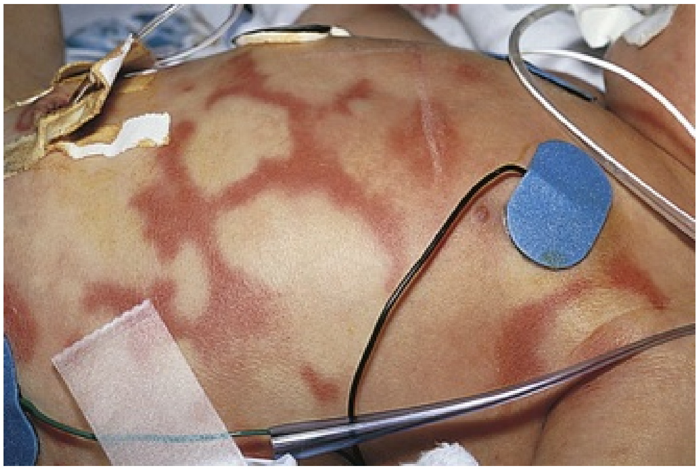

FIG. 173.1 Polycyclic lesions of urticaria associated with prostaglandin E_2 infusion. (From Eichenfield LF, Friedan IJ, Esterly NB: *Textbook of neonatal dermatology* , Philadelphia, 2001, WB Saunders, p. 300.)

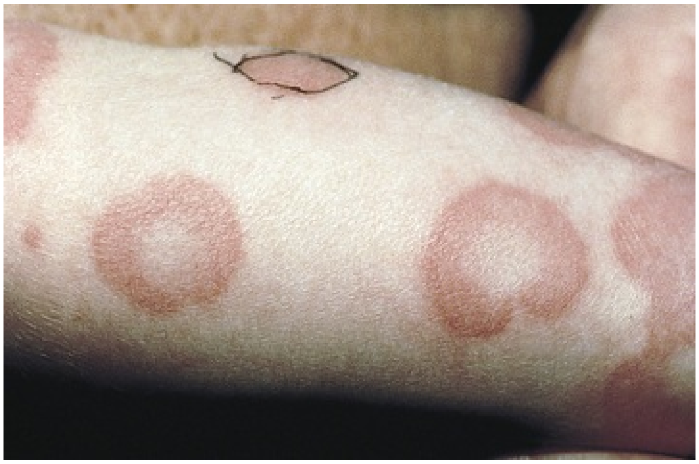

FIG. 173.2 Annular urticaria of unknown etiology. (From Eichenfield LF, Friedan IJ, Esterly NB: *Textbook of neonatal dermatology* , Philadelphia, 2001, WB Saunders, p. 301.)

Drugs and foods are the most common causes of acute urticaria. In children, viral infections also frequently trigger hives. Allergy skin testing for foods can be helpful in sorting out causes of acute urticaria, especially when supported by historical evidence. The role of an offending food can then be proved by elimination and careful challenge in a controlled setting, when needed. In the absence of information implicating an ingestant cause, skin testing for foods and implementation of elimination diets are generally not useful for either acute or chronic urticaria. Patients with delayed urticaria 3-6 hr after a meal consisting of mammalian meat should be evaluated for IgE to galactose-α-1,3-galactose (“alpha-gal”), a carbohydrate allergen. Alpha-gal has been identified as a trigger in this circumstance, with sensitization apparently linked to tick bites in specific geographic regions, such as the mid-Atlantic area of the United States. Skin testing for aeroallergens is not indicated unless there is a concern about contact urticaria (animal dander or grass pollen). Dermatographism is common in patients with urticaria and can complicate allergy skin testing by causing false-positive reactions, but this distinction is usually discernible.

Autoimmune diseases are rare causes of chronic urticarial or angioedema. In vitro testing for serum-derived activity that activates basophils involves detection of the expression of the surface marker CD63 or CD203c by donor basophils after incubation with patient serum. The clinical applicability and significance of these tests remains debated. The **differential diagnosis** of chronic urticaria includes cutaneous or systemic mastocytosis, complement-mediated mast cell degranulation as may occur with circulating immune complexes, malignancies, mixed connective tissue diseases, and cutaneous blistering disorders (e.g., bullous pemphigoid; see Table 173.2). In general, laboratory testing should be limited to a complete blood cell count with differential, ESR determination, urinalysis, thyroid autoantibody testing, and liver function tests. Further studies are warranted if the patient has fever, arthralgias, or elevated ESR (Table 173.6 ; see also Table 173.4). Testing for antibodies directed at the high-affinity IgE receptor may be warranted in patients with intractable urticaria. **Hereditary angioedema** is potentially life threatening, usually associated with deficient C1 inhibitor activity, and the most important familial form of angioedema (see Chapter 160.3), but it is not associated with typical urticaria. In patients with eosinophilia, stools should be obtained for ova and parasite testing, because infection with helminthic parasites has been associated with urticaria. A syndrome of episodic angioedema/urticaria and fever with associated **eosinophilia** has been described in both adults and children. In contrast to other hypereosinophilic syndromes, this entity has a benign course.

Table 173.6

Diagnostic Testing for Urticaria and Angioedema

DIAGNOSIS	DIAGNOSTIC TESTING
Food and drug reactions	Elimination of offending agent, skin testing, and challenge with suspected foods
Autoimmune urticaria	Autologous serum skin test; antithyroid antibodies; antibodies against the high-affinity IgE receptor
Thyroiditis	Thyroid-stimulating hormone; antithyroid antibodies
Infections	Appropriate cultures or serology
Collagen vascular diseases and cutaneous vasculitis	Skin biopsy, CH_{50} , C1q, C4, C3, factor B, immunofluorescence of tissues, antinuclear antibodies, cryoglobulins
Malignancy with angioedema	CH_{50} , C1q, C4, C1-INH determinations
Cold urticaria	Ice cube test usually positive but may be negative in some familial autoinflammatory disorders
Solar urticaria	Exposure to defined wavelengths of light, red blood cell protoporphyrin, fecal protoporphyrin, and coproporphyrin
Dermatographism	Stroking with narrow object (e.g., tongue blade, fingernail)
Pressure urticaria	Application of pressure for defined time and intensity
Vibratory urticaria	Vibration for 4 min
Aquagenic urticaria	Challenge with tap water at various temperatures
Urticaria pigmentosa	Skin biopsy, test for dermatographism
Hereditary angioedema	C4, C2, CH_{50} , C1-INH testing by protein and function
Familial cold urticaria	Challenge by cold exposure, measurement of temperature, white blood cell count, erythrocyte sedimentation rate, skin biopsy
C3b inactivator deficiency	C3, factor B, C3b inactivator determinations
Chronic idiopathic urticaria	Skin biopsy, immunofluorescence (negative result), autologous skin test

Skin biopsy for diagnosis of possible **urticarial vasculitis** is recommended for urticarial lesions that persist at the same location for >24 hr, those with pigmented or purpuric components, and those that burn more than itch. Collagen vascular diseases such as SLE may manifest urticarial vasculitis as a presenting feature. The skin biopsy in urticarial vasculitis typically shows endothelial cell swelling of postcapillary venules with necrosis of the vessel wall, perivenular neutrophil infiltrate, diapedesis of red blood cells, and fibrin deposition associated with deposition of immune complexes.

Mastocytosis is characterized by mast cell hyperplasia in the bone marrow, liver, spleen, lymph nodes, and skin. Clinical effects of mast cell activation are common, including pruritus, flushing, urtication, abdominal pain, nausea, and vomiting. The diagnosis is confirmed by a bone marrow biopsy showing increased numbers of spindle-shaped mast cells that express CD2 and CD25. **Urticaria pigmentosa** is the most common skin manifestation of mastocytosis and may occur as an isolated skin finding. It appears as small, yellow-tan to reddish brown macules or raised papules that urticate on scratching (**Darier sign**). This sign can be masked by antihistamines. The diagnosis is confirmed by a skin biopsy that shows increased numbers of dermal mast cells.

Physical urticaria should be considered in any patient with chronic urticaria and a suggestive history (see Table 173.2). Papular urticaria often occurs in small children, generally on the extremities. It manifests as grouped or linear, highly pruritic wheals or papules mainly on exposed skin at the sites of insect bites.

Exercise-induced anaphylaxis manifests as varying combinations of pruritus, urticaria, angioedema, wheezing, laryngeal obstruction, or hypotension after exercise (see Chapter 174). Cholinergic urticaria is differentiated by positive results of heat challenge tests and the rare occurrence of anaphylactic shock. The combination of ingestion of various food allergens and postprandial exercise has been associated with urticaria/angioedema and anaphylaxis. In patients with this combination disorder, food or exercise alone does not produce the reaction.

Muckle-Wells syndrome and familial cold autoinflammatory syndrome are rare, dominantly inherited conditions associated with recurrent urticaria-like lesions. **Muckle-Wells syndrome** is characterized by arthritis and joint pain that usually appears in adolescence. It is associated with progressive nerve deafness, recurrent fever, elevated ESR (see Tables 173.3 and 173.5), hypergammaglobulinemia, renal amyloidosis, and a poor prognosis. **Familial cold autoinflammatory syndrome** is characterized by a cold-induced rash that has urticarial features but is rarely pruritic. Cold exposure leads to additional symptoms such as conjunctivitis, sweating, headache, and nausea. Patient longevity is usually normal.

Treatment

Acute urticaria is a self-limited illness requiring little treatment other than antihistamines and avoidance of any identified trigger. Hydroxyzine and diphenhydramine are sedating but are effective and frequently used for treatment of urticaria. Loratadine, fexofenadine, and cetirizine are also effective and are preferable because of reduced frequency of drowsiness and longer duration of action (Table 173.7). Epinephrine 1 : 1,000, 0.01 mL/kg (maximum 0.3 mL) intramuscularly, usually provides rapid relief of acute, severe urticaria/angioedema but is seldom required. A short course of oral corticosteroids should be given only for severe episodes of urticaria and angioedema that are unresponsive to antihistamines.

Table 173.7

Treatment of Urticaria and Angioedema

CLASS/DRUG	DOSE	FREQUENCY
ANTIHISTAMINES, TYPE H_1 (SECOND GENERATION)		
Fexofenadine	6-11 yr: 30 mg	Twice daily
	>12 yr: 60 mg	
	Adult: 180 mg	Once daily
Loratadine	2-5 yr: 5 mg	Once daily
	>6 yr: 10 mg	
Desloratadine	6-11 mo: 1 mg 12 mo-5 yr: 1.25 mg	Once daily
	6-11 yr: 2.5 mg >12 yr: 5 mg	
Cetirizine	6-23 mo: 2.5 mg	Once daily
	2-6 yr: 2.5-5 mg	
	>6 yr: 5-10 mg	
Levocetirizine	6 mo-5 yr: 1.25 mg	Once daily
	6-11 yr: 2.5 mg	Once daily
	>12 yr: 5 mg	Once daily
ANTIHISTAMINES, TYPE H_2		
Cimetidine	Infants: 10-20 mg/kg/day	Divided q6-12h
	Children: 20-40 mg/kg/day	
Ranitidine	1 mo-16 yr: 5-10 mg/kg/day	Divided q12h
Famotidine	3-12 mo: 1 mg/kg/day	Divided q12h
	1-16 yr: 1-2 mg/kg/day	
LEUKOTRIENE PATHWAY MODIFIERS		

Montelukast	12 mo-5 yr: 4 mg	Once daily
	6-14 yr: 5 mg	
	>14 yr: 10 mg	
Zafirlukast	5-11 yr: 10 mg	Twice daily
IMMUNOMODULATORY DRUGS		
Omalizumab (anti IgE)	>11 yr: 150 mg or 300 mg	Every 28 days
Cyclosporine	3-4 mg/kg/day	Divided q12h[*]
Sulfasalazine	>6 yr: 30 mg/kg/day	Divided q6h [†]
Intravenous immune globulin (IVIG)	400 mg/kg/day	5 consecutive days

[*] Monitor blood pressure and serum creatinine, potassium, and magnesium levels monthly.

[†] Monitor complete blood count and liver function tests at baseline, every 2 wk for 3 mo, and then every 1-3 mo.

The best treatment of physical urticaria is avoidance of the stimulus. Antihistamines are also helpful. Cyproheptadine in divided doses is the drug of choice for cold-induced urticaria. Treatment of dermatographism consists of local skin care and antihistamines; for severe symptoms, high doses may be needed. The initial objective of therapy is to decrease pruritus so that the stimulation for scratching is diminished. A combination of antihistamines, sunscreens, and avoidance of sunlight is helpful for most patients.

Chronic urticaria only rarely responds favorably to dietary manipulation. The mainstay of therapy is the use of nonsedating or low-sedating H_1 antihistamines. In those patients not showing response to standard doses, pushing the H_1 blockade with higher than the usual recommended doses of these agents is a common next approach. The 3-drug combination of H_1 and H_2 antihistamine with a leukotriene receptor antagonist (montelukast) is helpful for many patients. If hives persist after maximal H_1 - and/or H_2 -receptor blockade has been achieved, a brief course of oral corticosteroids may be considered, but long-term steroid use is best avoided. The monoclonal antibody omalizumab (anti-IgE) is FDA approved for the treatment of chronic urticaria in children 12 years and older. Other agents that have been used for chronic urticaria but are not approved by the U.S. Food and Drug Administration (FDA) for this condition include cyclosporine, hydroxychloroquine, sulfasalazine, colchicine, dapsone, mycophenolate, intravenous immune globulin (IVIG), and plasmapheresis.

Hereditary Angioedema

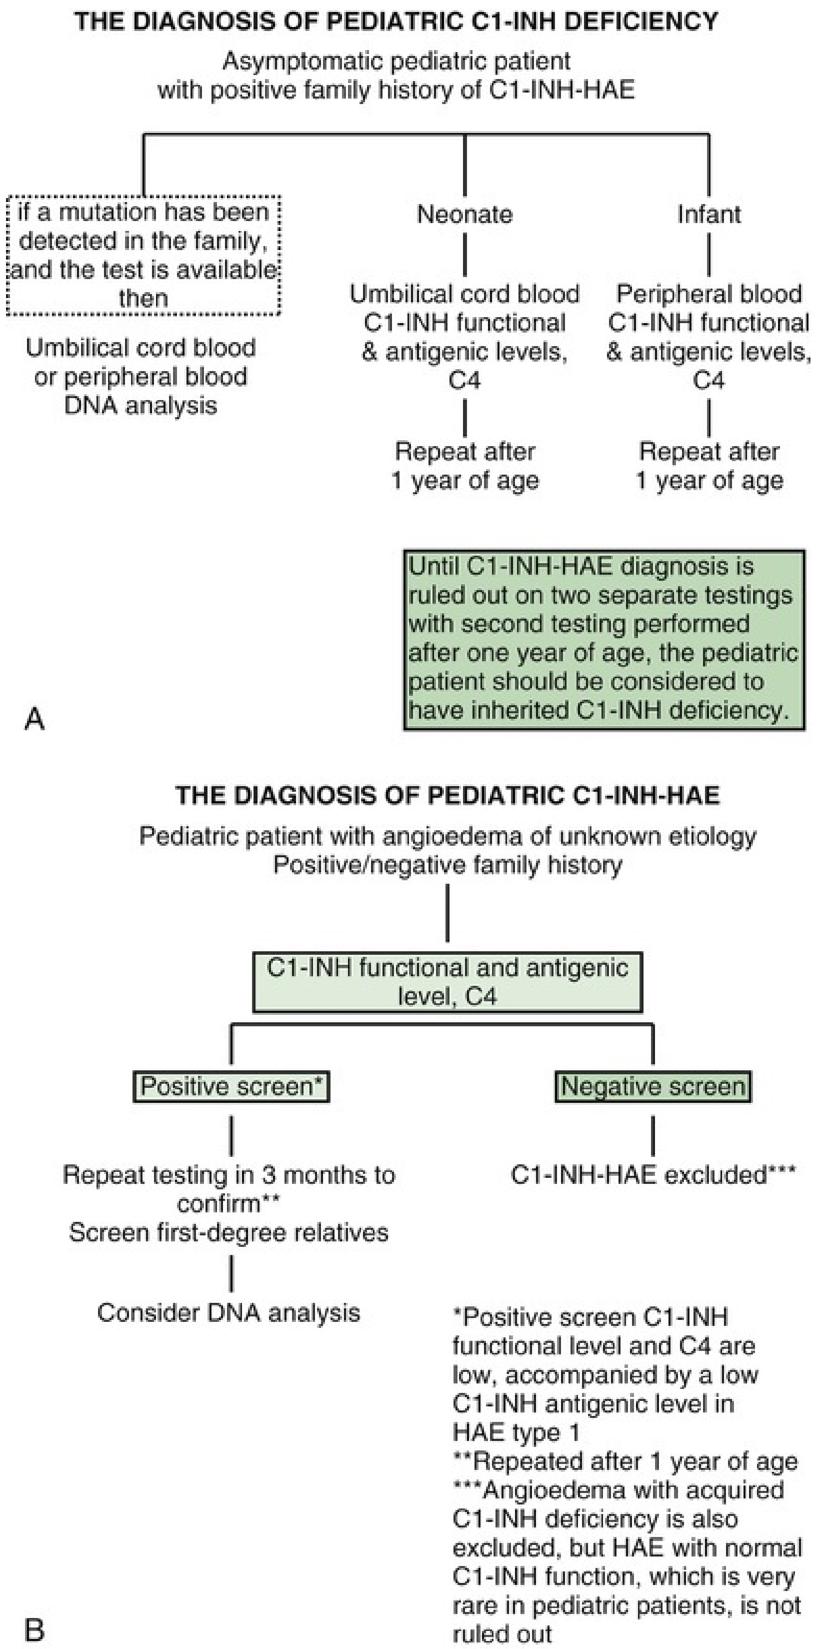
Hereditary angioedema (**HAE** , types 1 and 2) is an inherited autosomal dominant disease caused by low functional levels of the plasma protein **C1**

inhibitor (C1-INH) (see Chapter 160.3). Patients typically report episodic attacks of angioedema or deep localized swelling, most often on a hand or foot, that begin during childhood and become much more severe during adolescence. Cutaneous nonpitting and nonpruritic edema not associated with urticaria is the most common symptom. The swelling usually becomes more severe over about 1.5 days and then resolves over about the same period. However, the duration of attacks can be quite variable. In some patients, attacks are preceded by the development of a rash, **erythema marginatum** , that is erythematous, not raised, and not pruritic. A 2nd major symptom complex noted by patients is attacks of severe abdominal pain caused by edema of the mucosa of any portion of the GI tract. The intensity of the pain can approximate that of an acute abdomen, often resulting in unnecessary surgery. Either constipation or diarrhea during these attacks can be noted. The GI edema generally follows the same time course to resolution as the cutaneous attacks and often does not occur at the same time as the peripheral edema. Patients usually have a *prodrome*, a tightness or tingling in the area that will swell, usually lasting several hours, followed by the development of angioedema.

Laryngeal edema , the most feared complication of HAE, can cause complete respiratory obstruction. Although life-threatening attacks are infrequent, more than half of patients with HAE experience laryngeal involvement at some time during their lives. Dental work with the injection of procaine hydrochloride (Novocain) into the gums is a common precipitant, but laryngeal edema can be spontaneous. The clinical condition may deteriorate rapidly, progressing through mild discomfort to complete airway obstruction over hours. Soft tissue edema can be readily seen when the disease involves the throat and uvula. If this edema progresses to difficulty swallowing secretions or a change in the tone of the voice, the patient may require emergency intubation or even tracheostomy to ensure an adequate airway. Other presentations are less common. These patients typically do not respond well to treatment with epinephrine, antihistamines, or glucocorticoids.

In most cases the cause of the attack is unknown, but in some patients, trauma or emotional stress clearly precipitates attacks. Drugs such as angiotensin-converting enzyme (ACE) inhibitors that inhibit the degradation of bradykinin make the disease strikingly worse, and estrogens also make attacks more severe. In some females, menstruation also regularly induces attacks. The frequency of attacks varies greatly among affected individuals and at different times in the same individual. Some individuals experience weekly episodes, whereas others may go years between attacks. Episodes can start at any age.

C1-INH is a member of the serpin family of proteases, similar to α-antitrypsin, antithrombin III, and angiotensinogen. These proteins stoichiometrically inactivate their target proteases by forming stable, 1 : 1 complexes with the protein to be inhibited. Synthesized primarily by hepatocytes, C1-INH is also synthesized by monocytes. The regulation of the protein production is not completely understood, but it is believed that androgens may stimulate C1-INH synthesis, because patients with the disorder respond clinically to androgen therapy with elevated serum C1-INH levels. C1-INH deficiency is an autosomal dominant disease, with as many as 25% of patients giving no family history. Because all C1-INH–deficient patients are heterozygous for this gene defect, it is believed that half the normal level of C1-INH is not sufficient to prevent attacks. Fig. 173.3 shows the diagnostic approach.



THE DIAGNOSIS OF PEDIATRIC C1-INH DEFICIENCY
Asymptomatic pediatric patient with positive family history of C1-INH-HAE
if a mutation has been detected in the family, and the test is available then
Umbilical cord blood or peripheral blood DNA analysis
Neonate
Umbilical cord blood C1-INH functional & antigenic levels, C4
Repeat after 1 year of age
Infant
Peripheral blood C1-INH functional & antigenic levels, C4
Repeat after 1 year of age
Until C1-INH-HAE diagnosis is ruled out on two separate testings with second testing performed after one year of age, the pediatric patient should be considered to have inherited C1-INH deficiency.
A
THE DIAGNOSIS OF PEDIATRIC C1-INH-HAE
Pediatric patient with angioedema of unknown etiology Positive/negative family history
C1-INH functional and antigenic level, C4
Positive screen*
Repeat testing in 3 months to confirm**
Screen first-degree relatives
Consider DNA analysis
Negative screen
C1-INH-HAE excluded***
*Positive screen C1-INH functional level and C4 are low, accompanied by a low C1-INH antigenic level in HAE type 1
**Repeated after 1 year of age
***Angioedema with acquired C1-INH deficiency is also excluded, but HAE with normal C1-INH function, which is very rare in pediatric patients, is not ruled out
B

FIG. 173.3 **A,** Diagnosis of C1-INH deficiency in families with known C1-INH-HAE. **B,** Diagnosis of C1-INH-HAE in pediatric patients with

angioedema of unknown etiology. (From Farkas H, Martinez-Saguer I, Bork K, et al: International consensus on the diagnosis and management of pediatric patients with hereditary angioedema with C1 inhibitor deficiency. Eur J Allergy Clin Immunol 72:300-313, 2017, Fig.1, p. 304.)

Although named for its action on the 1st component of complement (C1 esterase), C1-INH also inhibits components of the fibrinolytic, clotting, and kinin pathways. Specifically, C1-INH inactivates plasmin-activated Hageman factor (factor XII), activated factor XI, plasma thromboplastin antecedent, and kallikrein. Within the complement system, C1-INH blocks the activation of C1 and the rest of the classical complement pathway by binding to C1r and C1s. Without adequate C1-INH, unchecked activation of C1 causes cleavage of C4 and C2, the proteins following in the complement cascade. Levels of C3 are normal. C1-INH also inhibits serine proteases associated with activation of the lectin activation pathway. The major factor responsible for the edema formation is bradykinin, an important nonapeptide mediator that can induce leakage of postcapillary venules. Bradykinin is derived from cleavage of the circulating protein high-molecular-weight kininogen by the plasma enzyme kallikrein.

Two major genetic types of C1-INH deficiency are described that result in essentially the same phenotypic expression. The C1-INH gene is located on chromosome 11 in the p11-q13 region. The inheritance is autosomal dominant with incomplete penetrance. Persons inheriting the abnormal gene can have a clinical spectrum ranging from asymptomatic to severely affected. **Type 1** HAE is the most common form, accounting for approximately 85% of cases. Synthesis of C1-INH is blocked at the site of the faulty allele, or the protein is not secreted normally because of faulty protein processing, but secretion occurs at the normal allele. The result is secretion of the normal protein, yielding quantitative serum concentrations of C1-INH approximately 20–40% of normal. **Type 2** HAE accounts for approximately 15% of cases. Mutations of 1 of the amino acids near the active site of the inhibitor lead to synthesis of nonfunctional C1-INH protein and again less than half of the normal functioning protein. Patients with type 2 HAE have either normal or increased concentrations of the protein but low values in assays of C1-INH function.

A clinical syndrome resembling HAE termed **HAE with normal C1-INH** has been described that affects mostly women, with a tendency to cause fewer abdominal attacks and more upper airway attacks. In this condition, no abnormalities of complement or of C1-INH have been described. Approximately 20% of affected patients have been found to have a gain-of-function abnormality of clotting factor XII, but the fundamental cause is of this syndrome still unknown.

The FDA has approved purified C1-INH for prophylaxis to prevent attacks. **Androgens** like the gonadotropin inhibitor danazol were previously used to prevent attacks. Weak androgens have many side effects that preclude their use in some patients. Their use in children is problematic because of the possibility of premature closure of the epiphyses, and these agents are not used in pregnant women. The fibrinolysis inhibitor ε-aminocaproic acid (**EACA**) is also effective in preventing attacks and has been used in children, but its use is attended by the development of severe fatigue and muscle weakness over time. A cyclized analog of EACA, **tranexamic acid** , has been used extensively in Europe; because of limited availability, it has been used less extensively in the United States. Tranexamic acid is believed to be more effective than EACA and has lower toxicity, but there have been few direct studies. Its mechanism of action is not clearly defined, and not all patients respond to this agent.

In 2008 the FDA approved, for adolescents and older patients, the use of purified C1-INH (Cinryze), prepared from human plasma and given intravenously, for *prophylaxis* of this disease. The half-life of this plasma protein is relatively short, about 40 hr, and the approved regimen is 1,000 units twice a week. In 2009 a similar purified C1-inhibitor product, Berinert, administered as 20 U/kg intravenously, was approved for the *treatment* of acute attacks. A recombinant C1-INH product has been FDA approved for *treatment* of acute attacks (and in Europe). In 2009 the FDA approved a kallikrein inhibitor, **ecallantide** , given subcutaneously, for *acute treatment* in patients age 16 yr and older. This 60–amino acid peptide causes anaphylaxis rarely and is approved only for administration by medical personnel. In 2010 a bradykinin type 2 receptor antagonist, **icatibant** , was approved for *acute treatment* in patients age 18 yr and older and in summer 2016 was approved for the treatment of all children. All treatments are most effective when given early in an attack and begin to have noticeable effect about 1-4 hr after treatment.

CHAPTER 174

Anaphylaxis

Hugh A. Sampson, Julie Wang, Scott H. Sicherer

Anaphylaxis is defined as a serious allergic reaction that is rapid in onset and may cause death. Anaphylaxis in children, particularly infants, is underdiagnosed. Anaphylaxis occurs when there is a sudden release of potent, biologically active mediators from mast cells and basophils, leading to cutaneous (urticaria, angioedema, flushing), respiratory (bronchospasm, laryngeal edema), cardiovascular (hypotension, dysrhythmias, myocardial ischemia), and gastrointestinal (nausea, colicky abdominal pain, vomiting, diarrhea) symptoms (Table 174.1 and Fig. 174.1).

Table 174.1

Symptoms and Signs of Anaphylaxis in Infants

ANAPHYLAXIS SYMPTOMS THAT INFANTS CANNOT DESCRIBE	ANAPHYLAXIS SIGNS THAT MAY BE DIFFICULT TO INTERPRET/UNHELPFUL IN INFANTS, AND WHY	ANAPHYLAXIS SIGNS IN INFANTS
GENERAL		
Feeling of warmth, weakness, anxiety, apprehension, impending doom	Nonspecific behavioral changes such as persistent crying, fussing, irritability, fright, suddenly becoming quiet	
SKIN/MUCOUS MEMBRANES		
Itching of lips, tongue, palate, uvula, ears, throat, nose, eyes, etc.; mouth-tingling or metallic taste	Flushing (may also occur with fever, hyperthermia, or crying spells)	Rapid onset of hives (potentially difficult to discern in infants with acute atopic dermatitis; scratching and excoriations will be absent in young infants); angioedema (face, tongue, oropharynx)
RESPIRATORY SYSTEM		

Nasal congestion, throat tightness; chest tightness; shortness of breath	Hoarseness, dysphonia (common after a crying spell); drooling or increased secretions (common in infants)	Rapid onset of coughing, choking, stridor, wheezing, dyspnea, apnea, cyanosis
GASTROINTESTINAL SYSTEM		
Dysphagia, nausea, abdominal pain/cramping	Spitting up/regurgitation (common after feeds), loose stools (normal in infants, especially if breastfed); colicky abdominal pain	Sudden, profuse vomiting
CARDIOVASCULAR SYSTEM		
Feeling faint, presyncope, dizziness, confusion, blurred vision, difficulty in hearing	Hypotension (need appropriate-size blood pressure cuff; low systolic blood pressure for children is defined as <70 mm Hg from 1 mo to 1 yr, and less than (70 mm Hg + [2 × age in yr]) from 1-10 yr; tachycardia, defined as >140 beats/min from 3 mo to 2 yr, inclusive; loss of bowel and bladder control (ubiquitous in infants)	Weak pulse, arrhythmia, diaphoresis/sweating, collapse/unconsciousness
CENTRAL NERVOUS SYSTEM		
Headache	Drowsiness, somnolence (common in infants after feeds)	Rapid onset of unresponsiveness, lethargy, or hypotonia; seizures

FIG. 174.1 **Summary of the pathogenesis of anaphylaxis. See text for details about mechanisms, triggers, key cells, and mediators. Two or more target organ systems are typically involved in anaphylaxis. CNS, Central nervous system; CVS, cardiovascular system; GI, gastrointestinal; PAF, platelet-activating factor. (From Leung DYM, Szefler SJ, Bonilla FA Akdis CA, Sampson HA, editors: *Pediatric allergy principles and practice,* ed 3, Philadelphia, 2016, Elsevier, p 525.)**

Etiology

The most common causes of anaphylaxis in children are different for hospital and community settings. Anaphylaxis occurring in the hospital results primarily from allergic reactions to medications and latex. **Food allergy** is the most common cause of anaphylaxis occurring outside the hospital, accounting for about half the anaphylactic reactions reported in pediatric surveys from the United States, Italy, and South Australia (Table 174.2). **Peanut allergy** is an important cause of food-induced anaphylaxis, accounting for the majority of fatal and near-fatal reactions. In the hospital, latex is a particular problem for children undergoing multiple operations, such as patients with spina bifida and urologic disorders, and has prompted many hospitals to switch to latex-free products. Patients with **latex allergy** may also experience food-allergic reactions from homologous proteins in foods such as bananas, kiwi, avocado, chestnut, and passion fruit. Anaphylaxis to galactose-α-1,3-galactose has been reported 3-6 hr after eating red meat.

Table 174.2

Anaphylaxis Triggers in the Community*

Allergen Triggers (IgE-Dependent Immunologic Mechanism)*

Foods (e.g., peanut, tree nuts, shellfish, fish, milk, egg, wheat, soy, sesame, meat [galactose-α-1,3-galactose])
Food additives (e.g., spices, colorants, vegetable gums, contaminants)
Stinging insects: Hymenoptera species (e.g., bees, yellow jackets, wasps, hornets, fire ants)
Medications (e.g., β-lactam antibiotics, ibuprofen)
Biologic agents (e.g., monoclonal antibodies [infliximab, omalizumab] and allergens [challenge tests, specific immunotherapy])
Natural rubber latex
Vaccines
Inhalants (rare) (e.g., horse or hamster dander, grass pollen)
Previously unrecognized allergens (foods, venoms, biting insect saliva, medications, biologic agents)

Other Immune Mechanisms (IgE Independent)

IgG mediated (infliximab, high-molecular-weight dextrans)
Immune aggregates (IVIG)
Drugs (aspirin, NSAID, opiates, contrast material, ethylene oxide/dialysis tubing)
Complement activation
Physical factors (e.g., exercise, [†] cold, heat, sunlight/ultraviolet radiation)
Ethanol
Idiopathic*

IVIG, Intravenous immune globulin; NSAID, nonsteroidal antiinflammatory drug.

[*] In the pediatric population, some anaphylaxis triggers, such as hormones (progesterone), seminal fluid, and occupational allergens, are uncommon, as is idiopathic anaphylaxis.

[†] Exercise with or without a co-trigger, such as a food or medication, cold air, or cold water.

Adapted from Leung DYM, Sampson HA, Geha RS, et al: *Pediatric allergy principles and practice* , Philadelphia, 2010, Elsevier, p 652.

Epidemiology

The overall annual incidence of anaphylaxis in the United States is estimated at 42 cases per 100,000 person-years, totaling >150,000 cases/yr. Food allergens are the most common trigger in children, with an incidence rate of approximately 20 per 100,000 person-years. An Australian parental survey found that 0.59% of children 3-17 yr of age had experienced at least 1 anaphylactic event. Having asthma and the severity of asthma are important anaphylaxis risk factors (Table 174.3). In addition, patients with systemic mastocytosis or monoclonal mast cell–activating syndrome are at increased risk for anaphylaxis, as are patients with an elevated baseline serum tryptase level.

Table 174.3

Patient Risk Factors for Anaphylaxis

Age-Related Factors

- Infants: anaphylaxis can be difficult to recognize, especially if the first episode; patients cannot describe symptoms.
- Adolescents and young adults: increased risk-taking behaviors, such as failure to avoid known triggers and to carry an epinephrine autoinjector consistently
- Pregnancy: risk of iatrogenic anaphylaxis, as from β lactam antibiotics to prevent neonatal group B streptococcal infection, agents used perioperatively during caesarean sections, and natural rubber latex
- Older people: increased risk of death because of concomitant disease and drugs

Concomitant Diseases

Asthma and other chronic respiratory diseases
Cardiovascular diseases
Systemic mastocytosis or monoclonal mast cell–activating syndrome
Allergic rhinitis and eczema*
Depression, cognitive dysfunction, substance misuse

Drugs

β-Adrenergic blockers †
Angiotensin-converting enzyme (ACE) inhibitors †
Sedatives, antidepressants, narcotics, recreational drugs, and alcohol may decrease the patient's ability to recognize triggers and symptoms.

Factors That May Increase Risk for Anaphylaxis or Make It More Difficult to Treat

Age
Asthma
Atopy
Drugs
Alcohol
Other cofactors such as exercise, infection, menses

---

* Atopic diseases are a risk factor for anaphylaxis triggered by food, latex, and exercise, but not for anaphylaxis triggered by most drugs or by insect stings.

† Patients taking β-blockers or ACE inhibitors seem to be at increased risk for severe anaphylaxis. In addition, those taking β-blockers may not respond optimally to epinephrine treatment and may need glucagon, a polypeptide with non–catecholamine-dependent inotropic and chronotropic cardiac effects, atropine for persistent bradycardia, or ipratropium for persistent bronchospasm.

Adapted from Lieberman P, Nicklas RA, Randolph C, et al: Anaphylaxis—a practice parameter update 2015, *Ann Allergy Asthma Immunol* 115(5):341–384, 2015, Table I-9.

Pathogenesis

Principal pathologic features in fatal anaphylaxis include acute bronchial obstruction with pulmonary hyperinflation, pulmonary edema, intraalveolar hemorrhaging, visceral congestion, laryngeal edema, and urticaria and angioedema. Acute hypotension is attributed to vasomotor dilation and cardiac dysrhythmias.

Most cases of anaphylaxis are believed to be the result of activation of mast cells and basophils via cell-bound allergen-specific IgE molecules (see Fig. 174.1). Patients initially must be exposed to the responsible allergen to generate allergen-specific antibodies. In many cases the child and the parent are unaware of the initial exposure, which may be from passage of food proteins in maternal breast milk or exposure to inflamed skin (e.g., eczematous lesions). When the child is reexposed to the sensitizing allergen, mast cells and basophils, and possibly other cells such as macrophages, release a variety of mediators (histamine, tryptase) and cytokines that can produce allergic symptoms in any or all target organs. Clinical anaphylaxis may also be caused by mechanisms other than IgE-mediated reactions, including direct release of mediators from mast cells by medications and physical factors (morphine, exercise, cold), disturbances of leukotriene metabolism (aspirin and nonsteroidal antiinflammatory drugs), immune aggregates and complement activation (blood products), probable complement activation (radiocontrast dyes, dialysis membranes), and IgG-mediated reactions (high-molecular-weight dextran, chimeric or humanized monoclonal antibodies) (see Table 174.2).

Idiopathic anaphylaxis is a diagnosis of exclusion when no inciting agent is identified and other disorders have been excluded (see Chapter 678.1). Symptoms are similar to IgE mediated causes of anaphylaxis; episodes often recur.

Clinical Manifestations

The onset of symptoms may vary depending on the cause of the reaction.

Reactions from ingested allergens (foods, medications) are delayed in onset (minutes to 2 hr) compared with those from injected allergens (insect sting, medications) and tend to have more gastrointestinal (GI) symptoms. Initial symptoms may include any of the following constellation of symptoms: pruritus about the mouth and face; flushing, urticaria and angioedema, oral or cutaneous pruritus; a sensation of warmth, weakness, and apprehension (sense of doom); tightness in the throat, dry staccato cough and hoarseness, periocular pruritus, nasal congestion, sneezing, dyspnea, deep cough and wheezing; nausea, abdominal cramping, and vomiting, especially with ingested allergens; uterine contractions (manifesting as lower back pain); and faintness and loss of consciousness in severe cases. Some degree of obstructive laryngeal edema is typically encountered with severe reactions. Cutaneous symptoms may be absent in up to 10% of cases, and the *acute* onset of severe bronchospasm in a previously well person with asthma should suggest the diagnosis of anaphylaxis. Sudden collapse in the absence of cutaneous symptoms should also raise suspicion of vasovagal collapse, myocardial infarction, aspiration, pulmonary embolism, or seizure disorder. Laryngeal edema, especially with abdominal pain, may also be a result of hereditary angioedema (see Chapter 173). Symptoms in infants may not be easy to identify (see Table 174.1).

Laboratory Findings

Laboratory studies may indicate the presence of IgE antibodies to a suspected causative agent, but this result is not definitive. Plasma histamine is elevated for a brief period but is unstable and difficult to measure in a clinical setting. **Plasma tryptase** is more stable and remains elevated for several hours but often is not elevated, especially in food-induced anaphylactic reactions.

Diagnosis

A National Institutes of Health (NIH)–sponsored expert panel has recommended an approach to the diagnosis of anaphylaxis (Table 174.4). The differential diagnosis includes other forms of shock (hemorrhagic, cardiogenic, septic); vasopressor reactions, including flushing syndromes (e.g., carcinoid syndrome); ingestion of monosodium glutamate; scombroidosis; and hereditary angioedema. In addition, panic attack, vocal cord dysfunction, pheochromocytoma, and red man syndrome (caused by vancomycin) should be considered.

Table 174.4

Diagnosis of Anaphylaxis

Anaphylaxis is **highly likely** when *any 1 of the following 3 criteria* is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin and/or mucosal tissue (e.g., *generalized* hives, pruritus or flushing, swollen lips/tongue/uvula)
   AND *at least 1 of the following* :
    a. Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced peak PEF, hypoxemia)
    b. Reduced BP or associated symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
2. *Two or more of the following* that occur rapidly after exposure **to a likely allergen for that patient** (minutes to several hours):
    a. Involvement of the skin/mucosal tissue (e.g., *generalized* hives, itch/flush, swollen lips/tongue/uvula)
    b. Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced PEF, hypoxemia)
    c. Reduced BP or associated symptoms (e.g., hypotonia [collapse], syncope, incontinence)
    d. **Persistent** gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced BP following exposure to **known allergen for that patient** (minutes to several hours):
    a. Infants and children: low systolic BP (age specific) or >30% drop in systolic BP
    b. Adults: systolic BP <90 mm Hg or >30% drop from patient's baseline

BP, Blood pressure; PEF, peak expiratory flow.

Adapted from Sampson HA, Muñoz-Furlong A, Campbell RL, et al: Second Symposium on the Definition and Management of Anaphylaxis: summary report, Second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network Symposium, *J Allergy Clin Immunol* 117:391–397, 2006.

Treatment

Anaphylaxis is a medical emergency requiring aggressive management with intramuscular (IM, first line) or intravenous (IV) epinephrine, IM or IV H_1 and H_2 antihistamine antagonists, oxygen, IV fluids, inhaled β-agonists, and corticosteroids (Table 174.5 and Fig. 174.2). The initial assessment should ensure an adequate airway with effective respiration, circulation, and perfusion. **Epinephrine** is the most important medication, and there should be no delay in its administration. Epinephrine should be given by the IM route to the lateral thigh (1 : 1000 dilution, 0.01 mg/kg; maximum 0.5 mg). For children ≥12 yr, many recommend the 0.5 mg IM dose. The IM dose can be repeated at intervals of 5-15 min if symptoms persist or worsen. If there is no response to multiple doses of epinephrine, IV epinephrine using the 1 : 10,000 dilution may be needed. If IV access is not readily available, epinephrine can be administered via the endotracheal or intraosseous routes.

Table 174.5

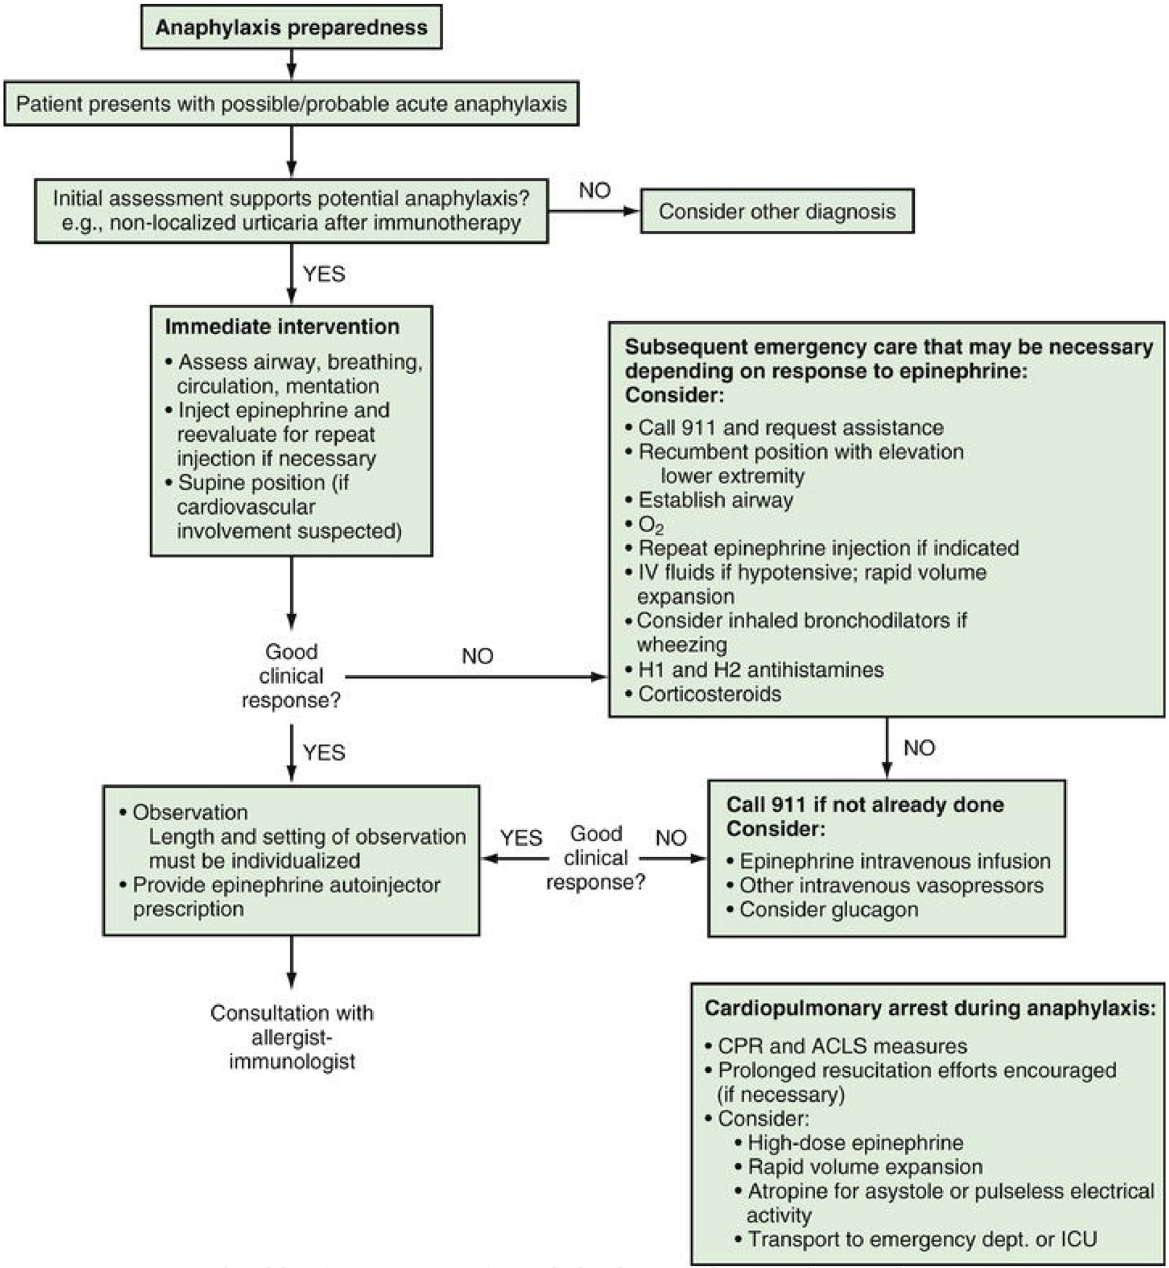
Management of a Patient With Anaphylaxis

TREATMENT	MECHANISM(S) OF EFFECT	DOSAGE(S)	COMMENTS; ADVERSE REACTIONS
PATIENT EMERGENCY MANAGEMENT (dependent on severity of symptoms)			
Epinephrine (adrenaline)	α_1-, β_1-, β_2-Adrenergic effects	0.01 mg/kg, up to 0.5 mg IM in lateral thigh Adrenaclick, Auvi-Q, EpiPen Jr/EpiPen: 0.15 mg IM for 8-25 kg 0.3 mg IM for 25 kg or more Epinephrine autoinjector: 0.1 mg for 7.5-15	Tachycardia, hypertension, nervousness, headache, nausea, irritability, tremor

		kg 0.15 mg for 15 to 25 kg 0.3 mg for 25 kg or more	
Cetirizine (liquid)	Antihistamine (competitive of H_1 receptor)	Cetirizine liquid: 5 mg/5 mL 0.25 mg/kg, up to 10 mg PO	Hypotension, tachycardia, somnolence
Alternative: Diphenhydramine	Antihistamine (competitive of H_1 receptor)	1.25 mg/kg up to 50 mg PO or IM	Hypotension, tachycardia, somnolence, paradoxical excitement
Transport to an emergency facility			
EMERGENCY PERSONNEL MANAGEMENT (dependent on severity of symptoms)			
Epinephrine (adrenaline)	α_1 -, β_1 -, β_2 - Adrenergic effects	0.01 mg/kg, up to 0.5 mg IM in lateral thigh Epinephrine autoinjector: 0.1 mg for 7.5-15 kg 0.15 mg for 15 to 25 kg 0.3 mg for 25 kg or more 0.01 mL/kg/dose of 1 : 1,000 (vial) solution, up to 0.5 mL IM May repeat every 10-15 min For severe hypotension: 0.01 mL/kg/dose of 1 : 10,000 slow IV push	Tachycardia, hypertension, nervousness, headache, nausea, irritability, tremor
Supplemental oxygen and airway management			
Volume Expanders			
Crystalloids (normal saline or Ringer lactate)		30 mL/kg in 1st hr	Rate titrated against BP response If tolerated, place patient supine with legs raised.
Colloids (hydroxyethyl starch)		10 mL/kg rapidly followed by slow infusion	Rate titrated against BP response If tolerated, place patient supine with legs raised.
Antihistamines			
Cetirizine (liquid)	Antihistamine (competitive of H_1 receptor)	Cetirizine liquid: 5 mg/5 mL 0.25 mg/kg, up to 10 mg PO	Hypotension, tachycardia, somnolence
Alternative: Diphenhydramine	Antihistamine (competitive of H_1 receptor)	1.25 mg/kg, up to 50 mg PO, IM, or IV	Hypotension, tachycardia, somnolence, paradoxical excitement
Ranitidine	Antihistamine (competitive of H_2	1 mg/kg, up to 50 mg IV	Headache, mental confusion

	receptor)	Should be administered slowly	
Alternative: Cimetidine	Antihistamine (competitive of H_2 receptor)	4 mg/kg, up to 200 mg IV Should be administered slowly	Headache, mental confusion
Corticosteroids			
Methylprednisolone	Antiinflammatory	Solu-Medrol (IV): 1-2 mg/kg, up to 125 mg IV Depo-Medrol (IM): 1 mg/kg, up to 80 mg IM	Hypertension, edema, nervousness, agitation
Prednisone	Antiinflammatory	1 mg/kg up, to 75 mg PO	Hypertension, edema, nervousness, agitation
Nebulized albuterol	β-Agonist	0.83 mg/mL (3 mL) via mask with O_2	Palpitations, nervousness, CNS stimulation, tachycardia; use to supplement epinephrine when bronchospasm appears unresponsive; may repeat
POSTEMERGENCY MANAGEMENT			
Antihistamine		Cetirizine (5-10 mg qd) or loratadine (5-10 mg qd) for 3 days	
Corticosteroids		*Optional:* Oral prednisone (1 mg/kg up to 75 mg) daily for 3 days	
Preventive Treatment Prescription for epinephrine autoinjector and antihistamine Provide written plan outlining patient emergency management (may download form from http://www.aap.org or http://www.foodallergy.org) Follow-up evaluation to determine/confirm etiology Immunotherapy for insect sting allergy			
Patient Education Instruction on avoidance of causative agent Information on recognizing early signs of anaphylaxis Stress early treatment of allergic symptoms to avoid systemic anaphylaxis Encourage wearing medical identification jewelry			

BP, Blood pressure; CNS, central nervous system; IM, Intramuscularly; IV, intravenously; PO, orally; qd, every day.



Anaphylaxis preparedness
Patient presents with possible/probable acute anaphylaxis
Initial assessment supports potential anaphylaxis? e.g., non-localized urticaria after immunotherapy
NO
Consider other diagnosis
YES
Immediate intervention
• Assess airway, breathing, circulation, mentation
• Inject epinephrine and reevaluate for repeat injection if necessary
• Supine position (if cardiovascular involvement suspected)
Good clinical response?
NO
Subsequent emergency care that may be necessary depending on response to epinephrine: Consider:
• Call 911 and request assistance
• Recumbent position with elevation lower extremity
• Establish airway
• O2
• Repeat epinephrine injection if indicated
• IV fluids if hypotensive; rapid volume expansion
• Consider inhaled bronchodilators if wheezing
• H1 and H2 antihistamines
• Corticosteroids
YES
NO
• Observation Length and setting of observation must be individualized
• Provide epinephrine autoinjector prescription
YES
Good clinical response?
NO
Call 911 if not already done Consider:
• Epinephrine intravenous infusion
• Other intravenous vasopressors
• Consider glucagon
Consultation with allergist-immunologist
Cardiopulmonary arrest during anaphylaxis:
• CPR and ACLS measures
• Prolonged resuscitation efforts encouraged (if necessary)
• Consider:
• High-dose epinephrine
• Rapid volume expansion
• Atropine for asystole or pulseless electrical activity
• Transport to emergency dept. or ICU

FIG. 174.2 **Algorithm for treatment of anaphylactic event in outpatient setting. ACLS, Advance cardiac life support; CPR, cardiopulmonary resuscitation; ICU, intensive care unit; IV, intravenous. (From Lieberman P, Nicklas RA, Oppenheimer J, et al: The diagnosis and management of anaphylaxis practice parameter: 2010 update, *J Allergy Clin Immunol* 126:477–480 e471–442, 2010.)**

For refractory hypotension, other vasopressors may be used as alternative agents to epinephrine. Anaphylaxis refractory to repeated doses of epinephrine in a patient receiving β-adrenergic blockers has anecdotally been treated with glucagon. The patient should be placed in a supine position when there is concern for hemodynamic compromise. Fluids are also important in patients with shock. Other drugs (antihistamines, glucocorticosteroids) have a secondary role in the management of anaphylaxis.

Patients may experience **biphasic anaphylaxis** , which occurs when anaphylactic symptoms recur after apparent resolution. The mechanism of this phenomenon is unknown, but it appears to be more common when therapy is initiated late and symptoms at presentation are more severe. It does not appear to be affected by the administration of corticosteroids during the initial therapy. More than 90% of biphasic responses occur within 4 hr, so patients should be observed for at least 4 hr before being discharged from the emergency department. Referrals should be made to appropriate specialists for further evaluation and follow-up.

Prevention

For patients experiencing anaphylactic reactions, the triggering agent should be avoided, and education regarding early recognition of anaphylactic symptoms and administration of emergency medications should be provided. Patients with food allergies must be educated in allergen avoidance, including active reading of food ingredient labels and knowledge of potential contamination and high-risk situations. Any child with food allergy and a history of asthma, peanut, tree nut, fish, or shellfish allergy or a previous systemic reaction should be given an epinephrine autoinjector. The expert panel also indicates that epinephrine autoinjectors should be considered for any patient with IgE-mediated food allergy. In addition, liquid cetirizine (or alternatively, diphenhydramine) and a written emergency plan should also be provided in case of accidental ingestion or allergic reaction. A form can be downloaded from the American Academy of Pediatrics (www.aap.org) or Food Allergy Research & Education (www.foodallergy.org).

In cases of food-associated exercise-induced anaphylaxis, children must not exercise within 2-3 hr of ingesting the triggering food and, as in children with exercise-induced anaphylaxis, should exercise with a friend, learn to recognize the early signs of anaphylaxis (sensation of warmth, facial pruritus), stop exercising, and seek help immediately if symptoms develop. Children experiencing a systemic anaphylactic reaction, including respiratory symptoms, to an insect sting should be evaluated and treated with immunotherapy, which is >90% protective. Reactions to medications can be reduced and minimized by using oral medications instead of injected forms and avoiding cross-reacting medications. Low-osmolarity radiocontrast dyes and pretreatment can be used in patients with suspected reactions to previous radiocontrast dye. Nonlatex gloves and materials should be used in children undergoing multiple operations.

Any child at risk for anaphylaxis should receive emergency medications (including epinephrine autoinjector), education on identification of signs and symptoms of anaphylaxis and proper administration of medications (Table 174.6), and a written emergency plan in case of accidental exposure. They should be encouraged to wear medical identification jewelry.

Table 174.6

Considerations With Epinephrine Injection for Anaphylaxis

Why Healthcare Professionals Fail to Inject Epinephrine Promptly

- Lack of recognition of anaphylaxis symptoms; failure to diagnose anaphylaxis
- Episode appears mild, or there is a history of previous mild episode(s)*
- Inappropriate concern about transient mild pharmacologic effects of epinephrine (e.g., tremor)
- Lack of awareness that serious adverse effects are almost always attributable to epinephrine overdose or IV administration, especially IV bolus, rapid IV infusion, or IV infusion of a 1 : 1,000 epinephrine solution instead of an appropriately diluted solution (1 : 10,000 or 1 : 100,000 concentration)

Why Patients and Caregivers Fail to Inject Epinephrine Promptly

- Lack of recognition of anaphylaxis symptoms; failure to diagnose anaphylaxis
- Episode appears mild, or there is a history of previous mild episode(s)*
- H_1 antihistamine or asthma puffer is used initially instead, relieving early warning signs such as itch or cough, respectively.
- Prescription for epinephrine autoinjectors (EAIs) is not provided by physician.
- Prescription for EAIs is provided but not filled at pharmacy (e.g., not affordable).

- Patients do not carry EAIs consistently (due to size and bulk, or “don't think they’ll need it”).
- Patients and caregivers are afraid to use EAIs (concern about making an error when giving the injection or about a bad outcome).
- Patients and caregivers are concerned about injury from EAIs.
- Competence in using EAIs is associated with regular allergy clinic visits; it decreases as time elapses from first EAI instruction; regular retraining is needed.
- Difficulty in understanding how to use EAIs (15% of mothers with no EAI experience could not fire an EAI immediately after a one-on-one demonstration)
- Errors in EAI use can occur despite education, possibly related to the design of some EAIs.

Why Patients Occasionally Fail to Respond to Epinephrine Injection

- Delayed recognition of anaphylaxis symptoms; delayed diagnosis
- Error in diagnosis: problem being treated (e.g., foreign body inhalation) is not anaphylaxis.
- Rapid progression of anaphylaxis [†]

    Epinephrine [†] :

    - Injected too late; dose too low on mg/kg basis; dose too low because epinephrine solution has degraded (e.g., past the expiration date, stored in a hot place)
    - Injection route or site not optimal; dose took too long to be absorbed.
    - Patient suddenly sits up or walks or runs, leading to the empty ventricle syndrome.
    - Concurrent use of certain medications (e.g., β-adrenergic blockers)

---

[*] Subsequent anaphylaxis episodes can be more severe, less severe, or similar in severity.

[†] Median times to respiratory or cardiac arrest are 5 min in iatrogenic anaphylaxis, 15 min in stinging-insect venom anaphylaxis, and 30 min in food anaphylaxis; however, regardless of the trigger, respiratory or cardiac arrest can occur within 1 min in anaphylaxis.

CHAPTER 175

Serum Sickness

Anna Nowak-Węgrzyn, Scott H. Sicherer

Serum sickness is a systemic, immune complex–mediated hypersensitivity vasculitis classically attributed to the therapeutic administration of foreign serum proteins or other medications (Table 175.1).

Table 175.1

Proteins and Medications That Cause Serum Sickness*

Proteins From Other Species

- Antibotulinum globulin
- Antithymocyte globulin
- Antitetanus toxoid
- Antivenin (Crotalidae) polyvalent (horse serum based)
- Crotalidae polyvalent immune Fab (ovine serum based)
- Antirabies globulin
- Infliximab
- Rituximab
- Etanercept
- Anti-HIV antibodies ([PE]HRG214)
- Hymenoptera stings
- Streptokinase
- H1N1 influenza vaccine

Drugs

Antibiotics

- Cefaclor
- Penicillins
- Trimethoprim sulfate
- Minocycline
- Meropenem

Neurologic

- Bupropion
- Carbamazepine
- Phenytoin
- Sulfonamides
- Barbiturates

HIV, Human immunodeficiency virus.

---

[*] Based on review of most current literature. Other medications that are not listed might also cause serum sickness.

From Aceves SS: Serum sickness. In Burg FD, Ingelfinger JR, Polin RA, Gershon AA, editors: *Current pediatric therapy* , ed 18, Philadelphia, 2006, Elsevier, p 1138.

Etiology

Immune complexes involving heterologous (animal) serum proteins and complement activation are important pathogenic mechanisms in serum sickness. Antibody therapies derived from the horse, sheep, or rabbit are available for treatment of envenomation by the black widow spider and a variety of snakes, for treatment of botulism, and for immunosuppression (**antithymocyte globulin** , ATG). The availability of alternative medical therapies, modified or bioengineered antibodies, and biologics of human origin have supplanted the use of nonhuman antisera, reducing the risk of serum sickness. However, rabbit-generated ATGs, which target human T cells, continue to be widely used as immunosuppressive agents during treatment of kidney allograft recipients; serum sickness is associated with a late graft loss in kidney transplant recipients. A **serum sickness–like reaction** may be attributed to drug allergy, triggered by antibiotics (particularly cefaclor). In contrast to a true serum sickness, serum sickness–like reactions do not exhibit the immune complexes, hypocomplementemia, vasculitis, and renal lesions that are seen in serum sickness reactions.

Pathogenesis

Serum sickness is a classic example of a type III hypersensitivity reaction caused by antigen-antibody complexes. In the rabbit model using bovine serum albumin as the antigen, symptoms develop with the appearance of antibody against the injected antigen. As free antigen concentration falls and antibody production increases over days, antigen-antibody complexes of various sizes develop in a manner analogous to a precipitin curve. Whereas small complexes usually circulate harmlessly and large complexes are cleared by the reticuloendothelial system, intermediate-sized complexes that develop at the point of slight antigen excess may deposit in blood vessel walls and tissues. There the immune microprecipitates induce vascular (leukocytoclastic vasculitis with immune complex deposition) and tissue damage through activation of complement and granulocytes.

Complement activation (C3a, C5a) promotes chemotaxis and adherence of neutrophils to the site of immune complex deposition. The processes of immune complex deposition and of neutrophil accumulation may be facilitated by increased vascular permeability, because of the release of vasoactive amines from tissue mast cells. Mast cells may be activated by binding of antigen to IgE or through contact with anaphylatoxins (C3a). Tissue injury results from the liberation of proteolytic enzymes and oxygen radicals from the neutrophils.

Clinical Manifestations

The symptoms of serum sickness generally begin 7-12 days after injection of the foreign material, but may appear as late as 3 wk afterward. The onset of symptoms may be accelerated if there has been earlier exposure or previous allergic reaction to the same antigen. A few days before the onset of generalized symptoms, the site of injection may become edematous and erythematous.

Symptoms usually include fever, malaise, and rashes. Urticaria and morbilliform rashes are the predominant types of skin eruptions (Fig. 175.1). In a prospective study of serum sickness induced by administration of equine ATG, an initial rash was noted in most patients. It began as a thin, serpiginous band of erythema along the sides of the hands, fingers, feet, and toes at the junction of the palmar or plantar skin with the skin of the dorsolateral surface. In most patients the band of erythema was replaced by petechiae or purpura, presumably because of low platelet counts or local damage to small blood vessels. Additional symptoms include edema, myalgia, lymphadenopathy, symmetric arthralgia or arthritis involving multiple joints, and gastrointestinal complaints, including pain, nausea, diarrhea, and melena. Symptoms typically resolve within 2 wk of removal of the offending agent, although in unusual cases, symptoms can persist for as long as 2-3 mo.

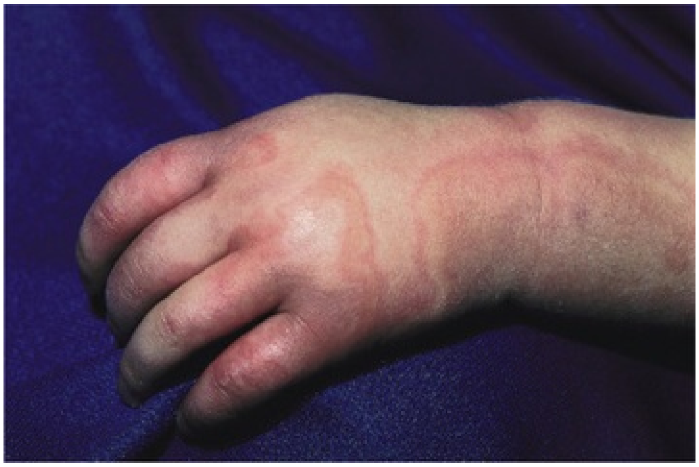

FIG. 175.1 **Serum sickness–like reaction (SSLR). Note the swollen hand and large urticarial wheals in this girl with SSLR and arthralgias. (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology* , ed 5, Philadelphia, 2016, Elsevier, p 476.)**

Carditis, glomerulonephritis, Guillain-Barré syndrome, and peripheral neuritis are rare complications. Serum sickness–like reactions from drugs are characterized by fever, pruritus, urticaria, and arthralgias that usually begin 1-3 wk after drug exposure. The urticarial skin eruption becomes increasingly erythematous as the reaction progresses and can evolve into dusky centers with round plaques.

Differential Diagnosis

The differential diagnosis of serum sickness and serum sickness–like reactions includes viral illnesses with exanthems, hypersensitivity vasculitis, Kawasaki disease, acute rheumatic fever, acute meningococcal or gonococcal infection, endocarditis, systemic-onset juvenile idiopathic arthritis (Still disease), Lyme disease, hepatitis, and other types of drug reactions (see Chapter 177).

Diagnosis

In most patients the diagnosis of serum sickness is made clinically based on the characteristic pattern of acute or subacute onset of a rash, fever, and severe arthralgia and myalgia disproportionate to the degree of swelling, occurring after exposure to a potential culprit. Patients who appear moderately or severely ill, or who are not taking a medication that can be readily identified as the culprit, should be evaluated with the following laboratory tests:

◆ Complete blood count and differential; thrombocytopenia is often present.
◆ Erythrocyte sedimentation rate (ESR) and C-reactive protein; ESR is usually elevated.
◆ Urinalysis; mild proteinuria, hemoglobinuria, and microscopic hematuria may be seen.
◆ Serum chemistries, including blood urea nitrogen, creatinine, and liver function tests.
◆ Complement studies, including CH_{50} , C3, and C4; serum complement levels (C3 and C4) are generally decreased and reach a nadir at about day 10. C3a anaphylatoxin may be increased.
◆ Testing for specific infectious diseases, if indicated by the history or physical examination.

◆ Appropriate viral or bacterial cultures if an infection is suspected.

Skin biopsies are not usually necessary for confirming the diagnosis, because the findings are variable and not specific for serum sickness. Direct immunofluorescence studies of skin lesions often reveal immune deposits of IgM, IgA, IgE, or C3.

Treatment

There are no evidence-based guidelines or controlled trials on which to base therapy recommendations. Treatment is primarily supportive, consisting of discontinuation of the offending agent, antihistamines for pruritus, and nonsteroidal antiinflammatory drugs and analgesics for low-grade fever and mild arthralgia. When the symptoms are especially severe, for example, fever >38.5°C (101.3°F), severe arthralgia or myalgia, or renal dysfunction, systemic corticosteroids can be used. Prednisone (1-2 mg/kg/day; maximum 60 mg/day) for 1-2 wk is usually sufficient. Once the offending agent is discontinued and depending on its half-life, symptoms resolve spontaneously in 1-4 wk. Symptoms lasting longer suggest another diagnosis.

Prevention

The primary mode of prevention of serum sickness is to seek alternative therapies. In some cases, non–animal-derived formulations may be available (human-derived botulinum immune globulin). Other alternatives are partially digested antibodies of animal origin and engineered (humanized) antibodies. The potential of these therapies to elicit serum sickness–like disease appears low. When only animal-derived antitoxin/antivenom is available, skin tests should be performed before administration of serum, but this procedure indicates the risk only of anaphylaxis, not of serum sickness. For patients who have evidence of anaphylactic sensitivity to horse serum, a risk/benefit assessment must be made to determine the need to proceed with treatment. If needed, the serum can usually be successfully administered by a process of rapid desensitization using protocols of gradual administration outlined by the manufacturers. Serum sickness is not prevented by desensitization or by pretreatment with corticosteroids.

CHAPTER 176

Food Allergy and Adverse Reactions to Foods

Anna Nowak-Węgrzyn, Hugh A. Sampson, Scott H. Sicherer

Adverse reactions to foods consist of any untoward reaction following the ingestion of a food or food additive and are classically divided into **food intolerances** (e.g., **lactose intolerance**), which are adverse *physiologic* responses, and **food allergies,** which are adverse *immunologic* responses and can be IgE mediated or non–IgE mediated (Tables 176.1 and 176.2). As with other atopic disorders, food allergies appear to have increased over the past 3 decades, primarily in countries with a Western lifestyle. Worldwide, estimates of food allergy prevalence range from 1–10%; food allergies affect an estimated 3.5% of the U.S. population. Up to 6% of children experience food allergic reactions in the 1st 3 yr of life, including approximately 2.5% with cow's milk allergy, 2% with egg allergy, and 2–3% with peanut allergy. **Peanut allergy** prevalence tripled over the past decade. Most children “outgrow” milk and egg allergies, with approximately 50% doing so by school-age. In contrast, 80–90% of children with peanut, tree nut, or seafood allergy retain their allergy for life.

Table 176.1

Adverse Food Reactions

Food Intolerance (non–immune system mediated, nontoxic, noninfectious)

Host Factors

Enzyme deficiencies—lactase (primary or secondary), sucrase/isomaltase, hereditary fructose intolerance, galactosemia
Gastrointestinal disorders—inflammatory bowel disease, irritable bowel

syndrome, pseudoobstruction, colic
Idiosyncratic reactions—caffeine in soft drinks (“hyperactivity”)
Psychologic—food phobias, obsessive/compulsive disorder
Migraines (rare)

Food Factors (Toxic or Infectious or Pharmacologic)

Infectious organisms—*Escherichia coli*, *Staphylococcus aureus*, *Clostridium perfringens*, *Shigella*, botulism, *Salmonella*, *Yersinia*, *Campylobacter*
Toxins—histamine (scombroid poisoning), saxitoxin (shellfish)
Pharmacologic agents—caffeine, theobromine (chocolate, tea), tryptamine (tomatoes), tyramine (cheese), benzoic acid in citrus fruits (perioral flare)
Contaminants—heavy metals, pesticides, antibiotics

Food Allergy

IgE Mediated

Cutaneous—urticaria, angioedema, morbilliform rashes, flushing, contact urticarial
Gastrointestinal—oral allergy syndrome, gastrointestinal anaphylaxis
Respiratory—acute rhinoconjunctivitis, bronchospasm
Generalized—anaphylactic shock, exercise-induced anaphylaxis

Mixed IgE Mediated and Non–IgE Mediated

Cutaneous—atopic dermatitis, contact dermatitis
Gastrointestinal—allergic eosinophilic esophagitis and gastroenteritis
Respiratory—asthma

Non–IgE Mediated

Cutaneous—contact dermatitis, dermatitis herpetiformis (celiac disease)
Gastrointestinal—food protein–induced enterocolitis, proctocolitis, and enteropathy syndromes, celiac disease

Respiratory—food-induced pulmonary hemosiderosis (Heiner syndrome)
Unclassified

IgE, Immunoglobulin E.

Table 176.2

Differential Diagnosis of Adverse Food Reactions

Gastrointestinal Disorders (with vomiting and/or diarrhea)

- Structural abnormalities (pyloric stenosis, Hirschsprung disease, reflux)
- **Enzyme deficiencies (primary or secondary)** :
  - Disaccharidase deficiency—lactase, fructase, sucrase-isomaltase
  - Galactosemia
- Malignancy with obstruction
- Other: pancreatic insufficiency (cystic fibrosis), peptic disease

Contaminants and Additives

- Flavorings and preservatives—rarely cause symptoms:
  - Sodium metabisulfite, monosodium glutamate, nitrites
- Dyes and colorings—very rarely cause symptoms (urticaria, eczema):
  - Tartrazine
- Toxins:
  - Bacterial, fungal (aflatoxin), fish related (scombroid, ciguatera)
- Infectious organisms:
  - Bacteria *(Salmonella, Escherichia coli, Shigella)*
  - Virus (rotavirus, enterovirus)
  - Parasites (*Giardia, Akis simplex* [in fish])
- Accidental contaminants:
  - Heavy metals, pesticides
- Pharmacologic agents:
  - Caffeine, glycosidal alkaloid solanine (potato spuds), histamine (fish), serotonin (banana, tomato), tryptamine (tomato), tyramine (cheese)

Psychologic Reactions

Food phobias

Genetics

Genetic factors play an important role in the development of food allergy. Family and twin studies show that family history confers a 2-10–fold increased risk, depending on the study setting, population, specific food, and diagnostic test. Candidate gene studies suggest that genetic variants in the HLA-DQ locus (HLA-DQB1*02 and DQB1*06:03P), filaggrin, interleukin-10, *STAT6*, and *FOXP3* genes are associated with food allergy, although the results are inconsistent across different populations. In a genome-wide association study, differential methylation at the HLA-DR and -DQ regions was associated with food allergy. Epigenetic studies implicate DNA methylation effects on interleukins 4, 5, and 10 and interferon (IFN)-γ genes and in the mitogen-activated protein kinase (MAPK) pathway.

Pathogenesis

Food intolerances are the result of a variety of mechanisms, whereas food allergy is predominantly caused by IgE-mediated and cell-mediated immune mechanisms. In susceptible individuals exposed to certain allergens, food-specific IgE antibodies are formed that bind to Fcε receptors on mast cells, basophils, macrophages, and dendritic cells. When food allergens penetrate mucosal barriers and reach cell-bound IgE antibodies, mediators are released that induce vasodilation, smooth muscle contraction, and mucus secretion, which result in symptoms of immediate hypersensitivity (allergy). Activated mast cells and macrophages may release several cytokines that attract and activate other cells, such as eosinophils and lymphocytes, leading to prolonged inflammation. Symptoms elicited during acute IgE-mediated reactions can affect the skin (urticaria, angioedema, flushing), gastrointestinal (GI) tract (oral pruritus, angioedema, nausea, abdominal pain, vomiting, diarrhea), respiratory tract (nasal congestion, rhinorrhea, nasal pruritus, sneezing, laryngeal edema, dyspnea, wheezing), and cardiovascular system (dysrhythmias, hypotension, loss of consciousness). In non-IgE food allergies, lymphocytes, primarily food allergen–

specific T cells, secrete excessive amounts of various cytokines that lead to a “delayed,” more chronic inflammatory process affecting the skin (pruritus, erythematous rash), GI tract (failure to thrive, early satiety, abdominal pain, vomiting, diarrhea), and respiratory tract (food-induced pulmonary hemosiderosis). Mixed IgE and cellular responses to food allergens can also lead to chronic disorders, such as atopic dermatitis, asthma, eosinophilic esophagitis, and gastroenteritis.

Children who develop IgE-mediated food allergies may be sensitized by food allergens penetrating the GI barrier, referred to as **class 1 food allergens** , or by food allergens that are partially homologous to plant pollens penetrating the respiratory tract, referred to as **class 2 food allergens** . Any food may serve as a class 1 food allergen, but *egg, milk, peanuts, tree nuts, fish, soy,* and *wheat* account for 90% of food allergies during childhood. Many of the major allergenic proteins of these foods have been characterized. There is variable but significant cross-reactivity with other proteins within an individual food group. Exposure and sensitization to these proteins often occur very early in life. Virtually all milk allergies develop by 12 mo of age and all egg allergies by 18 mo, and the median age of 1st peanut allergic reactions is 14 mo. Class 2 food allergens are typically vegetable, fruit, or nut proteins that are partially homologous with pollen proteins (Table 176.3). With the development of seasonal allergic rhinitis from birch, grass, or ragweed pollens, subsequent ingestion of certain uncooked fruits or vegetables provokes the **oral allergy syndrome** . *Intermittent ingestion* of allergenic foods may lead to acute symptoms such as urticaria or anaphylaxis, whereas *prolonged exposure* may lead to chronic disorders such as atopic dermatitis and asthma. Cell-mediated sensitivity typically develops to class 1 allergens.

Table 176.3

Natural History of Food Allergy and Cross-Reactivity Between Common Food Allergies

FOOD	USUAL AGE AT ONSET OF ALLERGY	CROSS REACTIVITY	USUAL AGE AT RESOLUTION
Hen's egg white	0-1 yr	Other avian eggs	7 yr (75% of cases resolve)*
Cow's milk	0-1 yr	Goat's milk, sheep's milk, buffalo milk	5 yr (76% of cases resolve)*
Peanuts	1-2 yr	Other legumes, peas, lentils; coreactivity with tree nuts	Persistent (20% of cases resolve)

Tree nuts	1-2 yr; in adults, onset occurs after cross reactivity to birch pollen	Other tree nuts; co-reactivity with peanuts	Persistent (9% of cases resolve)
Fish	Late childhood and adulthood	Other fish (low cross-reactivity with tuna and swordfish)	Persistent [†]
Shellfish	Adulthood (in 60% of patients with this allergy)	Other shellfish	Persistent
Wheat[*]	6-24 mo	Other grains containing gluten (rye, barley)	5 yr (80% of cases resolve)
Soybeans[*]	6-24 mo	Other legumes	2 yr (67% of cases resolve)
Kiwi	Any age	Banana, avocado, latex	Unknown
Apples, carrots, and peaches [§]	Late childhood and adulthood	Birch pollen, other fruits, nuts	Unknown

[*] Recent studies suggest that resolution may occur at a later age, especially in children with multiple food allergies and lifetime peak food-specific IgE >50 kU_A /L.

[†] Fish allergy that is acquired in childhood can resolve.

[§] Allergy to fresh apples, carrots, and peaches (**oral allergy syndrome**) is typically caused by heat-labile proteins. Fresh fruit causes oral pruritus, but cooked fruit is tolerated. There is generally no risk of anaphylaxis, although in rare cases, allergies to cross-reactive lipid transfer protein can cause anaphylaxis after ingestion of fruits (e.g., peach) and vegetables.

Adapted from Lack G: Food allergy, *N Engl J Med* 359:1252–1260, 2008.

Clinical Manifestations

From a clinical and diagnostic standpoint, it is most useful to subdivide food hypersensitivity disorders according to the predominant target organ (Table 176.4) and immune mechanism (see Table 176.1).

Table 176.4

Symptoms of Food-Induced Allergic Reactions

TARGET ORGAN	IMMEDIATE SYMPTOMS	DELAYED SYMPTOMS
Cutaneous	Erythema Pruritus Urticaria Morbilliform eruption Angioedema	Erythema Flushing Pruritus Morbilliform eruption Angioedema Eczematous rash
Ocular	Pruritus Conjunctival erythema Tearing Periorbital edema	Pruritus Conjunctival erythema Tearing Periorbital edema
Upper	Nasal congestion	

respiratory	Pruritus Rhinorrhea Sneezing Laryngeal edema Hoarseness Dry staccato cough	
Lower respiratory	Cough Chest tightness Dyspnea Wheezing Intercostal retractions Accessory muscle use	Cough, dyspnea, wheezing
Gastrointestinal (oral)	Angioedema of the lips, tongue, or palate Oral pruritus Tongue swelling	
Gastrointestinal (lower)	Nausea Colicky abdominal pain Reflux Vomiting Diarrhea	Nausea Abdominal pain Reflux Vomiting Diarrhea Hematochezia Irritability and food refusal with weight loss (young children)
Cardiovascular	Tachycardia (occasionally bradycardia in anaphylaxis) Hypotension Dizziness Fainting Loss of consciousness	
Miscellaneous	Uterine contractions Sense of “impending doom”	

From Boyce JA, Assa'ad A, Burks AW, et al: Guideline for the diagnosis and management of food allergy in the United States: report of the NIAID-sponsored expert panel, *J Allergy Clin Immunol* 126(6):S1–S58, 2010 (Table IV, p S19).

Gastrointestinal Manifestations

GI food allergies are often the 1st form of allergy to affect infants and young children and typically manifest as irritability, vomiting or “spitting-up,” diarrhea, and poor weight gain. Cell-mediated hypersensitivities without IgE involvement predominate, making standard allergy tests such as skin-prick tests and in vitro tests for food-specific IgE antibodies of little diagnostic value.

Food protein–induced enterocolitis syndrome (FPIES) typically manifests in the 1st several mo of life as irritability, intermittent vomiting, and protracted diarrhea and may result in dehydration (Table 176.5). Vomiting generally occurs 1-4 hr after feeding, and continued exposure may result in abdominal distention, bloody diarrhea, anemia, and failure to thrive. Symptoms are most often provoked by cow's milk or soy protein–based formulas. A similar enterocolitis syndrome occurs in older infants and children from rice, oat, wheat, egg, peanut, nut, chicken, turkey, or fish. Hypotension occurs in approximately 15% of patients after allergen ingestion and may initially be thought to be caused by sepsis. FPIES usually resolves by age 3-5 yr.

Table 176.5

Food Protein–Induced Gastrointestinal Syndromes

	FPIES	PROCTOCOLITIS	ENTEROPATHY	EOSINOPHILIC GASTROENTEROPATHIES*
Age at onset	1 day–1 year	1 day–6 months	Dependent of age of exposure to antigen, cow's milk and soy up to 2 yr	Infant to adolescent
Food proteins implicated				
Most common	Cow's milk, soy	Cow's milk, soy	Cow's milk, soy	Cow's milk, soy, egg white, wheat, peanut
Less common	Rice, chicken, turkey, fish, pea	Egg, corn, chocolate	Wheat, egg	Meats, corn, rice, fruits, vegetables, fish
Multiple food hypersensitivities	>50% both cow's milk and soy	40% both cow's milk and soy	Rare	Common
Feeding at the time of onset	Formula	>50% exclusive breastfeeding	Formula	Formula
Atopic background				
Family history of atopy	40–70%	25%	Unknown	~50% (often history of eosinophilic esophagitis)
Personal history of atopy	30%	22%	22%	~50%
Symptoms				
Emesis	Prominent	No	Intermittent	Intermittent
Diarrhea	Severe	No	Moderate	Moderate
Bloody stools	Severe	Moderate	Rare	Moderate
Edema	Acute, severe	No	Moderate	Moderate
Shock	15%	No	No	No
Failure to thrive	Moderate	No	Moderate	Moderate
Laboratory findings				
Anemia	Moderate	Mild	Moderate	Mild-moderate
Hypoalbuminemia	Acute	Rare	Moderate	Mild-severe
Methemoglobinemia	May be present	No	No	No
Allergy evaluation				
Food skin-prick test	Negative †	Negative	Negative	Positive in ~50%

Serum food allergen IgE	Negative[†]	Negative	Negative	Positive in ~50%
Total IgE	Normal	Negative	Normal	Normal to elevated
Peripheral blood eosinophilia	No	Occasional	No	Present in <50%
Biopsy findings				
Colitis	Prominent	Focal	No	May be present
Lymph nodular hyperplasia	No	Common	No	Yes
Eosinophils	Prominent	Prominent	Few	Prominent; also neutrophilic infiltrates, papillary elongation, and basal zone hyperplasia
Food challenge	Vomiting in 1-4 hr; diarrhea in 5-8 hr	Rectal bleeding in 6-72 hr	Vomiting, diarrhea, or both in 40-72 hr	Vomiting and diarrhea in hours to days
Treatment	Protein elimination, 80% respond to casein hydrolysate and symptoms clear in 3-10 days; rechallenge under supervision in 1.5-2 yr	Protein elimination, symptoms clear in 3 days with casein hydrolysate; resume/continue breastfeeding on maternal antigen-restricted diet; reintroduce at home after 9-12 mo of age	Protein elimination, symptoms clear in 1-3 wk; rechallenge and biopsy in 1-2 yr	Protein elimination, good response to casein hydrolysate, excellent response to elemental diet; symptoms clear in 2-3 wk, excellent acute response to steroids; rechallenge by introducing food at home and biopsy in 1-2 yr
Natural history	Cow's milk: 60% resolved by 2 yr Soy: 25% resolved by 2 yr	Resolved by 9-12 mo	Most cases resolve in 2-3 yr	Typically a prolonged, relapsing course
Reintroduction of the food	Supervised food challenge	At home, gradually advancing from 1 oz to full feedings over 2 wk	Home, gradually advancing	Home, gradually advancing

[*] Eosinophilic gastroenteropathies encompass esophagitis, gastritis, and gastroenterocolitis.

[†] If positive, may be a risk factor for persistent disease.

FPIES, Food protein–induced enterocolitis syndrome.

From Nowak-Węgrzyn A, Muraro A: Food protein-induced enterocolitis syndrome, *Curr Opin Allergy Immunol* 9:371–377, 2009 (Table 1, p 372).

Food protein–induced allergic proctocolitis (FPIAP) presents in the 1st few mo of life as blood-streaked stools in otherwise healthy infants (Table 176.5). Approximately 60% of cases occur among breastfed infants, with the remainder largely among infants fed cow's milk or soy protein–based formula. Blood loss is typically modest but can occasionally produce anemia.

Food protein–induced enteropathy (FPE) often manifests in the 1st several mo of life as diarrhea, often with steatorrhea and poor weight gain (Table 176.5). Symptoms include protracted diarrhea, vomiting in up to 65% of cases, failure to thrive, abdominal distention, early satiety, and malabsorption. Anemia, edema, and hypoproteinemia occur occasionally. **Cow's milk sensitivity** is the most common cause of FPE in young infants, but it has also been associated with sensitivity to soy, egg, wheat, rice, chicken, and fish in older children. **Celiac disease** , the most severe form of FPE, occurs in about 1 per 100 U.S. population, although it may be “silent” in many patients (see Chapter 364.2). The full-blown form is characterized by extensive loss of absorptive villi and hyperplasia of the crypts, leading to malabsorption, chronic diarrhea, steatorrhea, abdominal distention, flatulence, and weight loss or failure to thrive. Oral ulcers and other extraintestinal symptoms secondary to malabsorption may occur. Genetically susceptible individuals (HLA-DQ2 or HLA-DQ8) demonstrate a cell-mediated response to tissue transglutaminase deamidated gliadin (a fraction of gluten), which is found in wheat, rye, and barley.

Eosinophilic esophagitis (EoE) may appear from infancy through adolescence, more frequently in boys (see Chapter 350). In young children, EoE is primarily cell mediated and manifests as chronic gastroesophageal reflux (GER), intermittent emesis, food refusal, abdominal pain, dysphagia, irritability, sleep disturbance, and failure to respond to conventional GER medications. EoE is a clinicopathologic diagnosis. The diagnosis is confirmed when 15 eosinophils per high-power field are seen on esophageal biopsy following treatment with proton pump inhibitors. **Eosinophilic gastroenteritis** occurs at any age and causes symptoms similar to those of EoE, as well as prominent weight loss or failure to thrive, both of which are the hallmarks of this disorder. More than 50% of patients with this disorder are atopic; however, food-induced IgE-mediated reactions have been implicated only in a minority of patients. Generalized edema secondary to hypoalbuminemia may occur in some infants with marked protein-losing enteropathy.

Oral allergy syndrome (pollen-associated food allergy syndrome) is an IgE-mediated hypersensitivity that occurs in many older children with birch and ragweed pollen–induced allergic rhinitis. Symptoms are usually confined to the oropharynx and consist of the rapid onset of oral pruritus; tingling and angioedema of the lips, tongue, palate, and throat; and occasionally a sensation of pruritus in the ears and tightness in the throat. Symptoms are generally short lived and are caused by local mast cell activation following contact with fresh raw fruit and vegetable proteins that cross-react with birch pollen (apple, carrot, potato, celery, hazel nuts, peanuts, kiwi, cherry, pear), grass pollen (potato, tomato, watermelon, kiwi), and ragweed pollen (banana, melons such as watermelon and cantaloupe).

Acute gastrointestinal allergy generally manifests as acute abdominal pain, vomiting, or diarrhea that accompanies IgE-mediated allergic symptoms in other target organs.

Skin Manifestations

Cutaneous food allergies are also common in infants and young children.

Atopic dermatitis is a form of eczema that generally begins in early infancy and is characterized by pruritus, a chronically relapsing course, and association with asthma and allergic rhinitis (see Chapter 170). Although not often apparent from history, at least 30% of children with moderate to severe atopic dermatitis have food allergies. The younger the child and the more severe the eczema, the more likely food allergy is playing a pathogenic role in the disorder.

Acute urticaria and angioedema are among the most common symptoms of food allergic reactions (see Chapter 173). The onset of symptoms may be very rapid, within minutes after ingestion of the responsible allergen. Symptoms result from activation of IgE-bearing mast cells by food allergens that are absorbed and circulated rapidly throughout the body. Foods most commonly incriminated in children include egg, milk, peanuts, and nuts, although reactions to various seeds (sesame, poppy) and fruits (kiwi) are becoming more common. Chronic urticaria and angioedema are rarely caused by food allergies.

Perioral dermatitis is often a contact dermatitis caused by substances in toothpaste, gums, lipstick, or medications. **Perioral flushing** is often noted in infants fed citrus fruits and may be caused by benzoic acid in the food. It may also occur during nursing. In both situations the effect is benign. Flushing may also be caused by auriculotemporal nerve (Frey) syndrome (familial, forceps delivery), which resolves spontaneously.

Respiratory Manifestations

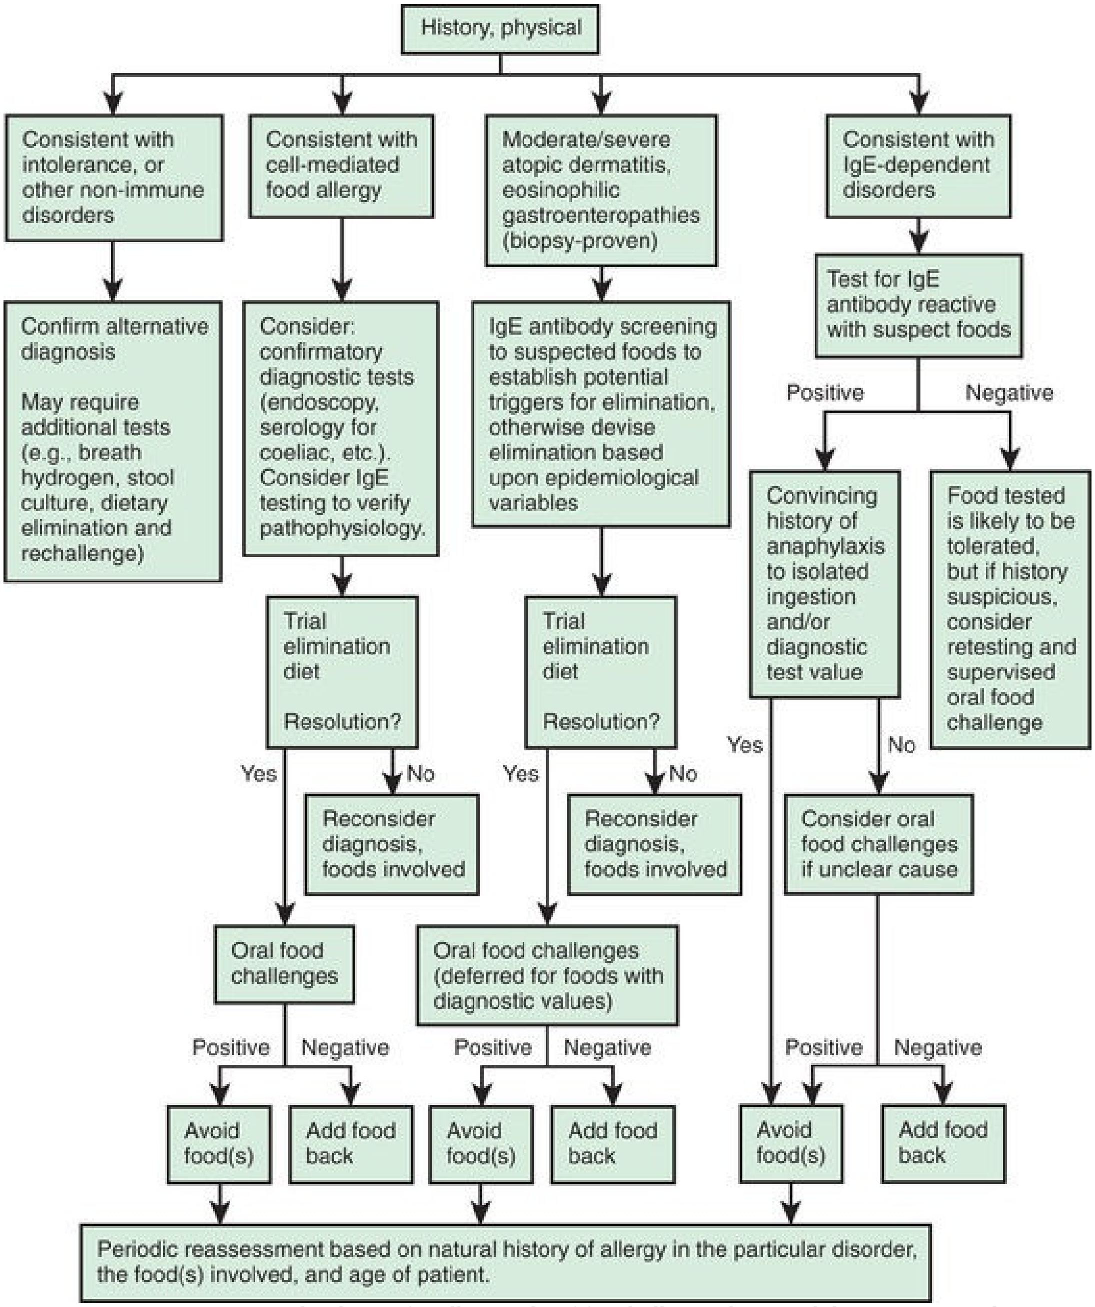
Respiratory food allergies are uncommon as isolated symptoms. Although many parents believe that nasal congestion in infants is often caused by milk allergy, studies show this not to be the case. **Food-induced rhinoconjunctivitis** symptoms typically accompany allergic symptoms in other target organs, such as skin, and consist of typical allergic rhinitis symptoms (periocular pruritus and tearing, nasal congestion and pruritus, sneezing, rhinorrhea). Wheezing occurs in approximately 25% of IgE-mediated food allergic reactions, but only 10% of asthmatic patients have food-induced respiratory symptoms.

Anaphylaxis

Anaphylaxis is defined as a serious, multisystem allergic reaction that is rapid in onset and potentially fatal. Food allergic reactions are the most common cause of anaphylaxis seen in U.S. hospital emergency departments. In addition to the rapid onset of cutaneous, respiratory, and GI symptoms, patients may demonstrate cardiovascular symptoms, including hypotension, vascular collapse, and cardiac dysrhythmias, which are presumably caused by massive mast cell–mediator release. **Food-dependent exercise-induced anaphylaxis** occurs more frequently among teenage athletes, especially females (see Chapter 174).

Diagnosis

A thorough medical history is necessary to determine whether a patient's symptomatology represents an adverse food reaction (see Table 176.2), whether it is an intolerance or food allergic reaction, and if the latter, whether it is likely to be an IgE-mediated or a cell-mediated response (Fig. 176.1). The following facts should be established: (1) the food suspected of provoking the reaction and the quantity ingested, (2) the interval between ingestion and the development of symptoms, (3) the types of symptoms elicited by the ingestion, (4) whether ingesting the suspected food produced similar symptoms on other occasions, (5) whether other inciting factors, such as exercise, are necessary, and (6) the interval from the last reaction to the food.



History, physical
Consistent with intolerance, or other non-immune disorders
Consistent with cell-mediated food allergy
Moderate/severe atopic dermatitis, eosinophilic gastroenteropathies (biopsy-proven)
Consistent with IgE-dependent disorders
Confirm alternative diagnosis
May require additional tests (e.g., breath hydrogen, stool culture, dietary elimination and rechallenge)
Consider: confirmatory diagnostic tests (endoscopy, serology for coeliac, etc.). Consider IgE testing to verify pathophysiology.
IgE antibody screening to suspected foods to establish potential triggers for elimination, otherwise devise elimination based upon epidemiological variables
Test for IgE antibody reactive with suspect foods
Positive
Negative
Convincing history of anaphylaxis to isolated ingestion and/or diagnostic test value
Food tested is likely to be tolerated, but if history suspicious, consider retesting and supervised oral food challenge
Trial elimination diet
Resolution?
Trial elimination diet
Resolution?
Yes
No
Yes
No
Yes
No
Reconsider diagnosis, foods involved
Reconsider diagnosis, foods involved
Consider oral food challenges if unclear cause
Oral food challenges
Oral food challenges (deferred for foods with diagnostic values)
Positive
Negative
Positive
Negative
Positive
Negative
Avoid food(s)
Add food back
Avoid food(s)
Add food back
Avoid food(s)
Add food back
Periodic reassessment based on natural history of allergy in the particular disorder, the food(s) involved, and age of patient.

FIG. 176.1 **General scheme for diagnosis of food allergy. (From Sicherer SH: Food allergy, *Lancet* 360:701–710, 2002.)**

Skin-prick tests and in vitro laboratory tests are useful for demonstrating *IgE sensitization*, defined as presence of food-specific IgE antibodies. Many fruits and vegetables require skin-prick testing with fresh produce because labile proteins are destroyed during commercial preparation. A negative skin test result virtually excludes an IgE-mediated form of food allergy. Conversely, most children with positive skin test responses to a food do not react when the food is ingested, so more definitive tests, such as quantitative IgE tests or food elimination and challenge, are often necessary to establish a diagnosis of food allergy. Serum food-specific IgE levels ≥15 kU_A /L for milk (≥5 kU_A /L for children ≤1 yr), ≥7 kU_A /L for egg (≥2 kU_A /L for children <2 yr), and ≥14 kU_A /L for peanut are associated with a >95% likelihood of clinical reactivity to these foods in children with suspected reactivity. In the absence of a clear history of reactivity to a food and evidence of food-specific IgE antibodies, definitive studies must be performed before recommendations are made for avoidance or the use of highly restrictive diets that may be nutritionally deficient, logistically impractical, disruptive to the family, expensive, or a potential source of future feeding disorders. IgE-mediated food allergic reactions are generally very food specific, so the use of broad exclusionary diets, such as avoidance of all legumes, cereal grains, or animal products, is not warranted (Table 176.6 ; see also Table 176.3).

Table 176.6

Clinical Implications of Cross-Reactive Proteins in IgE-Mediated Allergy

FOOD FAMILY	RISK OF ALLERGY TO ≥1 MEMBER (%; approximate)	FEATURE(S)
Legumes	5	Main causes of reactions are peanut, soybean, lentil, lupine, and garbanzo (chickpea).
Tree nuts (e.g., almond, cashew, hazelnut, walnut, brazil)	35	Reactions are often severe.
Fish	50	Reactions can be severe.
Shellfish	75	Reactions can be severe.
Grains	20	
Mammalian milks	90	Cow's milk is highly cross-reactive with goat's or sheep's milk (92%) but not with mare's milk (4%).
Rosaceae (pitted fruits)	55	Risk of reactions to >3 related foods is very low (<10%); symptoms are usually mild (oral allergy syndrome).
Latex-food	35	For individuals allergic to latex, banana, kiwi, fig, chestnut, and avocado are the main causes of reactions.
Food-latex	11	Individuals allergic to banana, kiwi, fig, chestnut, and avocado may be at an increased risk of reactions to latex.

Modified from Sicherer SH: Food allergy, *Lancet* 360:701–710, 2002.

There are no laboratory studies to help identify foods responsible for cell-mediated reactions. Consequently, *elimination diets followed by oral food* *challenges* are the only way to establish the diagnosis. Allergists experienced in dealing with food allergic reactions and able to treat anaphylaxis should perform food challenges. Before a food challenge is initiated, the suspected food should be eliminated from the diet for 10-14 days for IgE-mediated food allergy and up to 8 wk for some cell-mediated disorders, such as EoE. Some children with cell-mediated reactions to cow's milk do not tolerate hydrolysate formulas and must receive amino acid–derived formulas. If symptoms remain unchanged despite appropriate elimination diets, it is unlikely that food allergy is responsible for the child's disorder.

Treatment

Appropriate identification and elimination of foods responsible for food hypersensitivity reactions are the only validated treatments for food allergies. Complete elimination of common foods (milk, egg, soy, wheat, rice, chicken, fish, peanut, nuts) is very difficult because of their widespread use in a variety of processed foods. The lay organization **Food Allergy Research and Education** (**FARE** , www.foodallergy.org) provides excellent information to help parents deal with both the practical and emotional issues surrounding these diets. Validated educational materials are also available through the **Consortium of Food Allergy Research** (www.cofargroup.org).

Children with asthma and IgE-mediated food allergy, peanut or nut allergy, or a history of a previous severe reaction should be given self-injectable epinephrine and a written emergency plan in case of accidental ingestion (see Chapter 174). Because many food allergies are outgrown, children should be reevaluated periodically by an allergist to determine whether they have lost their clinical reactivity. A number of clinical trials are evaluating the efficacy of oral, sublingual, and epicutaneous (patch) immunotherapy for the treatment of IgE-mediated food allergies (milk, egg, peanut). Combining oral immunotherapy with anti-IgE treatment (omalizumab) may improve safety compared to oral immunotherapy alone. Furthermore, extensively heated milk or egg in baked products are tolerated by the majority of milk and egg–allergic children. Regular ingestion of baked products with milk and egg appears to accelerate resolution of milk and egg allergy. Table 176.7 provides vaccination recommendations for egg-allergic children who require immunization.

Table 176.7

ACIP and AAP Recommendations for Administering Vaccines to Patients With Egg Allergy

VACCINE	ACIP, CDC, 2016	AAP, 2016
MMR/MMRV	May be used	May be used
Influenza	Receive with no special precautions*	Receive with no special precautions*
Rabies	Use caution	No specific recommendation
Yellow fever	Contraindicated, but desensitization protocols may be followed to administer vaccine if necessary (citing PI)	Contraindicated, but desensitization protocols may be followed to administer vaccine if necessary (citing PI)

* In 2016, recommendations changed to suggest all children with any severity of egg allergy receive the injectable influenza vaccine as appropriate for age in a medical setting without any special testing and with the same precautions as those suggested for other vaccinations, including a 15 minute observation period and being in a setting where personnel and equipment are available to recognize and treat allergic reactions and anaphylaxis.

ACIP, Advisory Committee on Immunization Practices, Centers for Disease Control and Prevention; AAP, American Academy of Pediatrics; PI, product insert.

From Boyce JA, Assa'ad A, Burks AW, et al: Guideline for the diagnosis and management of food allergy in the United States: report of the NIAID-sponsored expert panel, *J Allergy Clin Immunol* 126(6):S1–S58, 2010 (Table V, p S31).

Prevention

It was once thought that avoidance of allergenic foods and delayed introduction to the diet would prevent allergy, but the opposite is probably true; *delayed introduction of these foods may increase the risk of allergy,* especially in children with atopic dermatitis. A trial of early introduction of dietary peanut randomized 640 infants age 4-11 mo with severe eczema, egg allergy, or both to consume or avoid peanut until age 60 mo. The early introduction of peanut dramatically decreased the development of peanut allergy among children at high risk for this allergy. A theory behind this approach is that early oral introduction of peanut induces oral tolerance that precedes the potential sensitization to peanut via the disrupted skin barrier. Infants with early-onset atopic disease (e.g., severe eczema) or egg allergy in the 1st 4 to 6 mo of life might benefit from evaluation by an allergist or physician trained in management of allergic diseases to diagnose any food allergy and assist in implementing appropriate early peanut introduction. The clinician can perform an observed peanut challenge for those with evidence of a positive peanut skin test response or serum peanut-specific IgE >0.35 kU_A /L to determine whether they are clinically reactive before initiating at-home introduction of infant-safe forms of peanut. Additional details for the early introduction of peanut are available from the National Institute of Allergy and Infectious Diseases (NIAID).*

There is no compelling evidence to support the practice of restricting the maternal diet during pregnancy or while breastfeeding, or of delaying introduction of various allergenic foods to infants from atopic families (Table 176.8). Exclusive breastfeeding for the 1st 4-6 mo of life may reduce allergic disorders in the 1st few yr of life in infants at high risk for development of allergic disease. Potentially allergenic foods (eggs, milk, wheat, soy, peanut/tree nut products, fish) should be introduced after this period of exclusive breastfeeding and may prevent the development of allergies later in life. Use of hydrolyzed formulas may be beneficial if breastfeeding cannot be continued for 4-6 mo or after weaning, especially to prevent eczema in high-risk families, but this approach remains controversial. **Probiotic supplements** may also reduce the incidence and severity of eczema. Because some **skin preparations** contain peanut oil, which may sensitize young infants, especially those with cutaneous inflammation, such preparations should be avoided. Since inflamed/disrupted skin barrier is a risk factor for food allergy, trials are underway to enhance the skin barrier from birth, using emollients and decreasing bathing frequency, to reduce the incidence of atopic dermatitis in high-risk neonates.

Table 176.8

Prevention of Food Allergy

Breastfeed exclusively for 4-6 mo.
Introduce solid (complementary) foods after 4-6 mo of exclusive breastfeeding.
Introduce low-risk complementary foods 1 at a time.
Introduce potentially highly allergenic foods (fish, eggs, peanut, milk, wheat) soon after the lower-risk foods (no need to avoid or delay).
    Infants with early-onset atopic disease (e.g., severe eczema) or egg allergy in the 1st 4-6 mo of life.
Do not avoid allergenic foods during pregnancy or nursing.
Soy-based formulas do not prevent allergic disease.

CHAPTER 177

Adverse Reactions to Drugs

Christine B. Cho, Mark Boguniewicz, Scott H. Sicherer

Adverse drug reactions can be divided into predictable (type A) and unpredictable (type B) reactions. **Predictable drug reactions** , including drug toxicity, drug interactions, and adverse effects, are dose dependent, can be related to known pharmacologic actions of the drug, and occur in patients without any unique susceptibility. **Unpredictable drug reactions** are dose independent, often are not related to the pharmacologic actions of the drug, and occur in patients who are genetically predisposed. These include idiosyncratic reactions, allergic (hypersensitivity) reactions, and pseudoallergic reactions. **Allergic reactions** require prior sensitization, manifest as signs or symptoms characteristic of an underlying allergic mechanism, such as anaphylaxis or urticaria, and occur in genetically susceptible individuals. They can occur at doses significantly below the therapeutic range. **Pseudoallergic reactions** resemble allergic reactions but are caused by non–IgE-mediated release of mediators from mast cells and basophils. Drug-independent cross-reactive antigens can induce sensitization manifesting as drug allergy. Patients with cetuximab-induced anaphylaxis have IgE antibodies in pretreatment samples specific for galactose-α-1,3-galactose. This antigen is present on the antigen-binding portion of the cetuximab heavy chain and is similar to structures in the ABO blood group. Sensitization to galactose-α-1,3-galactose may occur from tick bites caused by cross-reactive tick salivary antigens.

Epidemiology

The incidence of adverse drug reactions (ADRs) in the general as well as pediatric populations remains unknown, although data from hospitalized patients show it to be 6.7%, with a 0.32% incidence of fatal ADRs. Databases such as the

U.S. Food and Drug Administration (FDA) MedWatch program (http://www.fda.gov/medwatch/index.html) likely suffer from underreporting. Cutaneous reactions are the most common form of ADRs, with ampicillin, amoxicillin, penicillin, and trimethoprim/sulfamethoxazole (TMP/SMX) being the most frequently implicated drugs (Tables 177.1 and 177.2). Although the majority of ADRs do not appear to be allergic in nature, 6–10% can be attributed to an allergic or immunologic mechanism. Importantly, given the high probability of recurrence of allergic reactions, these reactions should be preventable, and information technology–based interventions may be especially useful to reduce risk of reexposure.

Table 177.1

Heterogeneity of Drug-Induced Allergic Reactions

ORGAN-SPECIFIC REACTIONS	CLINICAL FEATURES	EXAMPLES OF CAUSATIVE AGENTS
CUTANEOUS		
Exanthems	Diffuse fine macules and papules evolve over days after drug initiation Delayed-type hypersensitivity	Allopurinol, aminopenicillins, cephalosporins, antiepileptic agents, and antibacterial sulfonamides
Urticaria, angioedema	Onset within minutes of drug initiation Potential for anaphylaxis Often IgE mediated	IgE mediated: β-lactam antibiotics Bradykinin mediated: ACEI
Fixed drug eruption	Hyperpigmented plaques Recur at same skin or mucosal site	Tetracycline, sulfonamides, NSAIDs, and carbamazepine
Pustules	Acneiform Acute generalized exanthematous pustulosis (AGEP)	Acneiform: corticosteroids, sirolimus AGEP: antibiotics, calcium-channel blockers
Bullous	Tense blisters Flaccid blisters	Furosemide, vancomycin Captopril, penicillamine
SJS	Fever, erosive stomatitis, ocular involvement, purpuric macules on face and trunk with <10% epidermal detachment	Antibacterial sulfonamides, anticonvulsants, oxicam NSAIDs, and allopurinol
TEN	Similar features as SJS but >30% epidermal detachment Mortality as high as 50%	Same as SJS
Cutaneous lupus	Erythematous/scaly plaques in photodistribution	Hydrochlorothiazide, calcium channel blockers, ACEIs
Hematologic	Hemolytic anemia, thrombocytopenia, granulocytopenia	Penicillin, quinine, sulfonamides
Hepatic	Hepatitis, cholestatic jaundice	Paraaminosalicylic acid, sulfonamides, phenothiazines
Pulmonary	Pneumonitis, fibrosis	Nitrofurantoin, bleomycin, methotrexate
Renal	Interstitial nephritis, membranous glomerulonephritis	Penicillin, sulfonamides, gold, penicillamine, allopurinol
MULTIORGAN REACTIONS		

Anaphylaxis	Urticaria/angioedema, bronchospasm, gastrointestinal symptoms, hypotension IgE- and non–IgE-dependent reactions	β-Lactam antibiotics, monoclonal antibodies
DRESS	Cutaneous eruption, fever, eosinophilia, hepatic dysfunction, lymphadenopathy	Anticonvulsants, sulfonamides, minocycline, allopurinol
Serum sickness	Urticaria, arthralgias, fever	Heterologous antibodies, infliximab
Systemic lupus erythematosus	Arthralgias, myalgias, fever, malaise	Hydralazine, procainamide, isoniazid
Vasculitis	Cutaneous or visceral vasculitis	Hydralazine, penicillamine, propylthiouracil

ACEI, Angiotensin-converting enzyme inhibitor; DRESS, drug rash with eosinophilia and systemic symptoms; NSAID, nonsteroidal antiinflammatory drug; SJS, Stevens-Johnson syndrome; TEN, toxic epidermal necrolysis.

From Khan DA, Solensky R: Drug allergy, *J Allergy Clin Immunol* 125:S126–S137, 2010 (Table 1, p S127).

Table 177.2

Delayed Hypersensitivity Drug Rashes by Category

MACULOPAPULAR EXANTHEMS—ANY DRUG CAN PRODUCE A RASH 7-10 DAYS AFTER THE FIRST DOSE

Allopurinol

Antibiotics: penicillin, sulfonamides

Antiepileptics: phenytoin, phenobarbital

Antihypertensives: captopril, thiazide diuretics

Contrast dye: iodine

Gold salts

Hypoglycemic drugs

Meprobamate

Phenothiazines

Quinine

DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)

Anticonvulsants: phenytoin, phenobarbital, valproate, lamotrigine

Antibiotics: sulfonamides, minocycline, dapsone, ampicillin, ethambutol, isoniazid, linezolid, metronidazole, rifampin, streptomycin, vancomycin

Antihypertensives: amlodipine, captopril

Antidepressants: bupropion, fluoxetine

Allopurinol

Celecoxib

Ibuprofen

Phenothiazines

ERYTHEMA MULTIFORME/STEVENS-JOHNSON SYNDROME

Sulfonamides, phenytoin, barbiturates, carbamazepine, allopurinol, amikacin, phenothiazines

Toxic epidermal necrolysis: same as for erythema multiforme but also acetazolamide, gold, nitrofurantoin, pentazocine, tetracycline, quinidine

ACUTE GENERALIZED EXANTHEMIC PUSTULOSIS

Antibiotics: penicillins, macrolides, cephalosporins, clindamycin, imipenem, fluoroquinolones, isoniazid, vancomycin, minocycline, doxycycline, linezolid

Antimalarials: chloroquine, hydroxychloroquine

Antifungals: terbinafine, nystatin

Anticonvulsants: carbamazepine

Calcium-channel blockers

Furosemide

Systemic corticosteroids

Protease inhibitors

COLLAGEN VASCULAR OR LUPUS-LIKE REACTIONS

Procainamide, hydralazine, phenytoin, penicillamine, trimethadione, methyldopa, carbamazepine, griseofulvin, nalidixic acid, oral contraceptives, propranolol

ERYTHEMA NODOSUM

Oral contraceptives, penicillin, sulfonamides, diuretics, gold, clonidine, propranolol, opiates

FIXED DRUG REACTIONS

Phenolphthalein, barbiturates, gold, sulfonamides, meprobamate, penicillin, tetracycline, analgesics

See Chapter 664 and Table 664.3 .

From Duvic M: Urticaria, drug hypersensitivity rashes, nodules and tumors, and atrophic diseases. In Goldman L, Schafer AI, editors: Goldman-Cecil medicine, ed 25, Philadelphia, 2016, Elsevier, Table 440.3.

Pathogenesis and Clinical Manifestations

Immunologically mediated ADRs have been classified according to the Gell and Coombs classification: immediate hypersensitivity reactions (**type I**), cytotoxic antibody reactions (**type II**), immune complex reactions (**type III**), and delayed-type hypersensitivity reactions (**type IV**). **Immediate hypersensitivity reactions** occur when a drug or drug metabolite interacts with preformed drug-specific IgE antibodies that are bound to the surfaces of tissue mast cells and/or circulating basophils. The cross-linking of adjacent receptor-bound IgE by antigen causes the release of preformed and newly synthesized mediators, such as histamine and leukotrienes, that contribute to the clinical development of urticaria, bronchospasm, or anaphylaxis. **Cytotoxic antibody reactions** involve IgG or IgM antibodies that recognize drug antigen on the cell membrane. In the presence of serum complement, the antibody-coated cell is either cleared by the monocyte-macrophage system or is destroyed. Examples are drug-induced hemolytic anemia and thrombocytopenia. **Immune complex reactions** are caused by soluble complexes of drug or metabolite in slight antigen excess with IgG or IgM antibodies. The immune complex is deposited in blood vessel walls and causes injury by activating the complement cascade, as seen in serum sickness. Clinical manifestations include fever, urticaria, rash, lymphadenopathy, and arthralgias. Symptoms typically appear 1-3 wk after the last dose of an offending drug and subside when the drug and/or its metabolite is cleared from the body. **Delayed-type hypersensitivity reactions** are mediated by drug-specific T lymphocytes. Sensitization usually occurs by the topical route of administration, resulting in allergic contact dermatitis. Commonly implicated drugs include neomycin and local anesthetics in topical formulations.

Certain ADRs, including drug fever and the morbilliform rash seen with use of ampicillin or amoxicillin in the setting of Epstein-Barr virus (EBV) infection, are not easily classified. Studies point to the role of T cells and eosinophils in delayed maculopapular reactions to a number of antibiotics. The mechanisms of T-cell–mediated drug hypersensitivity are not well understood. A novel hypothesis, the **p-i concept** , suggests pharmacologic interactions of drugs with immune receptors as another class of drug hypersensitivity. In T-cell–mediated allergic drug reactions, the specificity of the T-cell receptor (TCR) that is stimulated by the drug may be directed to a cross-reactive major histocompatibility complex (MHC)–peptide compound. This information suggests that even poorly reactive native drugs are capable of transmitting a stimulatory signal through the TCR, which activates T cells and results in proliferation, cytokine production, and cytotoxicity. Previous contact with the causative drug is not obligatory, and an immune mechanism should be considered as the cause of hypersensitivity, even in reactions that occur with first exposure. Such reactions have been described for radiocontrast media and neuromuscular blocking agents.

Drug Metabolism and Adverse Reactions

Most drugs and their metabolites are not immunologically detectable until they have become covalently attached to a macromolecule. This multivalent hapten-protein complex forms a new immunogenic epitope that can elicit T- and B-lymphocyte responses. The penicillins and related β-lactam antibiotics are highly reactive with proteins and can directly haptenate protein carriers, possibly accounting for the frequency of immune-mediated hypersensitivity reactions with this class of antibiotics.

Incomplete or delayed metabolism of some drugs can give rise to toxic metabolites. Hydroxylamine, a reactive metabolite produced by cytochrome P450 oxidative metabolism, may mediate adverse reactions to sulfonamides. Patients who are *slow acetylators* appear to be at increased risk (see Chapter 72). In addition, cutaneous reactions in patients with AIDS treated with TMP/SMX, rifampin, or other drugs may be caused by glutathione deficiency resulting in toxic metabolites. Serum sickness–like reactions in which immune complexes have not been documented, which occur most often with cefaclor, may result from an inherited propensity for hepatic biotransformation of drugs into toxic or immunogenic metabolites.

Risk Factors for Hypersensitivity Reactions

Risk factors for ADRs include prior exposure, previous reactions, age (20-49 yr), route of administration (parenteral or topical), dose (high), and dosing schedule (intermittent), as well as genetic predisposition (slow acetylators). Atopy does not appear to predispose patients to allergic reactions to low-molecular-weight compounds, but atopic patients in whom an allergic reaction develops have a significantly increased risk of serious reaction. Atopic patients also appear to be at greater risk for pseudoallergic reactions induced by radiocontrast media. Pharmacogenomics has an important role in identifying individuals at risk for certain drug reactions (see Chapter 72).

Diagnosis

An accurate medical history is an important first step in evaluating a patient with a possible ADR. Suspected drugs need to be identified, along with dosages, route of administration, previous exposures, and dates of administration. In addition, underlying hepatic or renal disease may influence drug metabolism. A detailed description of past reactions may yield clues to the nature of the ADR. The propensity for a particular drug to cause the suspected reaction can be checked with information in *Physicians' Desk Reference, Drug Eruption Reference Manual,* or directly from the drug manufacturer. It is important to remember, however, that the history may be unreliable, and many patients are inappropriately labeled as being “drug allergic.” This label can result in inappropriate withholding of a needed drug or class of drugs. In addition, relying solely on the history can lead to overuse of drugs reserved for special indications, such as vancomycin in patients in whom penicillin allergy is suspected. *Approximately 90% of patients with a clinical history of penicillin allergy do not have evidence of penicillin-specific IgE antibodies on testing.*

Skin testing is the most rapid and sensitive method of demonstrating the presence of *IgE antibodies* to a specific allergen. It can be performed with high-molecular-weight compounds, such as foreign antisera, hormones, enzymes, and toxoids. Reliable skin testing can also be performed with penicillin, but not with most other antibiotics. Most immunologically mediated ADRs are caused by metabolites rather than by parent compounds, and the metabolites for most drugs other than penicillin have not been defined. In addition, many metabolites are unstable or must combine with larger proteins to be useful for diagnosis. Testing with nonstandardized reagents requires caution in interpretation of both positive and negative results, because some drugs can induce nonspecific irritant reactions. Whereas a wheal and flare reaction is suggestive of drug-specific IgE antibodies, a negative skin test result does not exclude the presence of such antibodies because the relevant immunogen may not have been used as the testing reagent.

A positive skin test response to the major or minor determinants of penicillin has a 60% positive predictive value (PPV) for an immediate hypersensitivity reaction to penicillin. In patients in whom skin test responses to the major and minor determinants of penicillin are negative, 97–99% (depending on the reagents used) tolerate the drug without an immediate reaction. At present, the major determinant of penicillin testing reagent benzylpenicilloyl polylysine (Pre-Pen) in the United States is available, but the minor determinant mixture has not been FDA approved as a testing reagent. Limited studies utilizing serum tests for IgE to β-lactams suggest high specificity (97–100%) but low sensitivity (29–68%). The PPV and negative predictive value (NPV) of skin testing for antibiotics other than penicillin are not well established. Nevertheless, positive immediate hypersensitivity skin test responses to nonirritant concentrations of nonpenicillin antibiotics may be interpreted as a presumptive risk of an immediate reaction to such agents.

Results of direct and indirect Coombs tests are often positive in drug-induced hemolytic anemia. Assays for specific IgG and IgM have been shown to correlate with a drug reaction in immune cytopenia, but in most other reactions, such assays are not diagnostic. In general, many more patients express humoral or T-cell immune responses to drug determinants than express clinical disease. Serum **tryptase** is elevated with systemic mast cell degranulation and can be seen with drug-associated mast cell activation, although it is not pathognomonic for drug hypersensitivity, and nonelevated tryptase values can be seen in well-defined anaphylaxis. **Patch testing** is the most reliable technique for diagnosis of contact dermatitis caused by topically applied drugs. **Graded challenge** is the administration of a drug under medical supervision in an incremental fashion dosed faster than used for desensitization (see later) until a therapeutic dose is achieved. This can be attempted when the risk of reactions are judged to be low, and is a means to prove that the drug is tolerated or to identify an adverse or allergic reaction.

Treatment

Specific **desensitization** , which involves the progressive administration of an allergen to render effector cells less reactive, is reserved for patients with IgE antibodies to a particular drug for whom an alternative drug is not available or appropriate. Specific protocols for many different drugs have been developed. Desensitization should be performed in a hospital setting, usually in consultation with an allergist and with resuscitation equipment available at all times. Although mild complications, such as pruritus and rash, are fairly common and often respond to adjustments in the drug dose or dosing intervals and medications to relieve symptoms, more severe systemic reactions can occur. Oral desensitization may be less likely to induce anaphylaxis than parenteral administration. Protocols for gradual exposure are also used for adverse reaction to drugs that are not IgE mediated, for example for aspirin- or nonsteroidal antiinflammatory drug (NSAID)–intolerant patients, particularly those with respiratory reactions and those with mild rashes from TMP/SMX. Pretreatment with antihistamines or corticosteroids is not usually recommended. It is important to recognize that desensitization to a drug is effective only while the drug continues to be administered, and that after a period of interruption or discontinuation, hypersensitivity can recur. Patients with severe non–IgE-mediated hypersensitivity reactions should not receive the predisposing agents even in the small amounts used for skin testing (see Table 177.2).

β-Lactam Hypersensitivity

Penicillin is a frequent cause of anaphylaxis and is responsible for the majority of all drug-mediated anaphylactic deaths in the United States. If a patient requires penicillin and has a previous history suggestive of penicillin allergy, it is necessary to perform skin tests on the patient for the presence of penicillin-specific IgE, ideally with both the major and minor determinants of penicillin. Skin tests for minor determinants of penicillin are important because approximately 20% of patients with documented anaphylaxis do not demonstrate skin reactivity to the major determinant. The major determinant is commercially available (Pre-Pen). The minor determinant mixture is currently not licensed and is synthesized as a nonstandardized testing reagent at select academic centers. Penicillin G is often used as a substitute for the minor determinant mixture and may have NPV similar to testing with major and minor determinants. Patients should be referred to an allergist capable of performing appropriate testing. If the skin test response is positive to either major or minor determinants of penicillin, the patient should receive an alternative non–cross-reacting antibiotic. If administration of penicillin is deemed necessary, desensitization can be performed by an allergist in an appropriate medical setting. Skin testing for penicillin-specific IgE is not predictive for delayed-onset cutaneous, bullous, or immune complex reactions. In addition, penicillin skin testing does not appear to resensitize the patient.

Other β-lactam antibiotics, including semisynthetic penicillins, cephalosporins, carbacephems, and carbapenems, share the β-lactam ring structure. Patients with late-onset morbilliform rashes with amoxicillin are not considered to be at risk for IgE-mediated reactions to penicillin and do not require skin testing before penicillin administration. Many patients with EBV infections treated with ampicillin or amoxicillin can experience a nonpruritic rash. Similar reactions occur in patients who receive allopurinol as treatment for elevated uric acid or have chronic lymphocytic leukemia. If the rash to ampicillin or amoxicillin is urticarial or systemic or the history is unclear, the patient should undergo penicillin skin testing if a penicillin is needed. There have been reports of antibodies specific for semisynthetic penicillin side chains in the absence of β-lactam ring–specific antibodies, although the clinical significance of such side chain–specific antibodies is unclear.

Varying degrees of in vitro cross-reactivity have been documented between *cephalosporins* and penicillins. Although the risk of allergic reactions to cephalosporins in patients with positive skin test responses to penicillin appears to be low (<2%), anaphylactic reactions have occurred after administration of cephalosporins in patients with a history of penicillin anaphylaxis. If a patient has a history of penicillin allergy and requires a cephalosporin, skin testing for major and minor determinants of penicillin should preferably be performed to determine whether the patient has penicillin-specific IgE antibodies. If skin test results are negative, the patient can receive a cephalosporin with no greater risk than found in the general population. If skin test results are positive for penicillin, recommendations may include administration of an alternative antibiotic; cautious graded challenge with appropriate monitoring, with the recognition that there is a 2% chance of inducing an anaphylactic reaction; and desensitization to the required cephalosporin. Cross-reactivity is most likely when the cephalosporin shares the same side chain as the penicillin (Table 177.3).

Table 177.3

Groups of β-Lactam Antibiotics That Share Identical R1-Group Side Chains*

Amoxicillin	Ampicillin	Ceftriaxone	Cefoxitin	Cefamandole	Ceftazidime
Cefadroxil	Cefaclor	Cefotaxime	Cephaloridine	Cefonicid	Aztreonam
Cefprozil	Cephalexin	Cefpodoxime	Cephalothin		
Cefatrizine	Cephradine	Cefditoren			
	Cephaloglycin	Ceftizoxime			
	Loracarbef	Cefmenoxime			

* Each column represents a group with identical R1 side chains.

From Solensky R, Khan DA: Drug allergy: an updated practice parameter, *Ann Allergy Asthma Immunol* 105:273e1–273e78, 2010 (Table 16, p 273e49).

Conversely, patients who require penicillin and have a history of an IgE-mediated reaction to a cephalosporin should also undergo penicillin skin testing. Patients with a negative result can receive penicillin. Patients with a positive result should either receive an alternative medication or undergo desensitization to penicillin. In patients with a history of allergic reaction to one cephalosporin who require another cephalosporin, skin testing with the required cephalosporin can be performed, with the recognition that the NPV of such testing is unknown. If the skin test response to the cephalosporin is positive, the significance of the test should be checked further in controls to determine whether the positive response is IgE mediated or an irritant response. The drug can then be administered by graded challenge or desensitization.

Carbapenems (imipenem, meropenem) represent another class of β-lactam antibiotics with a bicyclic nucleus that demonstrate a high degree of cross-reactivity with penicillins, although prospective studies suggest incidence of cross-reactivity on skin testing of approximately 1%. In contrast to β-lactam antibiotics, *monobactams* (aztreonam) have a monocyclic ring structure. Aztreonam-specific antibodies have been shown to be predominantly side chain-specific; data suggest that aztreonam can be safely administered to most penicillin-allergic patients. On the other hand, administration of aztreonam to a patient with ceftazidime allergy may be associated with increased risk of allergic reaction because of the similarity of side chains.

Sulfonamides

The most common type of reaction to sulfonamides is a maculopapular eruption often associated with fever that occurs after 7-12 days of therapy. Immediate reactions, including anaphylaxis, as well as other immunologic reactions, have also been suggested. Hypersensitivity reactions to sulfonamides occur with much greater frequency in HIV-infected individuals. For patients in whom maculopapular rashes develop after sulfonamide administration, both graded challenge and desensitization protocols have been shown to be effective. These regimens should not be used in individuals with a history of Stevens-Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN). Hypersensitivity reactions to *sulfasalazine* used for treatment of inflammatory bowel disease appear to result from the sulfapyridine moiety. Slow desensitization over about 1 mo permits tolerance of the drug in many patients. In addition, oral and enema forms of 5-aminosalicylic acid, thought to be the pharmacologically active agent in sulfasalazine, are effective alternative therapies.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Blistering mucocutaneous disorders induced by drugs encompass a spectrum of reactions, including SJS and TEN (see Chapters 673.2 and 673.3). While their pathophysiology remains incompletely understood, HLA associations including

HLA-B*1502 with carbamazepine-induced TEN have been recognized, and the pathogenic roles of drug-specific cytotoxic T cells and granulysin have been reported. Epidermal detachment of <10% is suggestive of SJS, 30% detachment suggests TEN, and 10–30% detachment suggests overlap of the 2 syndromes. The features of SJS include confluent purpuric macules on face and trunk and severe, explosive mucosal erosions, usually at more than 1 mucosal surface, accompanied by fever and constitutional symptoms. Ocular involvement may be particularly severe, and the liver, kidneys, and lungs may also be involved. TEN, which appears to be related to keratinocyte apoptosis, manifests as widespread areas of confluent erythema followed by epidermal necrosis and detachment with severe mucosal involvement. Skin biopsy differentiates subepidermal cleavage characteristic of TEN from intraepidermal cleavage characteristic of the scalded-skin syndrome induced by staphylococcal toxins. The risks of infection and mortality remain high, but improved outcomes have been demonstrated by immediate withdrawal of the implicated drug, early transfer to an intensive care or burn unit, and aggressive supportive care. Additional management is reviewed in Chapter 673.3 .

Hypersensitivity to Antiretroviral Agents

A growing number of ADRs have been observed with antiretroviral agents, including reverse-transcriptase inhibitors, protease inhibitors, and fusion inhibitors. Hypersensitivity to abacavir is a well-recognized, multiorgan, potentially life-threatening reaction that occurs in HIV-infected children. The reaction is independent of dose, with onset generally within 9-11 days of initiation of drug therapy. Rechallenge can be accompanied by significant hypotension and potential mortality (rate of 0.03%), and thus hypersensitivity to abacavir is an absolute contraindication for any subsequent use. Prophylaxis with prednisolone does not appear to prevent hypersensitivity reactions to abacavir. Importantly, genetic susceptibility appears to be conferred by the HLA-B*5701 allele, with a PPV >70% and NPV of 95–98%. Genetic screening would be cost-effective in white populations but not in populations of African or Asian descent, in which HLA-B*5701 allele frequency is <1%.

Chemotherapeutic Agents

Hypersensitivity reactions to chemotherapeutic drugs have been described, including to monoclonal antibodies. Rapid desensitization to a variety of unrelated agents, including carboplatin, paclitaxel, and rituximab, can be safely achieved in a 12-step protocol. Of note, this approach appears to be successful in both IgE-mediated and non–IgE-mediated reactions.

Biologics

An increasing number of biologic agents have become available for the treatment of autoimmune, allergic, cardiovascular, infectious, and neoplastic diseases. Their use may be associated with a variety of ADRs, including hypersensitivity reactions. Given the occurrence of anaphylaxis, including cases with delayed onset and protracted progression in spontaneous postmarketing adverse event reports, the FDA issued a black box warning regarding risk of anaphylaxis and need for patient monitoring with use of omalizumab (see Chapter 169).

Vaccines

Allergy to vaccines may occur from reactivity to various vaccine components. Measles-mumps-rubella (MMR) vaccine has been shown to be safe in egg-allergic patients (although rare reactions to gelatin or neomycin can occur). The ovalbumin content in influenza vaccine is extremely low. Skin testing with the influenza vaccine is not recommended for egg-allergic patients but may be helpful if allergy to the vaccine itself is suspected. Egg-allergic patients do not appear to be at higher risk of reacting to the influenza vaccine than those without egg allergy, and they may receive it in the usual manner with the same 15-min waiting period suggested for other vaccinations and in a medical setting prepared to treat anaphylaxis.

Perioperative Agents

Anaphylactoid (non–IgE-mediated anaphylaxis) reactions occurring during general anesthesia may be caused by induction agents (thiopental) or muscle-relaxing agents (succinylcholine, pancuronium). Quaternary ammonium muscle relaxants (succinylcholine) can act as bivalent antigens in IgE-mediated reactions. Negative skin test results do not necessarily predict that a drug will be tolerated. Latex allergy should always be considered in the differential diagnosis of a perioperative reaction.

Local Anesthetics

ADRs associated with local anesthetic agents are primarily toxic reactions resulting from rapid drug absorption, inadvertent intravenous (IV) injection, or overdose. Local anesthetics are classified as esters of benzoic acid (group I) or amides (group II). Group I includes benzocaine and procaine; group II includes lidocaine, bupivacaine, and mepivacaine. In suspected local anesthetic allergy, skin testing followed by a graded challenge can be performed or an anesthetic agent from a different group can be used.

Insulin

Insulin use has been associated with a spectrum of ADRs, including local and systemic IgE-mediated reactions, hemolytic anemia, serum sickness reactions, and delayed-type hypersensitivity. In general, human insulin is less allergenic than porcine insulin, which is less allergenic than bovine insulin, but for individual patients, porcine or bovine insulin may be the least allergenic. Patients treated with nonhuman insulin have had systemic reactions to recombinant human insulin even on the first exposure. More than 50% of patients who receive insulin develop antibodies against the insulin preparation, although there may not be any clinical manifestations. Local cutaneous reactions usually do not require treatment and resolve with continued insulin administration, possibly because of IgG-blocking antibodies. More severe local reactions can be treated with antihistamines or by splitting the insulin dose between separate administration sites. Local reactions to the protamine component of neutral protamine Hagedorn insulin may be avoided by switching to Lente insulin. Immediate-type reactions to insulin, including urticaria and anaphylactic shock, are unusual and almost always occur after reinstitution of insulin therapy in sensitized patients.

Insulin therapy should not be interrupted if a systemic reaction to insulin occurs, and continued insulin therapy is essential. Skin testing may identify a less antigenic insulin preparation. The dose following a systemic reaction is usually reduced to one-third, and successive doses are increased in 2-5 unit increments until the dose resulting in glucose control is attained. Insulin skin testing and desensitization are required if insulin treatment is subsequently interrupted for >24-48 hr.

Immunologic resistance usually occurs when high titers of predominantly IgG antibodies to insulin develop. A rare form of insulin resistance caused by circulating antibodies to tissue insulin receptors is associated with acanthosis nigricans and lipodystrophy. Coexisting insulin allergy may be present in up to one third of patients with insulin resistance. Approximately half of affected patients benefit from substitution with a less reactive insulin preparation, based on skin testing.

Drug-Induced Hypersensitivity Syndrome

Drug-induced hypersensitivity syndrome, or **DRESS** (drug rash with eosinophilia and systemic symptoms) syndrome, is a potentially life-threatening syndrome that has been described primarily with anticonvulsants, although many other medications have been implicated (see Tables 177.1 and 177.2). It is characterized by fever, maculopapular rash, facial edema, eosinophilia, generalized lymphadenopathy, and potentially life-threatening damage of one or more organs, usually renal or hepatic. Onset is delayed, usually weeks after initiation of the medication. It has been associated with reactivation of human herpesvirus 6. Treatment is withdrawal of the medication, systemic steroids, and supportive care, but symptoms can worsen or persist for weeks to months after the drug has been discontinued.

Red Man Syndrome

Red man syndrome is caused by nonspecific histamine release and is most often described with administration of IV vancomycin. It can be prevented by slowing the vancomycin infusion rate or by preadministration of H_1 -receptor blockers.

Radiocontrast Media

Anaphylactoid reactions to radiocontrast media or dye can occur after intravascular administration and during myelograms or retrograde pyelograms. No single pathogenic mechanism has been defined, but it is likely that mast cell activation accounts for the majority of these reactions. Complement activation has also been described. There is no evidence that sensitivity to seafood or iodine predisposes to radiocontrast media reactions. Predictive tests are not available. Patients who have atopic profiles, who are taking β-blockers, and who have had prior anaphylactoid reactions are at increased risk. Other diagnostic alternatives should be considered, or patients can be given low-osmolality radiocontrast media with a pretreatment regimen including oral prednisone, diphenhydramine, and albuterol, with or without cimetidine or ranitidine.

Narcotic Analgesics

Opiates such as morphine and related narcotics can induce direct mast cell degranulation. Patients may experience generalized pruritus, urticaria, and occasionally, wheezing. If there is a suggestive history and analgesia is required, a nonnarcotic medication should be considered. If this intervention does not control pain, graded challenge with an alternative opiate is an option.

Aspirin and Nonsteroidal Antiinflammatory Drugs

Aspirin and NSAIDs can cause anaphylactoid reactions or urticaria and angioedema in children and, rarely, asthma with or without rhinoconjunctivitis in adolescents. There is no skin or in vitro test to identify patients who may react to aspirin or other NSAIDs. Once aspirin or NSAID intolerance has been established, options include avoidance and pharmacologic desensitization and subsequent continued treatment with aspirin or NSAIDs, if indicated. A number of studies suggest that cyclooxygenase-2 inhibitors are tolerated by the majority of patients with NSAID-induced adverse reactions.

CHAPTER 178

Evaluation of Suspected Rheumatic Disease

C. Egla Rabinovich

Rheumatic diseases are defined by the constellation of results of the physical examination, autoimmune marker and other serologic tests, tissue pathology, and imaging. Defined diagnostic criteria exist for most rheumatic diseases. Recognition of clinical patterns remains essential for diagnosis because there is no single diagnostic test, and results may be positive in the absence of disease. Further complicating the diagnosis, children sometimes present with partial criteria that evolve over time or with features of more than one rheumatic disease (**overlap syndromes**). The primary mimics of rheumatic diseases are **infection** and **malignancy** but also include metabolic, orthopedic, immune deficiencies, autoinflammatory diseases, and chronic pain conditions. Exclusion of possible mimicking disorders is essential before initiation of treatment for a presumptive diagnosis, especially corticosteroids. After careful evaluation has excluded nonrheumatic causes, referral to a pediatric rheumatologist for confirmation of the diagnosis and treatment should be considered.

Symptoms Suggestive of Rheumatic Disease

There are no classic symptoms of a rheumatic disease, but common symptoms include joint pain, fever, fatigue, and rash. Presenting signs and symptoms help direct the evaluation and limit unnecessary testing. Once a differential diagnosis is developed on the basis of history and physical findings, a directed assessment assists in determining the diagnosis.

Arthralgias are common in childhood and are a frequent reason for referral to pediatric rheumatologists. Arthralgias without physical findings for arthritis suggest infection, malignancy, orthopedic conditions, benign syndromes, or pain syndromes such as fibromyalgia (Table 178.1). Although rheumatic diseases may manifest as arthralgias, **arthritis** is a stronger predictor of the presence of rheumatic disease and a reason for referral to a pediatric rheumatologist. The timing of joint pain along with associated symptoms, including poor sleep and interference with normal activities, provides important clues. Poor sleep, debilitating generalized joint pain that worsens with activity, school absences, and normal physical and laboratory findings in an adolescent suggest a **pain syndrome** (e.g., fibromyalgia). If arthralgia is accompanied by a history of dry skin, hair loss, fatigue, growth disturbance, or cold intolerance, testing for **thyroid disease** is merited. Nighttime awakenings because of severe pain along with decreased platelet or white blood cell count or, alternatively, a very high WBC count, may lead to the diagnosis of malignancy, especially marrow-occupying lesions such as **acute lymphocytic leukemia** and **neuroblastoma** . Pain with physical activity suggests a mechanical problem such as an overuse syndrome or orthopedic condition. An adolescent girl presenting with knee pain aggravated by walking up stairs and on patellar distraction likely has **patellofemoral syndrome** . Children age 3-10 yr who have a history of episodic pain that occurs at night after increased daytime physical activity that is relieved by rubbing, but who have no limp or complaints in the morning, likely have **growing pains** . There is often a positive family history for growing pains, which may aid in this diagnosis. Intermittent pain in a child, especially a girl 3-10 yr old, that is increased with activity and is associated with hyperextensible joints on examination, is likely **benign hypermobility syndrome** . Many febrile illnesses cause arthralgias that improve when the temperature normalizes, and arthralgias are part of the diagnostic criteria for **acute rheumatic fever** (**ARF** ; see Chapter 210.1).

Table 178.1

Symptoms Suggestive of Rheumatic Disease

SYMPTOM	RHEUMATIC DISEASE(S)	POSSIBLE NONRHEUMATIC DISEASES CAUSING SIMILAR SYMPTOMS
Fevers	Systemic JIA, SLE, vasculitis, acute rheumatic fever, sarcoidosis, MCTD	Malignancies, infections and postinfectious syndromes, inflammatory bowel disease, periodic fever (autoinflammatory) syndromes, Kawasaki disease, HSP
Arthralgias	JIA, SLE, rheumatic fever, JDM, vasculitis, scleroderma,	Hypothyroidism, trauma, endocarditis, other infections, pain syndromes, growing pains, malignancies, overuse syndromes

	sarcoidosis	
Weakness	JDM, myositis secondary to SLE, MCTD, and deep localized scleroderma	Muscular dystrophies, metabolic and other myopathies, hypothyroidism
Chest pain	Juvenile idiopathic arthritis, SLE (with associated pericarditis or costochondritis)	Costochondritis (isolated), rib fracture, viral pericarditis, panic attack, hyperventilation
Back pain	Enthesitis-related arthritis, juvenile ankylosing spondylitis	Vertebral compression fracture, diskitis, intraspinal tumor, spondylolysis, spondylolisthesis, bone marrow–occupying malignancy, pain syndromes, osteomyelitis, muscle spasm, injury
Fatigue	SLE, JDM, MCTD, vasculitis, JIA	Pain syndromes, chronic infections, chronic fatigue syndrome, depression

HSP, Henoch-Schönlein purpura; JDM, juvenile dermatomyositis; JIA, juvenile idiopathic arthritis; MCTD, mixed connective tissue disease; SLE, systemic lupus erythematosus.

Arthralgia may also be a presenting symptom of pediatric **systemic lupus erythematosus** (**SLE**) and chronic childhood arthritis such as **juvenile idiopathic arthritis (JIA).** Interestingly, many children with JIA do not complain of joint symptoms at presentation. Other symptoms more suggestive of arthritis include morning stiffness, joint swelling, limited range of motion, pain with joint motion, gait disturbance, fever, and fatigue or stiffness after physical inactivity *(gelling phenomenon)* . A diagnosis of JIA cannot be made without the finding of arthritis on physical examination (see Chapters 180 and 181). No laboratory test is diagnostic of JIA or any other chronic inflammatory arthritis in childhood.

Fatigue is a nonspecific symptom that may point to the presence of a rheumatic disease but is also common in nonrheumatic causes, such as viral infections, pain syndromes, depression, and malignancy. Fatigue, rather than the specific complaints of muscle weakness, is a common presenting complaint in **juvenile dermatomyositis (JDM)** . It is also frequently present in SLE, vasculitis, and the chronic childhood arthritides. Overwhelming fatigue with inability to attend school is more suggestive of chronic fatigue syndrome, pediatric fibromyalgia, or other amplified pain syndrome.

Signs Suggestive of Rheumatic Disease

A complete physical examination is mandated in any child with suspected rheumatic disease, because many diseases have associated subtle physical findings that will further refine the differential diagnosis. In addition, many rheumatic diseases have multisystem effects, and a stepped assessment should focus on delineating the extent of organ system involvement (e.g., skin, joints, muscle, hepatic, renal, cardiopulmonary).

Presence of a **photosensitive malar rash** that spares the nasolabial folds is suggestive of SLE (Table 178.2 ; see Fig. 183.1*A*), especially in an adolescent girl. Diffuse facial rash is more indicative of JDM. A hyperkeratotic rash on the face or around the ears of an adolescent black girl may represent discoid lupus (see Fig. 183.1*D*). A palpable purpuric rash on the extensor surfaces of the lower extremities points to **Henoch-Schönlein purpura** (see Fig. 192.2*A*). Less localized purpuric rashes and petechiae are present in systemic vasculitis or blood dyscrasias, including coagulopathies. Nonblanching erythematous papules on the palms are seen in vasculitis and SLE as well as endocarditis. Gottron papules (see Fig. 184.2) and heliotrope rashes (see Fig. 184.1) along with erythematous rashes on the elbows and knees are pathognomonic of JDM. Dilated capillary loops in the nail beds (periungual telangiectasias; see Fig. 184.3) are common in JDM, scleroderma, and secondary Raynaud phenomenon. An evanescent macular rash associated with fever is part of the diagnostic criteria for systemic-onset arthritis (see Fig. 180.12). Sun sensitivity or photosensitive rashes are indicative of SLE or JDM but can also be caused by antibiotics.

Table 178.2

Signs Suggestive of Rheumatic Disease

SIGN	RHEUMATIC DISEASES	COMMENTS	NONRHEUMATIC CAUSES
Malar rash	SLE, JDM	SLE classically spares nasolabial folds	Sunburn, parvovirus B19 (fifth disease), Kawasaki disease
Oral ulcers	SLE, Behçet disease	Behçet disease also associated with genital ulcers	HSV infection, PFAPA syndrome
Purpuric rash	Vasculitis, e.g., ANCA-associated vasculitis, HSP	HSP typically starts as small lesions on lower extremities and buttocks that coalesce	Meningococcemia, thrombocytopenia, clotting disorders
Gottron papules	JDM	Look for associated heliotrope rash, periungual telangiectasias	Psoriasis, eczema
Arthritis	Juvenile idiopathic arthritis, SLE, vasculitis, HSP, MCTD, scleroderma, acute rheumatic fever, reactive arthritis	Chronic joint swelling (>6 wk) required for diagnosis of chronic arthritis of childhood; MCTD associated with diffuse puffiness of hands	Postviral arthritis, reactive arthritis, trauma, infection, Lyme disease, Kawasaki disease, malignancy, overuse syndromes

ANCA, Antineutrophil cytoplasmic antibody; HSP, Henoch-Schönlein purpura; HSV, herpes simplex virus; JDM, juvenile dermatomyositis; MCTD, mixed connective tissue disease; PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and adenitis; SLE, systemic lupus erythematosus.

Mouth ulcers are part of the diagnostic criteria for SLE and Behçet disease (see Fig. 183.1*C*); painless nasal ulcers and erythematous macules on the hard palate are also common in SLE. Cartilage loss in the nose, causing a saddle nose deformity, is classically present in granulomatosis with polyangiitis (formally Wegener granulomatosis; see Fig. 192.8) but is also seen in relapsing polychondritis and syphilis. Alopecia can be associated with SLE but is also found in localized scleroderma (see Fig. 185.4) and JDM. **Raynaud phenomenon** may be a primary benign idiopathic disorder or can be a presenting complaint in the child with scleroderma, lupus, mixed connective tissue disease (MCTD), or an overlap syndrome. Diffuse lymphadenopathy is present in many rheumatic diseases, including SLE, polyarticular JIA, and systemic JIA. Irregular pupils may represent the insidious and unrecognized onset of **uveitis** associated with JIA. Erythematous conjunctivae may be a result of uveitis or episcleritis associated with JIA, SLE, sarcoidosis, spondyloarthropathies, or vasculitis.

A pericardial rub and orthopnea are suggestive of **pericarditis** , often seen in systemic JIA, SLE, and sarcoid. Coronary artery dilation is strongly suggestive of Kawasaki disease but may also be a finding in systemic arthritis and other forms of systemic vasculitis. Interstitial lung disease, suggested by dyspnea on exertion or the finding of basilar rales with decreased carbon monoxide diffusion capacity, occurs in SLE, MCTD, and systemic sclerosis. Signs consistent with pulmonary hemorrhage points to granulomatosis with polyangiitis, microscopic angiitis, or SLE. Pulmonary vascular aneurysms are indicative of Behçet disease.

Arthritis is defined by the presence of intraarticular swelling or 2 or more of the following findings on joint examination: pain on motion, loss of motion, erythema, and heat. Arthritis is present in all the chronic childhood arthritis syndromes, along with SLE, JDM, vasculitis, Behçet disease, sarcoidosis, Kawasaki disease, and Henoch-Schönlein purpura. Nonrheumatic causes of arthritis include malignancy, septic arthritis, Lyme disease, osteomyelitis, viral infections (e.g., rubella, hepatitis B, parvovirus B19, chikungunya), and postinfectious etiologies such as Epstein-Barr virus (EBV), ARF, and reactive arthritis. ARF typically involves a migratory (lasting hours to days), painful arthritis. Pain on palpation of long bones is suggestive of malignancy. Specific muscle testing for weakness should be performed in a child presenting with fatigue or difficulty with daily tasks, because both these symptoms may be manifestations of muscle inflammation.

Laboratory Testing

There are no specific screening tests for rheumatologic disease. Once a differential diagnosis is determined, appropriate testing can be performed (Tables 178.3 and 178.4). Initial studies are generally performed in standard local laboratories. Screening for specific autoantibodies can be performed in commercial laboratories, but confirmation of results in a tertiary care center immunology laboratory is often necessary.

Table 178.3

Autoantibody Specificity and Disease Associations

ANTIBODY	DISEASE	PREVALENCE (%)	SPECIFICITY
Antinuclear antibody (ANA)	SLE, juvenile rheumatoid arthritis, dermatomyositis, scleroderma, psoriatic arthritis, MCTD	—	Associated with increased risk of uveitis in JIA and psoriatic arthritis Up to 30% of children testing positive for ANAs have no underlying rheumatic disease
Double-stranded DNA (dsDNA)	SLE	60-70	High specificity for SLE; associated with lupus nephritis
Smith (Sm)	SLE	20-30	Highly specific for SLE; associated with lupus nephritis
Smooth muscle (Sm)	Autoimmune hepatitis	—	—
Pm-Scl (polymyositis-scleroderma)	Sclerodermatomyositis	—	—
SSA (Ro)	SLE, Sjögren syndrome	25-30	Associated with neonatal lupus syndrome, subacute cutaneous lupus, thrombocytopenia
SSB (La)	SLE, Sjögren syndrome	25-30	Usually coexists with anti-SSA antibody
Ribonuclease protein (RNP)	MCTD, SLE	30-40	Suggestive of MCTD unless meets criteria for SLE
Histone	Drug-induced lupus, SLE	—	—
Centromere	Limited cutaneous systemic sclerosis	70	Nonspecific for systemic sclerosis
Topoisomerase I (Scl-70)	Systemic sclerosis	—	Rare in childhood
Antineutrophil cytoplasmic antibodies (ANCAs)	Vasculitis	—	—
Cytoplasmic (cANCAs)/PR3-ANCA		—	cANCAs associated with granulomatosis with polyangiitis (Wegener), cystic fibrosis
Perinuclear (pANCAs)/MPO-ANCA		—	pANCAs associated with microscopic polyangiitis, polyarteritis nodosa, SLE, inflammatory bowel disease, cystic fibrosis,

			primary sclerosing cholangitis, Henoch-Schönlein purpura, Kawasaki disease, Churg-Strauss syndrome
Anticitrullinated protein (ACPA); also called anti–cyclic citrullinated protein (anti-CCP)	RF-positive JIA	50-90	Specific for JIA (RF+), may be positive before RF

MCTD, Mixed connective tissue disease; MPO-ANCA, antimyeloperoxidase; PR3-ANCA, antiproteinase 3; RF, rheumatoid factor; SLE, systemic lupus erythematosus.

Adapted from Aggerwal A: Clinical application of tests used in rheumatology, *Indian J Pediatr* 69:889–892, 2002.

Table 178.4

Evaluation Based on Suspected Diagnosis of Rheumatic Disease

SUSPECTED RHEUMATIC DISEASE(S)	INITIAL EVALUATION	FURTHER EVALUATION	SUBSPECIALTY EVALUATION
Systemic lupus erythematosus (SLE) Mixed connective tissue disease (MCTD)	CBC, ESR, ANA, ALT, AST, CPK, creatinine, albumin, total protein, urinalysis, BP, thyroid profile	If ANA test result is positive: anti-SSA (Ro), anti-SSB (La), anti-Smith, and anti-RNP Abs; anti-dsDNA Ab, C3, C4, Coombs, spot urine protein/creatinine ratio, CXR	Antiphospholipid Abs, lupus anticoagulant, anti–β_2 -glycoprotein, echocardiogram; consider renal biopsy, PFTs, bronchoscopy with lavage, HRCT of chest; consider lung biopsy
Juvenile dermatomyositis (JDM)	CBC, CPK, ALT, AST, LDH, aldolase, ANA; check gag reflex	Consider MRI of muscle	Consider electromyography and possible muscle biopsy, PFTs, swallowing study, serum neopterin
Juvenile idiopathic arthritis (JIA)	CBC, ESR, creatinine, ALT, AST, consider anti–streptolysin O/anti–DNAase B for streptococcus-induced arthritis, Epstein-Barr virus titers, Lyme titer, parvovirus B19 titer, plain radiograph of joints	Consider Ab titers to unusual infectious agents, purified protein derivative, RF, ANA, HLA-B27, anti-CCP	MRI
Granulomatosis with polyangiitis (Wegener granulomatosis)	CBC, ANCA, AST, ALT, albumin, creatinine, ESR, urinalysis, CXR, BP	Spot urine protein/creatinine ratio, anti–myeloperoxidase and anti–proteinase-3 Abs, PFTs	Bronchoscopy with lavage, HRCT chest; consider lung and kidney biopsies
Sarcoidosis	CBC, electrolytes, AST, ALT, albumin, creatinine, calcium, phosphorous, ACE, BP	CXR, PFTs	Consider testing for Blau syndrome in infants (see Chapter 184); HRCT of chest; consider renal and lung biopsy

Localized scleroderma	Skin biopsy, CBC, ESR		Serum IgG, ANA, RF, single-stranded DNA Ab, antihistone Ab, CPK
Systemic scleroderma	ANA, CBC, ESR, BP, AST, ALT, CPK, creatinine, CXR	Anti-Scl70, PFTs	HRCT of chest, echocardiogram, upper GI radiography series

Ab, Antibody; ACE, angiotensin-converting enzyme (normally elevated in childhood; interpret with caution); ALT, alanine transaminase; ANA, antinuclear antibody; anti-dsDNA Ab, anti–double-stranded DNA antibody; AST, aspartate transaminase; BP, blood pressure; CBCD, complete blood count with differential; CCP, cyclic citrullinated protein; CPK, creatine phosphokinase; CXR, chest radiograph; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; HRCT, high-resolution CT; LDH, lactate dehydrogenase; PFTs, pulmonary function tests; RF, rheumatoid factor; RNP, ribonucleoprotein.

One essential laboratory test for rheumatic disease assessment is the *complete blood count* (CBC), since it yields many diagnostic clues. Elevated WBC count is compatible with malignancy, infection, systemic JIA, and vasculitis. Leukopenia can be postinfectious, especially viral, or caused by SLE or malignancy. Lymphopenia is more specific for SLE than is leukopenia. Platelets are acute-phase reactants and are therefore elevated with inflammatory markers. Exceptions are a bone marrow–occupying malignancy, such as leukemia or neuroblastoma, SLE, and early Kawasaki disease. **Anemia** is nonspecific and may be caused by any chronic illness, but hemolytic anemia (positive Coombs test result) may point to SLE or MCTD. Rheumatoid factor (RF) is present in <10% of children with JIA and thus has poor sensitivity as a diagnostic tool; RF may be elevated by infections such as endocarditis, tuberculosis, syphilis, and viruses (parvovirus B19, hepatitides B and C, mycoplasma), as well as primary biliary cirrhosis and malignancies. In a child with chronic arthritis, RF serves as a prognostic indicator.

Inflammatory markers (erythrocyte sedimentation rate, C-reactive protein) are nonspecific and are elevated in infections and malignancies as well as rheumatic diseases (Tables 178.5 and 178.6). Their levels may also be normal in rheumatic diseases such as arthritis, scleroderma, and dermatomyositis. Inflammatory marker measurements are more useful in rheumatic diseases for following response to treatment than as diagnostic tests. Muscle enzymes include aspartate transaminase (AST), alanine transaminase (ALT), creatinine phosphokinase (CPK), aldolase, and lactate dehydrogenase (LDH), any of which may be elevated in JDM as well as in other diseases causing muscle breakdown. Muscle-building supplements, medications, and extreme physical activity may also cause muscle breakdown and enzyme elevations. AST, ALT, and aldolase are also elevated secondary to liver disease, and a γ-glutamyltransferase (GGT) measurement may help differentiate whether the source is muscle or liver.

Table 178.5

Comparison of Erythrocyte Sedimentation Rate and C-Reactive Protein

	ERYTHROCYTE SEDIMENTATION RATE	C-REACTIVE PROTEIN
Advantages	Much clinical information in the literature May reflect overall health status	Rapid response to inflammatory stimuli Wide range of clinically relevant values are detectable Unaffected by age and gender Reflects value of a single acute-phase protein Can be measured on stored sera Quantitation is precise and reproducible
Disadvantages	Affected by red blood cell morphology Affected by anemia and polycythemia Reflects levels of many plasma proteins, not all of which are acute-phase proteins Responds slowly to inflammatory stimuli Requires fresh sample May be affected by drugs (IVIG)	Not sensitive to changes in SLE disease activity

IVIG, Intravenous immune globulin; SLE, systemic lupus erythematosus.

From Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley & Firestein's textbook of rheumatology,* ed 10, Philadelphia, 2017, Elsevier (Table 57.3 , p 849).

Table 178.6

Conditions Associated With Elevated C-Reactive Protein Levels

Normal Or Minor Elevation (<1 mg/dL)

1. Vigorous exercise
2. Common cold
3. Pregnancy
4. Gingivitis
5. Seizures
6. Depression
7. Insulin resistance and diabetes
8. Several genetic polymorphisms

9. Obesity

Moderate Elevation (1-10 mg/dL)

1. Myocardial infarction
2. Malignancies
3. Pancreatitis
4. Mucosal infection (bronchitis, cystitis)
5. Most systemic autoimmune diseases
6. Rheumatoid arthritis

Marked Elevation (>10 mg/dL)

1. Acute bacterial infection (80–85%)
2. Major trauma, surgery
3. Systemic vasculitis

From Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley & Firestein's textbook of rheumatology,* ed 10, Philadelphia, 2017, Elsevier (Table 57-4, p 849).

The use of an antinuclear antibody (ANA) measurement as a screening test is *not* recommended because it has low specificity. A positive ANA test result may be induced by infection, especially EBV infection, endocarditis, and parvovirus B19 infection. The ANA test result is also positive in up to 30% of normal children, and ANA level is increased in those with a first-degree relative with a known rheumatic disease. In the majority of children with a positive ANA test result without signs of a rheumatic disease on initial evaluation, autoimmune disease does not develop over time, so this finding does not necessitate referral to a pediatric rheumatologist. A positive ANA test result is found in many rheumatic diseases, including JIA, in which it serves as a predictor of the risk for inflammatory eye disease (Table 178.7). Once a positive ANA test result is discovered in a child, the need for specific autoantibody testing is directed by the presence of clinical signs and symptoms (see Table 178.3).

Table 178.7

Other Nonrheumatic Conditions With Elevated Acute Phase Responses

Neuroendocrine Changes

Fever, somnolence, and anorexia
Increased secretion of corticotropin-releasing hormone, corticotropin, and cortisol
Increased secretion of arginine vasopressin
Decreased production of insulin-like growth factor I
Increased adrenal secretion of catecholamines

Hematopoietic Changes

Anemia of chronic disease
Leukocytosis
Thrombocytosis

Metabolic Changes

Loss of muscle and negative nitrogen balance
Decreased gluconeogenesis
Osteoporosis
Increased hepatic lipogenesis
Increased lipolysis in adipose tissue
Decreased lipoprotein lipase activity in muscle and adipose tissue
Cachexia

Hepatic Changes

Increased metallothionein, inducible nitric oxide synthase, heme oxygenase, manganese superoxide dismutase, and tissue inhibitor of metalloproteinase 1
Decreased phosphoenolpyruvate carboxykinase activity

Changes in Nonprotein Plasma Constituents

Hypozincemia, hypoferremia, and hypercupremia
Increased plasma retinol and glutathione concentrations

From Gabay C, Kushner I: Acute-phase proteins and other systemic responses to inflammation, *N Engl J Med* 340:448–454, 1999.

Imaging Studies

Plain radiographs are useful in evaluation of arthralgias and arthritis, as they offer reassurance in benign pain syndromes and their findings may be abnormal in malignancies, osteomyelitis, and long-standing chronic juvenile arthritis. Radionucleotide bone scans help localize areas of abnormality in the patient with diffuse pains caused by osteomyelitis, neuroblastoma, chronic multifocal osteomyelitis, and systemic arthritis. MRI findings are abnormal in inflammatory myositis and suggest the optimal site for biopsy. *MRI is more sensitive than plain radiographs in detecting the presence of early erosive arthritis and demonstrates increased joint fluid, synovial enhancement, and sequela of trauma with internal joint derangement.* MRI is also helpful in ruling out infection or malignancy. Cardiopulmonary evaluation is suggested for diseases commonly affecting the heart and lung, including SLE, systemic scleroderma, MCTD, JDM, and sarcoid, as clinical manifestations may be subtle. This evaluation, which may include echocardiogram, pulmonary function tests, and high-resolution CT of the lungs along with consideration of bronchoalveolar lavage, is generally performed by a pediatric rheumatologist to whom the patient is referred (see Table 178.4).

CHAPTER 179

Treatment of Rheumatic Diseases

Jeffrey A. Dvergsten, Esi Morgan, C. Egla Rabinovich

Nonpharmacologic as well as pharmacologic interventions are often necessary to meet the desired goals of disease management. Optimal disease management requires family-centered care delivered by a multidisciplinary team of healthcare professionals providing medical, psychological, social, and school support. Rheumatologic conditions most often follow a course marked by flares and periods of remission, although some children have unremitting disease. The goals of treatment are to control disease, relieve discomfort, avoid or limit drug toxicity, prevent or reduce organ damage, and maximize the physical function and quality of life of affected children. Nonpharmacologic therapy is an important adjunct to medical management of rheumatic diseases (see Chapter 76). A key predictor of long-term outcome is early recognition and referral to a rheumatology team experienced in the specialized care of children with rheumatic diseases. Significant differences in outcome are seen 10 yr after disease onset in patients with **juvenile idiopathic arthritis (JIA)** depending on whether referral to a pediatric rheumatology center was accomplished within 6 mo of onset.

Pediatric Rheumatology Teams and Primary Care Physicians

The **multidisciplinary pediatric rheumatology team** offers coordinated services for children and their families (Table 179.1). General principles of treatment include: early recognition of signs and symptoms of rheumatic disease with timely referral to rheumatology for prompt initiation of treatment; monitoring for disease complications and adverse effects of treatment;

coordination of subspecialty care and rehabilitation services with communication of clinical information; and child- and family-centered chronic illness care, including self-management support, alliance with community resources, partnership with schools, resources for dealing with the financial burdens of disease, and connection with advocacy groups. Planning for transition to adult care providers needs to start in adolescence. Central to effective care is partnership with the primary care provider, who helps coordinate care, monitor compliance with treatment plans, ensure appropriate immunization, monitor for medication toxicities, and identify disease exacerbations and concomitant infections. Communication between the primary care provider and subspecialty team permits timely intervention when needed.

Table 179.1

Multidisciplinary Treatment of Rheumatic Diseases in Childhood

Accurate diagnosis and education of family	Pediatric rheumatologist Pediatrician
	Nurse: • Disease-related education • Medication administration (injection teaching) • Safety monitoring
	Social worker: • Facilitation of school services • Resource identification (community, government, financial, advocacy groups, vocational rehabilitation)
Physical medicine and rehabilitation	Physical therapy: • Addressing deficits in joint or muscle mobility, limb length discrepancies, gait abnormalities, and weakness
	Occupational therapy: • Splinting to reduce joint contractures/deformities and lessen stress on joints; adaptive devices for activities of daily living
Consultant team	Ophthalmology: • Eye screening for uveitis (see Table 180.4) • Screening for medication-related ocular toxicity (hydroxychloroquine, glucocorticoids)
	Nephrology
	Orthopedics
	Dermatology
	Gastroenterology
Physical and psychosocial growth and development	Nutrition: • Addressing undernourishment from systemic illness and obesity/overnourishment from glucocorticoids
	School integration: • Individualized educational plan (IEP) or 504 plan
	Peer-group relationships

	Individual and family counseling
Coordination of care	Involvement of patient and family as active team members
	Communication among healthcare providers
	Involvement of school (school nurse) and community (social worker) resources

Therapeutics

A key principle of pharmacologic management of rheumatic diseases is that early disease control, striving for induction of remission, leads to less tissue and organ damage with improved short- and long-term outcomes. Medications are chosen from broad therapeutic classes on the basis of diagnosis, disease severity, anthropometrics, and adverse effect profile. Many drug therapies used do not have U.S. Food and Drug Administration (FDA) indications for pediatric rheumatic diseases given the relative rarity of these conditions. The evidence base may be limited to case series, uncontrolled studies, or extrapolation from use in adults. The exception is JIA, for which there is a growing body of randomized controlled trial (RCT) evidence, particularly for newer therapeutics. Therapeutic agents used for treatment of childhood rheumatic diseases have various mechanisms of action, but all suppress inflammation (Table 179.2). *Both biologic and nonbiologic* **disease-modifying antirheumatic drugs (DMARDs** *) directly affect the immune system.* DMARDs should be prescribed by specialists. Live vaccines are contraindicated in patients taking immunosuppressive glucocorticoids or DMARDs. A negative test result for tuberculosis (purified protein derivative and/or QuantiFERON-TB Gold) should be verified and the patient's immunization status updated, if possible, before such treatment is initiated. Killed vaccines are not contraindicated, and annual injectable influenza vaccine is recommended.

Table 179.2

Therapeutics for Childhood Rheumatic Diseases[*]

CLASSIFICATION	THERAPEUTIC [†]	DOSE	INDICATION [†]	ADVERSE REACTIONS
Nonsteroidal antiinflammatory drugs (NSAIDs) [‡]	Etodolac [a]	PO once-daily dose: 20-30 kg: 400 mg 31-45 kg: 600 mg 46-60 kg: 800	JIA Spondyloarthropathy Pain Serositis Cutaneous vasculitis Uveitis	GI intolerance (abdominal pain, nausea), gastritis, hepatitis, tinnitus, anemia, pseudoporphyria, aseptic meningitis,

		mg >60 kg: 1,000 mg		headache, renal disease
	Ibuprofen [a]	40 mg/kg/day PO in 3 divided doses Max: 2400 mg/day		
	Naproxen [a]	15 mg/kg/day PO in 2 divided doses Max 1,000 mg/day		
	Celecoxib [a]	10-25 kg: 50 mg PO bid >25 kg: 100 mg PO bid		
	Meloxicam [a]	0.125 mg/kg PO qd Max 7.5 mg		
Disease-modifying antirheumatic drugs (DMARDs)	Methotrexate [a]	10-20 mg/m^2 /wk (0.35-0.65 mg/kg/wk) PO 20-30 mg/m^2 /wk (0.65-1 mg/kg/wk) SC; higher doses better absorbed by SC injection	JIA Uveitis	GI intolerance (nausea, vomiting), hepatitis, myelosuppression, mucositis, teratogenesis, lymphoma, interstitial pneumonitis
	Leflunomide	PO once daily: 10 to <20 kg: 10 mg 20-40 kg: 15 mg >40 kg: 20 mg	JIA	Hepatitis, hepatic necrosis, cytopenias, mucositis, teratogenesis, peripheral neuropathy
	Hydroxychloroquine	5 mg/kg PO qd; do not exceed 5 mg/kg/daily Max 400 mg daily	SLE JDMS Antiphospholipid antibody syndrome	Retinal toxicity, GI intolerance, rash, skin discoloration, anemia, cytopenias, myopathy, CNS stimulation, death (overdose)
	Sulfasalazine [a]	30-50 mg/kg/day in 2 divided doses Adult max 3 g/day	Spondyloarthropathy, JIA	GI intolerance, rash, hypersensitivity reactions, Stevens-Johnson syndrome, cytopenias, hepatitis, headache

Tumor necrosis factor (TNF)-α antagonists	Adalimumab [a]	SC once every other wk: 10 to <15 kg: 10 mg 15 to <30 kg: 20 mg ≥30 kg: 40 mg	JIA Spondyloarthropathy Psoriatic arthritis Uveitis	Injection site reaction, infection, rash, cytopenias, lupus-like syndrome, potential increased malignancy risk
	Etanercept [a]	0.8 mg/kg SC once weekly (max 50 mg/dose) or 0.4 mg/kg SC twice weekly (max 25 mg/dose)	JIA	Injection site reactions, infections, rash, demyelinating disorders, cytopenias, potential increased malignancy risk
	Infliximab	5-10 mg/kg IV every 4-8 wk	JIA Spondyloarthropathy Uveitis Sarcoidosis	Infusion reactions, hepatitis, potential increased malignancy risk
Modulate T-cell activation	Abatacept [a]	IV every 2 wk ×3 doses, then monthly for ≥6 yr of age: <75 kg: 10 mg/kg 75-100 kg: 750 mg >100 kg: 1,000 mg	JIA	Infection, headache, potential increased malignancy risk
		SC once weekly: 10 to <25 kg: 50 mg ≥25 to <50 kg: 87.5 mg ≥50 kg: 125 mg		
Anti-CD20 (B-cell) antibody	Rituximab	575 mg/m^2 , max 1,000 mg, IV on days 1 and 15	SLE	Infusion reactions, lymphopenia, reactivation hepatitis B, rash, serum sickness, arthritis, PML
Anti-BLyS antibody	Belimumab [e]	10 mg/kg IV every 2 wk ×3 doses, then every 4 wk	SLE	Infusion reactions, infection, depression
Interleukin (IL)-1 antagonist	Anakinra	1-2 mg/kg/daily Adult max 100 mg	Systemic JIA CAPS	Injection site reactions, infection
	Canakinumab [b]	Given SC every 8 wk (CAPS) every 4 wk (systemic JIA): 15-40 kg: 2 mg/kg (up to 3 mg/kg if	CAPS Systemic JIA	Injection site reaction, infection, diarrhea, nausea, vertigo, headache

		needed) >40 kg: 150 mg		
		IV: <30 kg: 10 mg/kg/dose every 4 wk ≥30 kg: 8 mg/kg/dose every 4 wk; maximum dose: 800 mg/dose SC: <30 kg: 162 mg/dose once every 3 wk ≥30 kg: 162 mg/dose once every 2 wk	Polyarticular JIA	
IL-6 antagonist	Tocilizumab [a]	≥2 yr and ≥30 kg: 8 mg/kg/dose every 2 wk ≥2 yr and ≤30 kg: 12 mg/kg/dose every 2 wk	Systemic JIA	Infusion reactions, elevated LFTs, elevated lipids, thrombocytopenia, infections
Intravenous immune globulin	IVIG [c]	1,000-2,000 mg/kg IV infusion For JDMS, give monthly	Kawasaki disease JDMS SLE	Infusion reaction, aseptic meningitis, renal failure
Cytotoxic	Cyclophosphamide	0.5-1 g/m^2 IV (max 1.5 g) monthly for 6 mo induction, then every 2-3 mo Oral regimen: 1-2 mg/kg/daily; max 150 mg/daily	SLE Vasculitis JDMS Pulmonary hemorrhage	Nausea, vomiting, myelosuppression, mucositis, hyponatremia, alopecia, hemorrhagic cystitis, gonadal failure, teratogenesis, secondary malignancy
Immunosuppressive	Mycophenolate mofetil	Oral suspension: max 1,200 mg/m^2 /day PO (up to 2 g/day) divided bid Capsules: max 1,500 mg/day PO for BSA 1.25-1.5 m^2 , 2 g/day PO for BSA >1.5 m^2 divided bid	SLE Uveitis	GI intolerance (diarrhea, nausea, vomiting), renal impairment, neutropenia, teratogenesis, secondary malignancy, PML

Glucocorticoids	Prednisone[a, d-f]	0.05-2 mg/kg/day PO given in 1-4 divided doses; max varies by individual (80 mg/daily) Adverse effects are dose dependent; lowest effective dose should be used	SLE JDMS Vasculitis JIA Uveitis Sarcoidosis	Cushing syndrome, osteoporosis, increased appetite, weight gain, striae, hypertension, adrenal suppression, hyperglycemia, infection, avascular necrosis
	Methylprednisolone[a, d-g]	0.5-1.7 mg/kg/day or 5-25 mg/m^2 /day IM/IV in divided doses every 6-12 hr For severe manifestations: 30 mg/kg/dose (max 1 g) daily for 1-5 days	SLE JDMS Vasculitis Sarcoidosis Localized scleroderma	
	Intraarticular	Dose varies by joint and formulation	JIA	Subcutaneous atrophy, skin hypopigmentation, calcification, infection
	Prednisolone ophthalmic suspension	1-2 drops into eye up to every hr while awake Needs monitoring by ophthalmologist	Uveitis	Ocular hypertension, glaucoma, nerve damage, cataract, infection

[*] Consult a clinical pharmacology reference for current dosing and monitoring guidelines, and complete list of known adverse effects.

[†] Therapeutics used in practice may not have a FDA-approved indication. Individual therapeutics annotated with FDA-approved indication as follows: a , JIA; b , CAPS; c , Kawasaki disease; d , sarcoidosis; e , SLE; f , uveitis; g , dermatomyositis.

[‡] Many more products available in this class.

qd, Once daily; bid, twice daily; Blys, B-lymphocyte stimulator; BMP, basic metabolic panel; BSA, body surface area; BUN, blood urea nitrogen; CAPS, cryopyrin-associated periodic syndrome; CBC, complete blood count; CNS, central nervous system; dsDNA, double-stranded DNA; GI, gastrointestinal; IM, intramuscular(ly); IV, intravenous(ly); IVIG, intravenous immune globulin; JDMS, juvenile dermatomyositis; JIA, juvenile idiopathic arthritis; LFTs, liver function tests; PML, progressive multifocal leukoencephalopathy; PO, by mouth; SC, subcutaneous(ly); SLE, systemic lupus erythematosus; TB, tuberculosis.

Nonsteroidal Antiinflammatory Drugs

NSAIDs are prescribed to decrease both the pain and the acute and chronic inflammation associated with arthritis, pleuritis, pericarditis, uveitis, and cutaneous vasculitis, but they are not disease modifying. NSAID antiinflammatory effects require regular administration at adequate doses based on weight (mg/kg) or body surface area (mg/m^2), for longer periods than needed for analgesia alone. The mean time to achieve antiinflammatory effect in JIA is 4-6 wk of consistent administration. NSAIDs work primarily by inhibiting the enzyme cyclooxygenase (COX), which is critical in the production of **prostaglandins** , a family of substances that promote inflammation. Two types of COX receptors have been demonstrated; **selective** COX-2 inhibitors such as *celecoxib* and *meloxicam* inhibit receptors responsible for promoting inflammation, with potential for fewer gastrointestinal (GI) adverse effects. Clinical trials in children with JIA found that celecoxib and meloxicam were similar in effectiveness and tolerability to the **nonselective** NSAID *naproxen* .

The most frequent adverse effects of NSAIDs in children are nausea, decreased appetite, and abdominal pain. Gastritis or ulceration occurs less frequently in children. Less common adverse effects(≤5% of children undergoing long-term NSAID therapy), include mood change, concentration difficulty that can simulate attention deficit disorder, sleepiness, irritability, headache, tinnitus, alopecia, anemia, elevated liver enzyme values, proteinuria, and hematuria. Certain agents (indomethacin) have a higher risk of toxicity than others (ibuprofen); naproxen has an intermediate risk. These NSAID-associated adverse effects reverse quickly once the medication is stopped. Additional rare NSAID-specific adverse reactions may also occur. Aseptic meningitis has been associated with ibuprofen, primarily in patients with lupus. Naproxen is more likely than other NSAIDs to cause a unique skin reaction called **pseudoporphyria** , which is characterized by small, hypopigmented depressed scars occurring in areas of minor skin trauma, such as fingernail scratches. Pseudoporphyria is more likely to occur in fair-skinned individuals and on sun-exposed areas. If pseudoporphyria develops, the inciting NSAID should be discontinued because scars can persist for years or may be permanent. NSAIDs should be used cautiously in patients with dermatomyositis or systemic vasculitis because of an increased frequency of GI ulceration with these disorders. *Salicylates have been supplanted by other NSAIDs because of the relative frequency of salicylate hepatotoxicity and the association with Reye syndrome.*

The response to NSAIDs varies greatly among individual patients, but overall, 40–60% of children with JIA experience improvement in their arthritis with NSAID therapy. Patients may try several different NSAIDs for 6 wk trials before finding one that demonstrates clinical benefit. NSAIDs with longer half-lives or sustained-release formulations allow for once- or twice-daily dosing and improve compliance. Laboratory monitoring for toxicity includes a complete blood count (CBC), serum creatinine, liver function tests (LFTs), and urinalysis every 6-12 mo, although guidelines for frequency of testing are not established.

Nonbiologic Disease-Modifying Antirheumatic Drugs

Methotrexate

Methotrexate (MTX), an antimetabolite, is a cornerstone of therapy in pediatric rheumatology because of its sustained effectiveness and relative low toxicity over prolonged periods of treatment. The mechanism of action low-dose MTX in arthritis is complex but is believed to result from the inhibition of folate-dependent processes by MTX polyglutamates, primarily their effect on the enzyme 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, leading to an increase of extracellular adenosine and consequently, cyclic adenosine monophosphate (cAMP), which inhibits the production of proinflammatory cytokines such as tumor necrosis factor (TNF)-α and interleukin (IL)-1β and their downstream effects on lymphocyte activation and proliferation.

MTX has a central role in the treatment of arthritis, especially in children with polyarticular JIA. The response to oral MTX (10 mg/m^2 once a week) is better than the response to placebo (63% vs 36%). Children who show no response to standard doses of MTX often do show response to higher doses (15 or 30 mg/m^2 /wk). Subcutaneous (SC) administration of MTX is similar in absorption and pharmacokinetic properties to intramuscular (IM) injection, with less pain. MTX is typically used in treatment of juvenile dermatomyositis as a steroid-sparing agent, with efficacy in 70% of patients. It has also been used successfully at a dosage of 10-20 mg/m^2 /wk in patients with systemic lupus erythematosus (SLE) to treat arthritis, serositis, and rash.

Because of the lower dose used in treating rheumatic diseases, MTX is well tolerated by children, with toxicity being milder and qualitatively different from that observed with treatment of neoplasms. Adverse effects include elevated liver enzyme values (15%), GI toxicity (13%), stomatitis (3%), headache (1–2%), and leukopenia, interstitial pneumonitis, rash, and alopecia (<1%). Hepatotoxicity observed among adults with rheumatoid arthritis (RA) treated with MTX has raised concern about similar problems in children. Analysis of liver biopsy specimens in children with JIA undergoing long-term MTX treatment has revealed occasional mild fibrosis but no evidence of even moderate liver damage. Children receiving MTX should be counseled to avoid alcohol, smoking, and pregnancy. *Folic acid* (1 mg daily) is given as an adjunct to minimize adverse effects. Lymphoproliferative disorders have been reported in adults treated with MTX, primarily in association with Epstein-Barr virus (EBV) infection. Regression of lymphoma may follow withdrawal of MTX.

Monitoring laboratory tests for MTX toxicity include CBC and LFTs at regular intervals, initially every 4 wk for the 1st 3 mo of treatment, then every 8-12 wk, with more frequent intervals after dosing adjustments or in response to abnormal values.

Hydroxychloroquine

Hydroxychloroquine sulfate is an antimalarial drug important in the treatment of SLE and dermatomyositis, particularly cutaneous manifestations of disease and to reduce lupus flares. It is not indicated to treat JIA because of lack of efficacy. The most significant potential adverse effect is retinal toxicity, which occurs rarely but results in irreversible color blindness or loss of central vision. Complete ophthalmologic examinations, including assessment of peripheral vision and color fields, are conducted at baseline and every 6-12 mo to screen for retinal toxicity. Retinal toxicity is rare (1/5,000 patients) and is associated with weight-based dosing exceeding 6.5 mg/kg/day; therefore recommended dosing is <6.5 mg/kg/day, not to exceed 400 mg/day. Other potential adverse effects include rash, skin discoloration, gastric irritation, bone marrow suppression, central nervous system (CNS) stimulation, and myositis.

Leflunomide

Leflunomide is a DMARD approved for treatment of RA that offers an alternative to MTX for treatment of JIA. MTX outperformed leflunomide for treatment of JIA in a randomized trial (at 16 wk, 89% of patients receiving MTX achieved a 30% response rate vs 68% of those receiving leflunomide), although both drugs were effective. Dosing is oral, once daily, and weight based: 10 mg for children 10 to <20 kg, 15 mg for children 20-40 kg, and 20 mg for children >40 kg. Adverse reactions include paresthesias and peripheral neuropathy, GI intolerance, elevated liver transaminases and hepatic failure, cytopenias, alopecia, and teratogenesis. Leflunomide has a long half-life, and in cases in which discontinuation of the agent is required, a drug elimination protocol with cholestyramine may be indicated. Avoidance of pregnancy is essential. Laboratory tests (e.g., CBC, LFTs) are monitored every 4 wk for the 1st 6 mo of treatment, then every 8-12 wk.

Sulfasalazine

Sulfasalazine is used to treat children with polyarticular JIA, oligoarticular JIA, and the peripheral arthritis and enthesitis associated with **juvenile ankylosing spondylitis** . In JIA, sulfasalazine, 50 mg/kg/day (adult maximum: 3,000 mg/day), achieves greater improvement in joint inflammation, global assessment parameters, and laboratory parameters than placebo. More than 30% of sulfasalazine-treated patients withdraw from the treatment because of adverse effects, primarily GI irritation and skin rashes. Sulfasalazine is associated with severe systemic hypersensitivity reactions, including Stevens-Johnson syndrome. Sulfasalazine is generally considered contraindicated in children with active systemic JIA because of increased hypersensitivity reactions. Sulfasalazine should not be used in patients with sulfa or salicylate hypersensitivity or porphyria.

Monitoring laboratory tests for sulfasalazine toxicity include CBC, LFTs, serum creatinine/blood urea nitrogen (BUN), and urinalysis, every other week for the 1st 3 mo of treatment, monthly for 3 mo, every 3 mo for 1 yr, then every 6 mo.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is an immunosuppressive drug approved by the FDA for organ transplant rejection. In rheumatology, MMF is used primarily for treatment of lupus, uveitis, and autoimmune skin manifestations. In adult clinical trials, MMF was noninferior to cyclophosphamide for induction therapy of lupus nephritis, with a potential for less adverse effects (infection, gonadal toxicity). Dosing is based on body surface area (BSA): 600 mg/m^2 orally twice daily, with maximum dosage limits varying by formulation and BSA. The most common adverse reaction is GI intolerance; infections, cytopenias, and secondary malignancies are also reported.

Glucocorticoids

Glucocorticoids are given through oral, intravenous (IV), ocular, topical, and intraarticular administration as part of treatment of rheumatic disease. **Oral** corticosteroids are foundational treatment for moderate to severe lupus, dermatomyositis, and most forms of vasculitis; their long-term use is associated with many well-described, dose-dependent complications, including linear growth suppression, Cushingoid features, osteoporosis, avascular necrosis, hypertension, impaired glucose tolerance, mood disturbance, and increased infection risk. Glucocorticoids should be tapered to the lowest effective dose over time and DMARDs introduced as steroid-sparing agents.

Intravenous corticosteroids have been used to treat severe, acute manifestations of systemic rheumatic diseases such as SLE, dermatomyositis, and vasculitis. The IV route allows for higher doses to obtain an immediate, profound antiinflammatory effect. *Methylprednisolone,* 10-30 mg/kg/dose up to a maximum of 1 g, given over 1 hr daily for 1-5 days, is the IV preparation of choice. Although generally associated with fewer adverse effects than oral corticosteroids, IV steroids are associated with significant and occasionally life-threatening toxicities, such as cardiac arrhythmia, acute hypertension, hypotension, hyperglycemia, shock, pancreatitis, and avascular necrosis.

Ocular corticosteroids are prescribed by ophthalmologists as ophthalmologic drops or injections into the soft tissue surrounding the globe (sub–Tenon capsule injection) for active **uveitis** . Long-term ocular corticosteroid use leads to cataract formation and glaucoma. Current ophthalmologic management has significantly decreased the frequency of blindness as a complication of JIA-associated uveitis.

Intraarticular corticosteroids are being used with increasing frequency as initial therapy for children with oligoarticular JIA or as bridge therapy while awaiting efficacy of a DMARD in polyarticular disease. Most patients have significant clinical improvement within 3 days. Duration of response depends on steroid preparation used, joint affected, and arthritis subtype; the anticipated response rate to knee injection is 60–80% at 6 mo. Intraarticular administration may result in subcutaneous atrophy and hypopigmentation of the skin at the injection site, as well as subcutaneous calcifications along the needle track.

Biologic Agents

Biologic agents are proteins that have been engineered to target and modulate specific components of the immune system, with the goal of decreasing the inflammatory response. Antibodies have been developed to target specific cytokines such as IL-1 and IL-6 or to interfere with specific immune cell function through depletion of B cells or suppression of T-cell activation (Table 179.3). The availability of biologic agents has dramatically increased the therapeutic options for treating rheumatic disease recalcitrant to nonbiologic therapies, and in some cases biologics are becoming first-line interventions. A primary concern is the increased risk of malignancy when biologics are combined with other immunosuppressants.

Table 179.3

Method of Action of Biologic Therapies Studied in Juvenile Idiopathic Arthritis

DRUG	METHOD OF ACTION
Etanercept	Soluble TNF p75 receptor fusion protein that binds to and inactivates TNF-α
Infliximab	Chimeric human/mouse monoclonal antibody that binds to soluble TNF-α and its membrane-bound precursor, neutralizing its action
Adalimumab	A humanized IgG_1 monoclonal antibody that binds to TNF-α
Abatacept	Soluble, fully human fusion protein of the extracellular domain of (CTLA-4, linked to a modified Fc portion of the human IgG_1 . It acts as a co-stimulatory signal inhibitor by binding competitively to CD80 or CD86, where it selectively inhibits T-cell activation
Tocilizumab	A humanized anti–human IL-6 receptor monoclonal antibody
Anakinra	An IL-1 receptor antagonist (IL-1RA)

CTLA, Cytotoxic T lymphocyte–associated antigen; IL, interleukin; TNF, tumor necrosis factor.

From Beresford MW, Baildam EM: New advances in the management of juvenile idiopathic arthritis. Part 2. The era of biologicals, *Arch Dis Child Educ Pract Ed* 94:151–156, 2009.

Tumor Necrosis Factor-α Antagonists

Two TNF antagonists have an FDA indication for treatment of children with moderate to severe polyarticular JIA (etanercept and adalimumab). *Etanercept* is a genetically engineered fusion protein consisting of 2 identical chains of the recombinant extracellular TNF receptor monomer fused with the Fc domain of human immunoglobulin G_1 . Etanercept binds both TNF-α and lymphotoxin-α (formerly called TNF-β) and inhibits their activity. Three fourths of children with active polyarticular JIA that fails to respond to MTX demonstrate response to etanercept after 3 mo of therapy. Dosing is 0.8 mg/kg subcutaneously weekly (max 50 mg/dose) or 0.4 mg/kg SC twice weekly (max 25 mg/dose). *Adalimumab* is a fully human anti-TNF monoclonal antibody (mAb) used alone or in combination with MTX. In a placebo-controlled withdrawal-design study, children continuing to receive adalimumab were less likely to experience disease flares (43% vs. 71%) even if they were also taking MTX (37% vs 65%). Adalimumab is administered subcutaneously every other week at a dose of 10 mg for children weighing 10 to <15 kg, 20 mg for children weighing 15 to <30 kg and 40 mg for those weighing ≥30 kg.

Infliximab, a chimeric mouse-human mAb, was tested in an RCT for use in JIA but did not achieve study end-points. However, it is FDA approved for pediatric inflammatory bowel disease and has been used “off label” for treatment of polyarticular JIA, uveitis, Behçet syndrome, and sarcoidosis. Two additional anti-TNF agents—*golimumab* , a human mAb against TNF, and *certolizumab pegol* , a pegylated humanized antibody against TNF—have been approved by the FDA for RA in adults and are currently in pediatric trials.

The most common adverse effects are injection site reactions that diminish over time. TNF blockade is associated with an increased frequency of serious systemic infections, including sepsis, dissemination of latent tuberculosis (TB), and invasive fungal infections in endemic areas. TNF blockade should not be initiated in patients with a history of chronic or frequent recurrent infections. TB testing should be done before initiation of therapy with TNF antagonists. If test results are positive, antitubercular treatment must be administered before anti-TNF treatment can be started. Theoretically, risk of malignancy increases with TNF-α antagonists. Case reports describe the development of lupus-like syndromes, leukocytoclastic vasculitis, interstitial lung disease, demyelinating syndromes, antibody formation to the drug, rashes, cytopenias, anaphylaxis, serum sickness, and other reactions. The benefit/risk profile appears favorable after a decade of experience with this therapeutic class; the safety of longer-term suppression of TNF function is unknown.

Modulator of T-Cell Activation

Abatacept is a selective inhibitor of T-cell co-stimulation resulting in T-cell anergy. It is FDA approved for treatment of moderate to severe polyarticular JIA. In a double-blind withdrawal RCT in children whose disease had not responded to DMARDs, 53% of placebo-treated patients vs 20% of abatacept-treated patients experienced disease flares during the withdrawal period. The frequency of adverse events did not differ between the groups. Abatacept is administered

IV every other week for 3 doses (<75 kg: 10 mg/kg/dose; 75-100 kg: 750 mg/dose; >100 kg: 1,000 mg/dose; maximum 1,000 mg/dose at 0, 2, and 4 wk) and then monthly thereafter. Abatacept administered by SC injection was given FDA approval in March 2017 for children ≥4 yr old for treatment of polyarticular JIA, at doses given weekly: 50 mg for 10-25 kg, 87.5 mg for ≥25 to <50 kg, and 125 mg for ≥50 kg.

B-Cell Depletion

Rituximab is a chimeric mAb to the antigen CD20, a transmembrane protein on the surface of B-cell precursors and mature B lymphocytes. This antibody induces B-cell apoptosis and causes depletion of circulating and tissue-based B cells. Antibody production is not completely abrogated because plasma cells are not removed. Rituximab is licensed for treatment of B-cell non-Hodgkin lymphoma and is FDA approved for use in adult RA and idiopathic thrombocytopenic purpura but does not have a pediatric indication. Rituximab may also have a role in treatment of SLE, particularly its hematologic manifestations. Adverse events include serious infusion reactions, cytopenias, hepatitis B virus reactivation, hypogammaglobulinemia, infections, serum sickness, vasculitis, and a rare but fatal side effect, **progressive multifocal leukoencephalopathy** . Resistance to rituximab may develop over time in patients being treated for lymphoma.

Belimumab is a human mAb to B-lymphocyte stimulator that negatively affects B-cell proliferation, differentiation, and long-term survival. It is approved for treatment of SLE in adults, and studies of long-term safety and efficacy are ongoing. Belimumab is *not* FDA approved for use in pediatric SLE.

Interleukin-1 Antagonists

Anakinra, a recombinant form of the human IL-1 receptor antagonist, competitively inhibits binding of IL-1α and IL-1β to the natural receptor, interrupting the cytokine proinflammatory cascade. Anakinra has been approved for RA in adults. In meta-analyses of treatments for RA, anakinra was outperformed by TNF-α antagonists but has a special niche in pediatric rheumatology for treatment of **systemic JIA (sJIA)** and other autoinflammatory syndromes, such as **cryopyrin-associated periodic syndrome (CAPS)** . The medication is dosed SC, 1-2 mg/kg, once daily. An IL-1β mAb, *canakinumab,* is FDA approved for use in CAPS, dosed SC every 8 wk, and sJIA, dosed SC every

4 wk. Adverse reactions include significant injection site reactions and increased bacterial infections.

Interleukin-6 Receptor Antagonist

Tocilizumab is an anti–IL-6 receptor antibody binding to both soluble as well as membrane-associated receptors. Tocilizumab has FDA approval for treatment of sJIA and polyarticular JIA. Adverse reactions include transaminase and lipid elevations. Tocilizumab is given as an IV infusion every 2 wk (sJIA) to 4 wk (polyarticular JIA), and SC for polyarticular JIA 162 mg every 3 wk for those <30 kg and every 2 wk for ≥30 kg.

Intravenous Immune Globulin

IVIG is thought to be beneficial in various clinical conditions. IVIG significantly improves the short- and long-term natural history of **Kawasaki disease** . Open studies have supported benefit for juvenile dermatomyositis, lupus-associated thrombocytopenia, and polyarticular JIA. IVIG is given as 1-2 g/kg/dose, administered once monthly. It has been occasionally associated with severe, systemic allergy–like reactions and postinfusion aseptic meningitis (headache, stiff neck).

Cytotoxics

Cyclophosphamide

Cyclophosphamide requires metabolic conversion in the liver to its active metabolites, which alkylate the guanine in DNA, leading to immunosuppression by inhibition of the S2 phase of mitosis. The subsequent decrease in numbers of T and B lymphocytes results in diminished humoral and cellular immune responses. Cyclophosphamide infusions (500-1,000 mg/m^2) given monthly for 6 mo, then every 3 mo for 12-18 mo, have been shown to reduce the frequency of renal failure in patients with lupus and diffuse proliferative glomerulonephritis. Open trials suggest efficacy in severe CNS lupus. Oral cyclophosphamide (1-2 mg/kg/day) is effective as induction treatment of severe antineutrophilic cytoplasmic antibody (ANCA)–associated vasculitis and other forms of systemic vasculitis, as well as interstitial lung disease or pulmonary hemorrhage associated with rheumatic disease.

Cyclophosphamide is a potent cytotoxic drug associated with significant toxicities. Potential short-term adverse effects include nausea, vomiting, anorexia, alopecia, mucositis, hemorrhagic cystitis, and bone marrow suppression. Long-term complications include an increased risk for sterility and cancer, especially leukemia, lymphoma, and bladder cancer. In adult women with lupus treated with IV cyclophosphamide, 30–40% become infertile; the risk of ovarian failure appears to be significantly lower in adolescent and premenarchal girls. Ovarian suppression with an inhibitor of gonadotropin-releasing hormone to preserve fertility is currently being studied.

Other Drugs

Azathioprine is sometimes used to treat ANCA-associated vasculitis following induction therapy or to treat SLE. *Cyclosporine* has been used occasionally in the treatment of dermatomyositis on the basis of uncontrolled studies and is helpful in the treatment of macrophage activation syndrome complicating sJIA (see Chapter 155). Case reports describe the successful use of *thalidomide* , or its analog *lenalidomide*, as treatment for sJIA, inflammatory skin disorders, and Behçet disease.

Several drugs commonly used in the past to treat arthritis are no longer part of standard treatment, including salicylates, gold compounds, and D -penicillamine.

CHAPTER 180

Juvenile Idiopathic Arthritis

Eveline Y. Wu, C. Egla Rabinovich

Juvenile idiopathic arthritis (JIA) is the most common rheumatic disease in children and one of the more common chronic illnesses of childhood. JIA represents a heterogeneous group of disorders sharing the clinical manifestation of arthritis. The etiology and pathogenesis of JIA are largely unknown, and the genetic component is complex, making clear distinction among various subtypes difficult. As a result, several classification schemes exist, each with its own limitations. The former classification of the **American College of Rheumatology (ACR)** uses the term *juvenile rheumatoid arthritis* and categorizes the disease into 3 onset types (Table 180.1). Attempting to standardize nomenclature, the **International League of Associations for Rheumatology (ILAR)** proposed a different classification using the term *juvenile idiopathic arthritis* (Table 180.2), inclusive of all subtypes of chronic juvenile arthritis. We refer to the ILAR classification criteria; see Chapter 181 for enthesitis-related arthritis (ERA) and psoriatic JIA (Tables 180.3 and 180.4).

Table 180.1

Criteria for the Classification of Juvenile Rheumatoid Arthritis

Age at onset: <16 yr
Arthritis (swelling or effusion, or the presence of ≥2 of the following signs: limitation of range of motion, tenderness or pain on motion, increased heat) in ≥1 joint
Duration of disease: ≥6 wk
Onset type defined by type of articular involvement in the 1st 6 mo after onset:

Polyarthritis: ≥5 inflamed joints
Oligoarthritis: ≤4 inflamed joints
Systemic-onset disease: arthritis with rash and a characteristic quotidian fever
Exclusion of other forms of juvenile arthritis

Adapted from Cassidy JT, Levison JE, Bass JC, et al: A study of classification criteria for a diagnosis of juvenile rheumatoid arthritis, *Arthritis Rheum* 29:174–181, 1986.

Table 180.2

International League of Associations for Rheumatology Classification of Juvenile Idiopathic Arthritis (JIA)

CATEGORY	DEFINITION	EXCLUSIONS
Systemic JIA	Arthritis in ≥1 joint with, or preceded by, fever of at least 2 wk in duration that is documented to be daily (quotidian[*]) for at least 3 days and accompanied by ≥1 of the following: 1. Evanescent (nonfixed) erythematous rash 2. Generalized lymph node enlargement 3. Hepatomegaly or splenomegaly or both 4. Serositis [†]	a. Psoriasis or a history of psoriasis in patient or first-degree relative b. Arthritis in an HLA-B27–positive boy beginning after 6th birthday c. Ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with IBD, Reiter syndrome, or acute anterior uveitis, or history of 1 of these disorders in first-degree relative d. Presence of IgM RF on at least 2 occasions at least 3 mo apart
Oligoarthritis	Arthritis affecting 1-4 joints during 1st 6 mo of disease; 2 subcategories are recognized: 1. Persistent oligoarthritis—affecting ≤4 joints throughout the disease course 2. Extended oligoarthritis—affecting >4 joints after 1st 6 mo of disease	a, b, c, d (above) *plus* e. Presence of systemic JIA in the patient
Polyarthritis (RF negative)	Arthritis affecting ≥5 joints during 1st 6 mo of disease; a test for RF is negative	a, b, c, d, e
Polyarthritis (RF positive)	Arthritis affecting ≥5 joints during 1st 6 mo of disease; ≥2 tests for RF at least 3 mo apart during 1st 6 mo of disease are positive	a, b, c, e
Psoriatic arthritis	Arthritis and psoriasis, or arthritis and at least 2 of the following:	b, c, d, e
	1. Dactylitis [‡] 2. Nail pitting [§] and onycholysis 3. Psoriasis in first-degree relative	
Enthesitis-related arthritis	Arthritis and enthesitis, [‖] or arthritis or enthesitis with at least 2 of the following:	a, d, e
	1. Presence of or history of sacroiliac joint	

	tenderness or inflammatory lumbosacral pain, or both[¶] 2. Presence of HLA-B27 antigen 3. Onset of arthritis in a male >6 yr old 4. Acute (symptomatic) anterior uveitis 5. History of ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with IBD, Reiter syndrome, or acute anterior uveitis in first-degree relative	
Undifferentiated arthritis	Arthritis that fulfills criteria in no category or in ≥2 of the above categories.	

[*] *Quotidian fever* is defined as a fever that rises to 39°C (102.2°F) once daily and returns to 37°C (98.6°F) between fever peaks.

[†] *Serositis* refers to pericarditis, pleuritis, or peritonitis, or some combination of the 3.

[‡] *Dactylitis* is swelling of ≥1 digit(s), usually in an asymmetric distribution, that extends beyond the joint margin.

[§] A minimum of 2 pits on any 1 or more nails at any time.

[‖] *Enthesitis* is defined as tenderness at the insertion of a tendon, ligament, joint capsule, or fascia to bone.

[¶] *Inflammatory lumbosacral pain* refers to lumbosacral pain at rest with morning stiffness that improves on movement.

IBD, Inflammatory bowel disease; RF, rheumatoid factor.

From Firestein GS, Budd RC, Harris ED Jr, et al, editors: *Kelley's textbook of rheumatology,* ed 8, Philadelphia, 2009, Saunders.

Table 180.3

Characteristics of ACR and ILAR Classifications of Childhood Chronic Arthritis

PARAMETER	**ACR (1977)**	**ILAR (1997)**
Term	Juvenile rheumatoid arthritis (JRA)	Juvenile idiopathic arthritis (JIA)
Minimum duration	≥6 wk	≥6 wk
Age at onset	<16 yr	<16 yr
≤4 joints in 1st 6 mo after presentation	Pauciarticular	Oligoarthritis: Persistent: <4 joints for course of disease Extended: >4 joints after 6 mo
>4 joints in 1st 6 mo after presentation	Polyarticular	Polyarthritis, RF negative Polyarthritis, RF positive
Fever, rash, arthritis	Systemic onset	Systemic

Other categories included	Exclusion of other forms	Psoriatic arthritis Enthesitis-related arthritis Undifferentiated: Fits no other category Fits >1 category
Inclusion of psoriatic arthritis, inflammatory bowel disease, ankylosing spondylitis	No (see Chapter 181)	Yes

ACR, American College of Rheumatology; ILAR, International League of Associations for Rheumatology; RF, rheumatoid factor.

Table 180.4

Overview of Main Features of Subtypes of Juvenile Idiopathic Arthritis (JIA)

ILAR SUBTYPE	PEAK AGE at ONSET (yr)	FEMALE:MALE RATIO	% of ALL JIA CASES	ARTHRITIS PATTERN	EXTRAARTICULAR FEATURES	LABORA INVESTI
Systemic arthritis	1-5	1 : 1	5-15	Polyarticular, often affecting knees, wrists, and ankles; also fingers, neck, and hips	Daily fever; evanescent rash; pericarditis; pleuritis	Anemia; W ESR ↑↑; C ferritin ↑; p (normal or MAS)
Oligoarthritis	2-4	3 : 1	40-50 (but ethnic variation)	Knees ++; ankles, fingers +	Uveitis in 30% of cases	ANA positi 60%; other results usu normal; ma mildly ↑ E
Polyarthritis:						
RF negative	2-4 and 10-14	3 : 1 and 10 : 1	20-35	Symmetric or asymmetric; small and large joints; cervical spine; temporomandibular joint	Uveitis in 10%	ANA positi 40%; RF n ESR ↑ or ↑ or normal; anemia

RF positive	9-12	9 : 1	<10	Aggressive symmetric polyarthritis	Rheumatoid nodules in 10%; low-grade fever	RF positive CRP ↑/norr anemia
Psoriatic arthritis	2-4 and 9-11	2 : 1	5-10	Asymmetric arthritis of small or medium-sized joints	Uveitis in 10%; psoriasis in 50%	ANA positi 50%; ESR or normal; anemia
Enthesitis-related arthritis	9-12	1 : 7	5-10	Predominantly lower limb joints affected; sometimes axial skeleton (but less than in adult, ankylosing spondylitis)	Acute anterior uveitis; association with reactive arthritis and inflammatory bowel disease	80% of pati positive for B27

ILAR, International League of Associations for Rheumatology; ANA, antinuclear antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; MAS, macrophage activation syndrome; MTX, methotrexate; NSAIDs, nonsteroidal antiinflammatory drugs; RF, rheumatoid factor; TNF, tumor necrosis factor; WBC, white blood cell count.

From Firestein GS, Budd RC, Harris ED Jr, et al, editors: *Kelley's textbook of rheumatology,* ed 8, Philadelphia, 2009, Saunders.

Epidemiology

The worldwide incidence of JIA ranges from 0.8-22.6 per 100,000 children per year, with prevalence ranges from 7-401 per 100,000. These wide-ranging numbers reflect population differences, particularly environmental exposure and immunogenetic susceptibility, along with variations in diagnostic criteria, difficulty in case ascertainment, and lack of population-based data. An estimated 300,000 U.S. children have arthritis, including 100,000 with a form of JIA. **Oligoarthritis** is the most common subtype (40–50%), followed by **polyarthritis** (25–30%) and **systemic JIA** (5–15%) (see Table 180.4). There is no sex predominance in systemic JIA (**sJIA**), but more girls than boys are affected in both oligoarticular (3 : 1) and polyarticular (5 : 1) JIA. The peak age at onset is 2-4 yr for oligoarticular disease. Age of onset has a bimodal distribution in polyarthritis, with peaks at 2-4 yr and 10-14 yr. sJIA occurs throughout childhood, with a peak at 1-5 yr.

Etiology

The etiology and pathogenesis of JIA are not completely understood, although both immunogenetic susceptibility and an external trigger are considered necessary. Twin and family studies suggest a substantial role for **genetic** factors. JIA is a complex genetic trait in which multiple genes may affect disease susceptibility. Variants in major histocompatibility complex (MHC) class I and class II regions have indisputably been associated with different JIA subtypes. Non-HLA candidate loci are also associated with JIA, including polymorphisms in the genes encoding protein tyrosine phosphatase nonreceptor 22 (PTPN22), tumor necrosis factor (TNF)-α, macrophage inhibitory factor, interleukin (IL)-6 and its receptor, and IL-1α. Possible **nongenetic** triggers include bacterial and viral infections, enhanced immune responses to bacterial or mycobacterial heat shock proteins, abnormal reproductive hormone levels, and joint trauma.

Pathogenesis

JIA is an autoimmune disease associated with alterations in both humoral and cell-mediated immunity. T lymphocytes have a central role, releasing proinflammatory cytokines favoring a type 1 helper T lymphocyte response. Studies of T-cell receptor expression confirm recruitment of T lymphocytes specific for synovial non–self-antigens. B-cell activation, immune complex formation, and complement activation also promote inflammation. Inheritance of specific cytokine alleles may predispose to upregulation of inflammatory networks, resulting in systemic disease or more severe articular disease.

Systemic JIA is characterized by dysregulation of the innate immune system with a lack of autoreactive T cells and autoantibodies. It therefore may be more accurately classified as an **autoinflammatory disorder** , more like familial Mediterranean fever, than the other subtypes of JIA. This theory is also supported by work demonstrating similar expression patterns of a phagocytic protein (S100A12) in sJIA and familial Mediterranean fever, as well as the same marked responsiveness to IL-1 inhibitors.

All these immunologic abnormalities cause inflammatory synovitis, characterized pathologically by villous hypertrophy and hyperplasia with hyperemia and edema of the synovial tissue. Vascular endothelial hyperplasia is prominent and is characterized by infiltration of mononuclear and plasma cells with a predominance of T lymphocytes (Fig. 180.1). Advanced and uncontrolled disease leads to pannus formation and progressive erosion of articular cartilage and contiguous bone (Figs. 180.2 and 180.3).

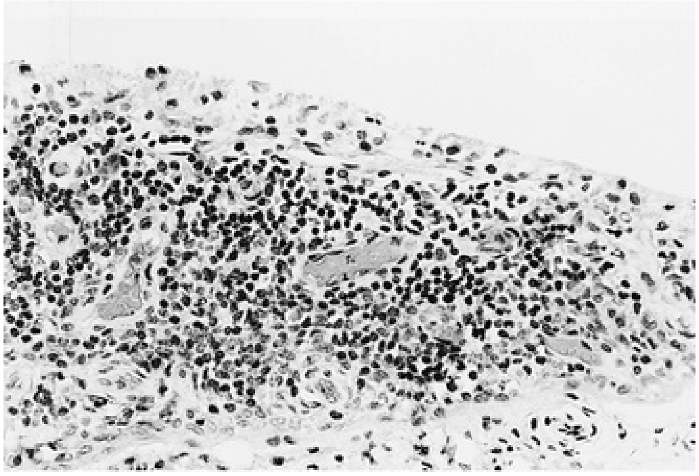

FIG. 180.1 Synovial biopsy specimen from a 10 yr old child with oligoarticular juvenile idiopathic arthritis. There is a dense infiltration of lymphocytes and plasma cells in the synovium.

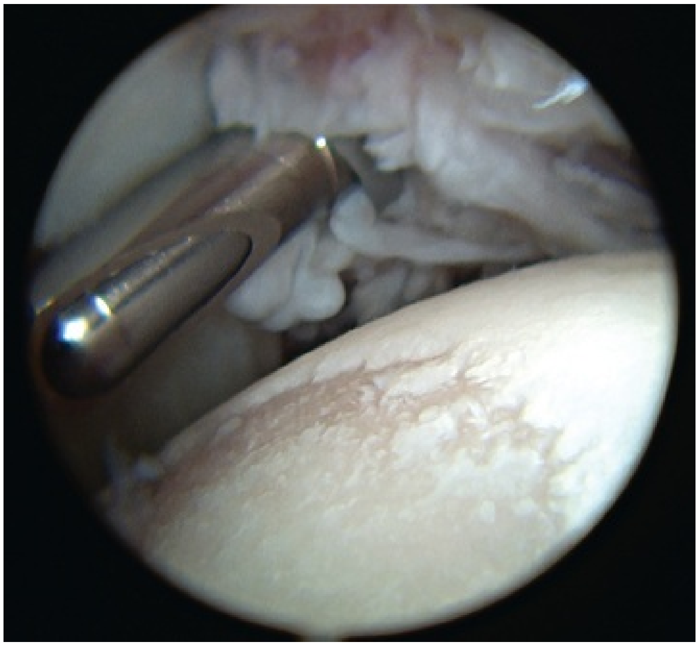

FIG. 180.2 Arthroscopy in the shoulder of a child with juvenile idiopathic arthritis showing pannus formation and cartilage erosions. (Courtesy of Dr. Alison Toth.)

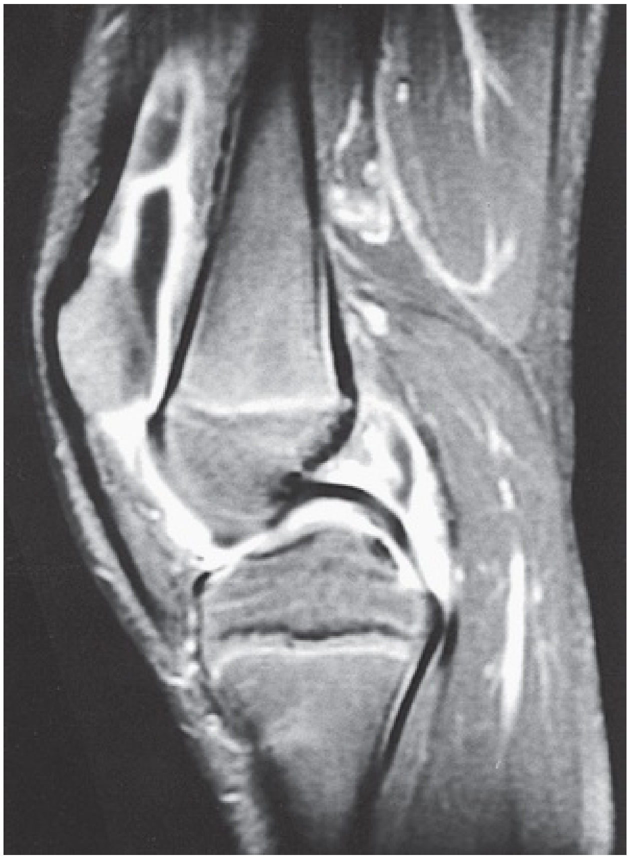

FIG. 180.3 MRI with gadolinium of a 10 yr old child with juvenile idiopathic arthritis (same patient as in Fig. 180.1). The dense white signal in the synovium near the distal femur, proximal tibia, and patella reflects inflammation. MRI of the knee is useful to exclude ligamentous injury, chondromalacia of the patella, and tumor.

Clinical Manifestations

Arthritis must be present ≥6 wk to make a diagnosis of any JIA subtype. Arthritis is defined by intraarticular swelling or the presence of ≥2 of the following signs: limitation in range of motion (ROM), tenderness or pain on motion, and warmth. Initial symptoms may be subtle or acute and often include morning stiffness with a limp or gelling after inactivity. Easy fatigability and poor sleep quality may be present. Involved joints are often swollen, warm to touch, and uncomfortable on movement or palpation with reduced ROM, but usually are not erythematous. Arthritis in large joints, especially knees, initially accelerates linear growth and causes the affected limb to be longer, resulting in a discrepancy in limb lengths. Continued inflammation stimulates rapid and premature closure of the growth plate, resulting in shortened bones.

Oligoarthritis is defined as involving ≤4 joints within the 1st 6 mo of disease onset, and often only a single joint is involved (see Table 180.4). It predominantly affects the large joints of the lower extremities, such as the knees and ankles (Fig. 180.4). Isolated involvement of upper-extremity large joints is less common. Those in whom disease never develops in >4 joints are regarded as having **persistent oligoarticular JIA** , whereas evolution of disease in >4 joints after 6 mo changes the classification to **extended oligoarticular JIA** and is associated with a worse prognosis. Isolated involvement of the hip is *almost never* a presenting sign and suggests ERA (see Chapter 181) or a nonrheumatic cause. The presence of a positive antinuclear antibody (ANA) test confers increased risk for asymptomatic anterior uveitis, requiring periodic slit-lamp examination (Table 180.5). ANA positivity may also be correlated with younger age at disease onset, female sex, asymmetric arthritis, and fewer involved joints over time.

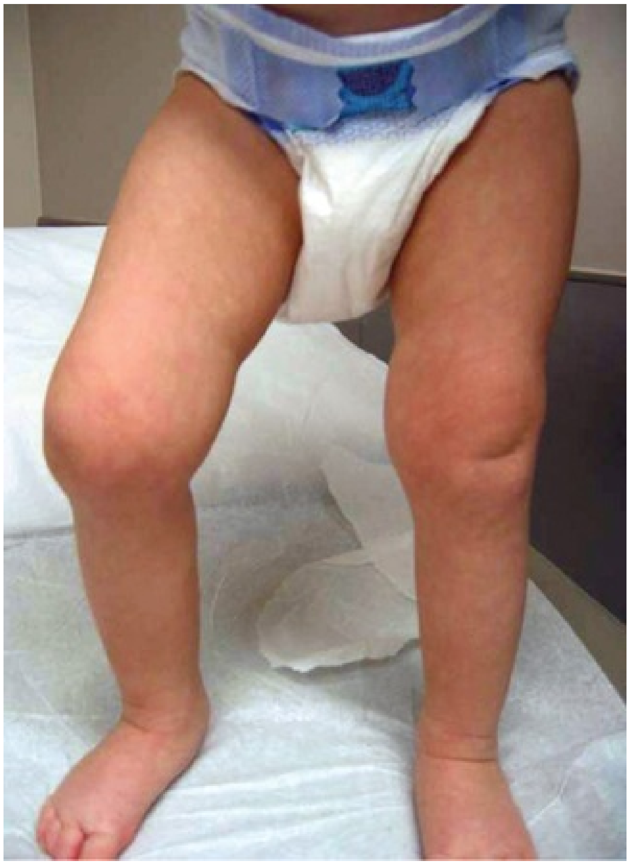

FIG. 180.4 Oligoarticular juvenile idiopathic arthritis with swelling and flexion contracture of the right knee.

Table 180.5

Frequency of Ophthalmologic Examination in Patients With Juvenile Idiopathic Arthritis

Referral	
• Patients should be referred at time of diagnosis, or suspicion, of JIA	
Initial screening examination	
• Should occur as soon as possible and no later than 6 wk from referral	
• Symptomatic ocular patients should be seen within a week of referral	
Ongoing screening	
• Screening at two monthly intervals from onset of arthritis for 6 mo	
• Followed by 3-4 monthly screening for time outlined below	
Oligoarticular JIA, psoriatic arthritis, and enthesitis-related arthritis irrespective of ANA status, onset under 11 yr	
AGE AT ONSET (YR)	**LENGTH OF SCREENING (YR)**
<3	8
3-4	6
5-8	3
9-10	1

Polyarticular, ANA-positive JIA, onset <10 yr	
AGE AT ONSET (YR)	**LENGTH OF SCREENING (YR)**
<6	5
6-9	2
• Polyarticular, ANA-negative JIA, onset <7 yr	
• 5-yr screening for all children	
• Systemic JIA and rheumatoid factor–positive polyarticular JIA	
Uveitis risk very low; however, diagnostic uncertainty in the early stages and overlap of symptoms may mean initial screening is indicated	
• All categories, onset >11 yr	
1-yr screening for all children	
• After stopping immunosuppression (eg, methotrexate)	
Two monthly screening for 6 mo, then revert to previous screening frequency as above	
• After discharge from screening	
Patients should receive advice about regular self-monitoring by checking vision uniocularly once weekly and when to seek medical advice	
Screening may need to continue indefinitely in situations where a young person may be unable to detect a change in vision or be unwilling to seek re-referral	
Annual check by optometrist as a useful adjunct	

From Clarke SLN, Sen ES, Ramanan AV: Juvenile idiopathic arthritis-associated uveitis. *Pediatr Rheumatol* 14:27, 2016. p. 3.

Polyarthritis is characterized by inflammation of ≥5 joints in both upper and lower extremities (Figs. 180.5 and 180.6). Rheumatoid factor (RF)–positive polyarthritis resembles the characteristic symmetric presentation of adult rheumatoid arthritis. **Rheumatoid nodules** on the extensor surfaces of the elbows, spine, and over the Achilles tendons, although unusual, are associated with a more severe course and almost exclusively occur in RF-positive individuals (Fig. 180.7). **Micrognathia** reflects chronic temporomandibular joint disease (Fig. 180.8). Cervical spine involvement (Fig. 180.9), manifesting as decreased neck extension, occurs with a risk of atlantoaxial subluxation and neurologic sequelae. Hip disease may be subtle, with findings of decreased or painful ROM on examination (Fig. 180.10).

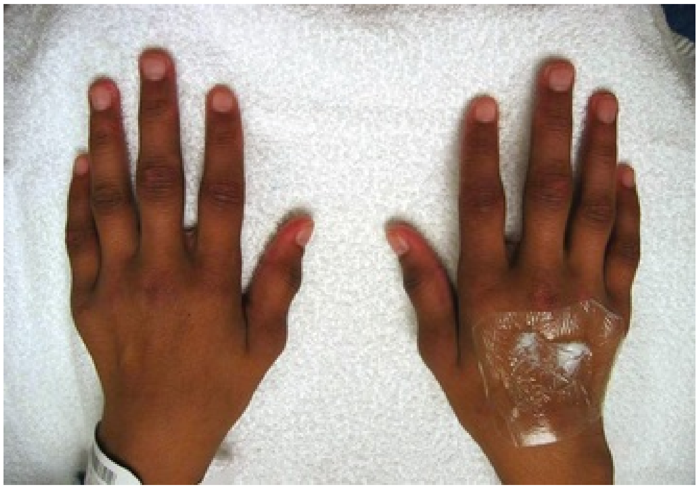

FIG. 180.5 Hands and wrists of a girl with polyarticular juvenile idiopathic arthritis, rheumatoid factor negative. Notice the symmetric involvement of the wrists, metacarpophalangeal joints, and proximal and distal interphalangeal joints. In this photograph, there is cream with occlusive dressing on the patient's right hand in preparation for placement of an intravenous line for administration of a biologic agent.

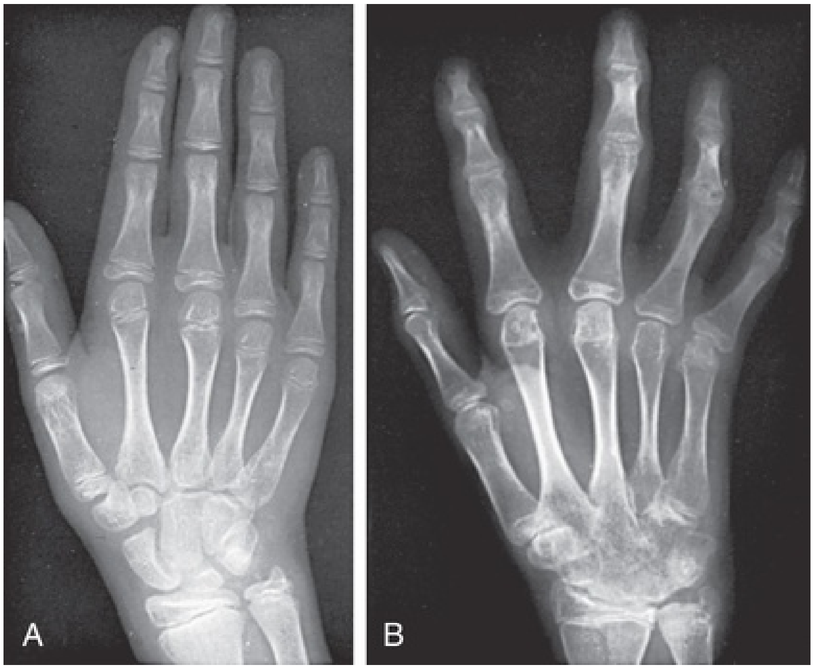

FIG. 180.6 Progression of joint destruction in a girl with polyarticular juvenile idiopathic arthritis, rheumatoid factor positive, despite doses of corticosteroids sufficient to suppress symptoms in the interval between the radiographs shown in **A** and **B. A,** Radiograph of the hand at onset. **B,** Radiograph taken 4 yr later, showing a loss of articular cartilage and

destructive changes in the distal and proximal interphalangeal and metacarpophalangeal joints as well as destruction and fusion of wrist bones.

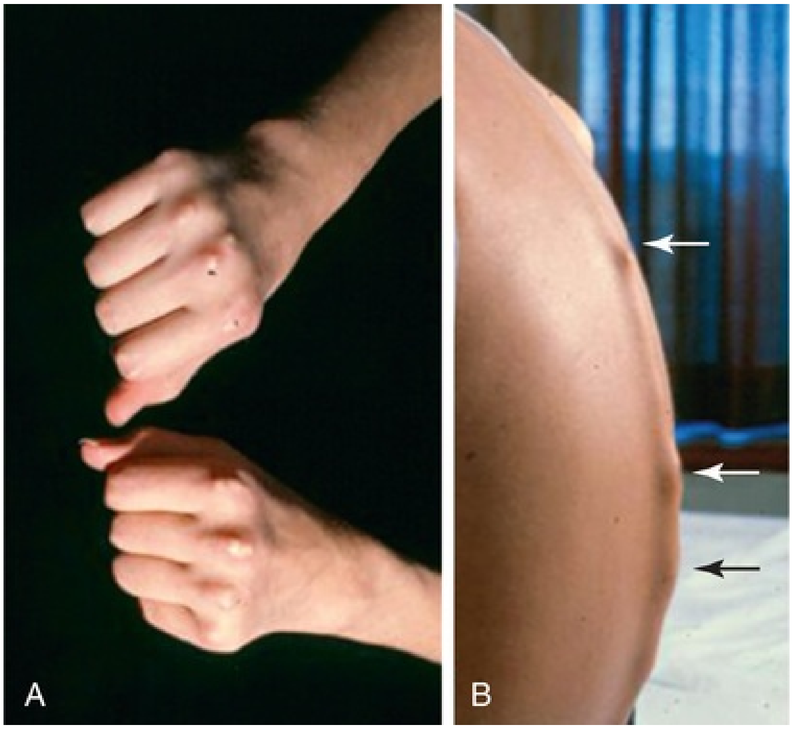

FIG. 180.7 Rheumatoid nodules overlying bony prominences in an adolescent with rheumatoid factor–positive polyarthritis. (From Rosenberg AM, Oen KG: Polyarthritis. In Cassiday JT, Petty RE, Laxer RM, et al, editors: *Textbook of pediatric rheumatology,* ed 6, Philadelphia, 2011, Saunders Elsevier, Fig 15-5, p 257.)

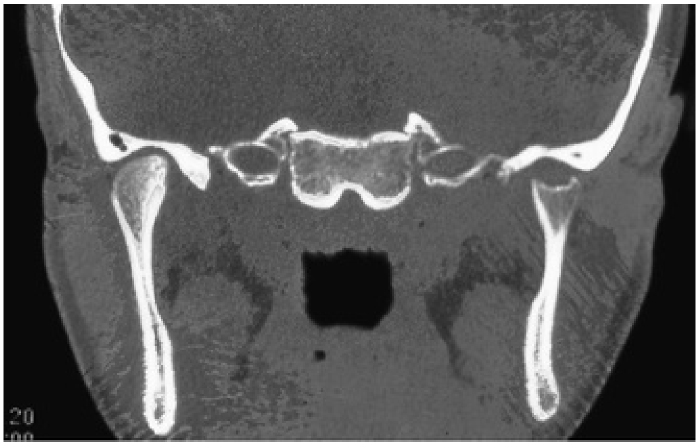

FIG. 180.8 CT scan of the temporomandibular joint of a patient with juvenile idiopathic arthritis exhibiting destruction on the right.

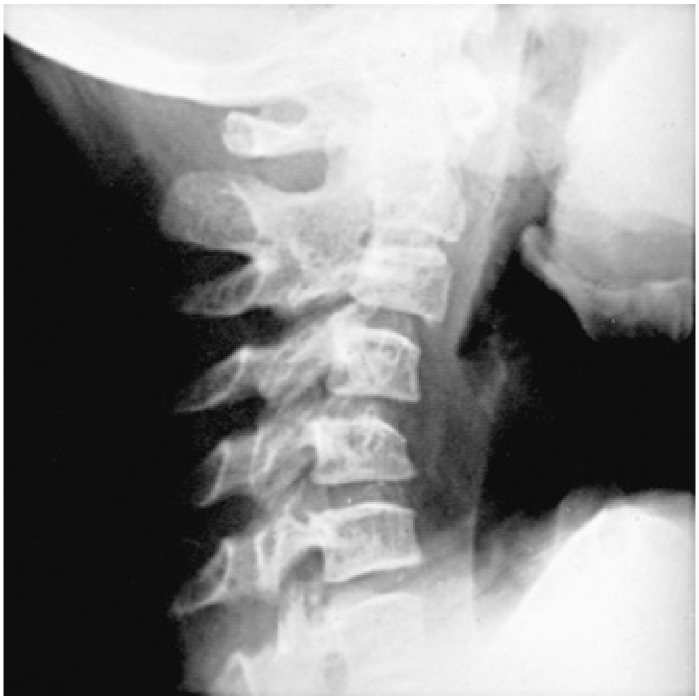

FIG. 180.9 Radiograph of the cervical spine of a patient with active juvenile idiopathic arthritis, showing fusion of the neural arch between joints C2 and C3, narrowing and erosion of the remaining neural arch joints, obliteration of the apophyseal space, and loss of the normal lordosis.

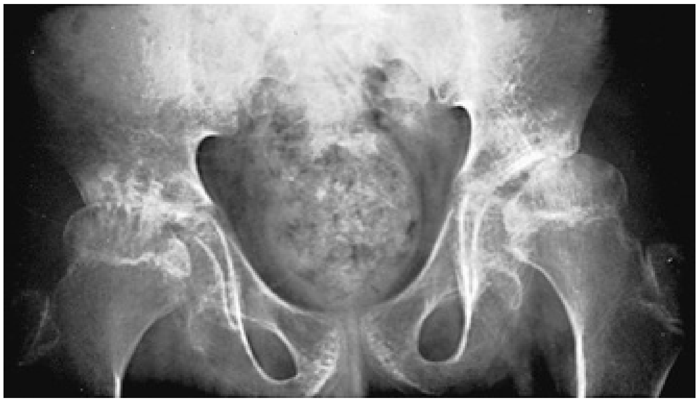

FIG. 180.10 Severe hip disease in 13 yr old boy with active systemic juvenile idiopathic arthritis. Radiograph shows destruction of the femoral head and acetabula, joint space narrowing, and subluxation of left hip. The patient had received corticosteroids systemically for 9 yr.

Systemic JIA is characterized by arthritis, fever, rash, and prominent visceral involvement, including hepatosplenomegaly, lymphadenopathy, and serositis (pericarditis). The characteristic fever, defined as spiking temperatures to ≥39°C (102.2°F), occurs on a daily or twice-daily basis for at least 2 wk, with a rapid return to normal or subnormal temperatures (Fig. 180.11). The fever is often present in the evening and is frequently accompanied by a characteristic faint, erythematous, macular rash. The evanescent **salmon-colored lesions,** classic for sJIA, are linear or circular and are usually distributed over the trunk and proximal extremities (Fig. 180.12). The classic rash is nonpruritic and migratory with lesions lasting <1 hr. **Koebner phenomenon** , a cutaneous hypersensitivity in which classic lesions are brought on by superficial trauma, is often present. Heat can also evoke rash. Fever, rash, hepatosplenomegaly, and lymphadenopathy are present in >70% of affected children. Without arthritis, the **differential diagnosis** includes the episodic fever (autoinflammatory) syndromes (see Chapter 188), infection (endocarditis, rheumatic fever, brucellosis), other rheumatic disorders (SLE, vasculitis syndromes, serum sickness, Kawasaki disease, sarcoidosis, Castleman disease), inflammatory bowel disease, hemophagocytic syndromes, and malignancy. Some children initially present with only systemic features and evolve over time, but definitive diagnosis requires presence of arthritis. Arthritis may affect any number of joints, but the course is classically polyarticular, may be very destructive, and can include hip, cervical spine, and temporomandibular joint involvement.

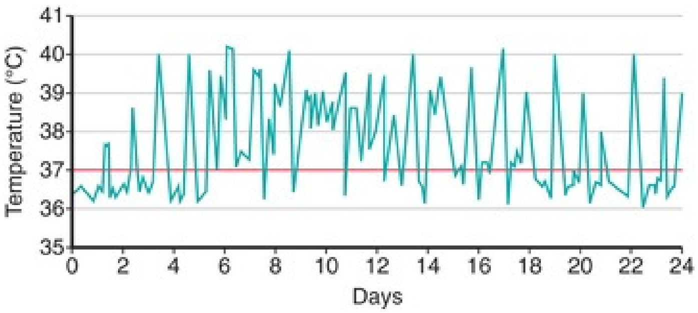

FIG. 180.11 High-spiking intermittent fever in 3 yr old patient with systemic juvenile idiopathic arthritis. (From Ravelli A, Martini A: Juvenile idiopathic arthritis, *Lancet* 369:767–778, 2007.)

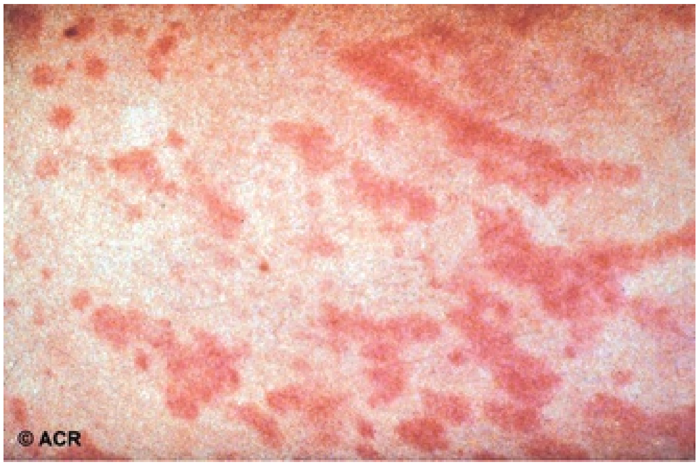

FIG. 180.12 The rash of systemic juvenile idiopathic arthritis is salmon-colored, macular, and nonpruritic. Individual lesions are transient and occur in crops over the trunk and extremities. (Reprinted from the American College of Rheumatology: *Clinical slide collection on the rheumatic diseases,* Atlanta, copyright 1991, 1995, 1997, ACR. Used with permission of the American College of Rheumatology.)

Macrophage activation syndrome (MAS) is a rare but potentially fatal complication of sJIA that can occur at any time (onset, medication change, active or remission) during the disease course. It is also referred to as *secondary hemophagocytic syndrome* or *hemophagocytic lymphohistiocytosis* (HLH) (see Chapter 534.2). There is increasing evidence that sJIA/MAS and HLH share similar functional defects in granule-dependent cytotoxic lymphocyte activity. In addition, sJIA-associated MAS and HLH share genetic variants in approximately 35% of patients with sJIA/MAS. MAS classically manifests as acute onset of high-spiking fevers, lymphadenopathy, hepatosplenomegaly, and encephalopathy. Laboratory evaluation shows thrombocytopenia and leukopenia with elevated liver enzymes, lactate dehydrogenase, ferritin, and triglycerides. Patients may have purpura and mucosal bleeding, as well as elevated fibrin split product values and prolonged prothrombin and partial prothromboplastin times. The erythrocyte sedimentation rate (ESR) falls because of hypofibrinogenemia and hepatic dysfunction, a feature useful in distinguishing MAS from a flare of systemic disease (Table 180.6). An international consensus panel developed a set of classification criteria for sJIA-associated MAS, including hyperferritinemia (>684 ng/mL) and any 2 of the following: thrombocytopenia (≤181 × 10^9 /L), elevated liver enzymes (aspartate transaminase >48 U/L), hypertriglyceridemia (>156 mg/dL), and hypofibrinogenemia (≤360 mg/dL) (Table 180.6). These criteria apply to a febrile patient suspected of sJIA *and* in the absence of disorders such as immune-mediated thrombocytopenia, infectious hepatitis, familial hypertriglyceridemia or visceral leishmaniasis. *A relative change in laboratory values is likely more relevant in making an early diagnosis than are absolute normal values* . A bone marrow aspiration and biopsy may be helpful in diagnosis, but evidence of hemophagocytosis is not always evident. Emergency treatment with high-dose intravenous methylprednisolone, cyclosporine, or anakinra may be effective. Severe cases may require therapy similar to that for primary HLH (see Chapter 534.2).

Table 180.6

Macrophage Activation Syndrome (MAS)

Laboratory Features*

1. Cytopenias
2. Abnormal liver function tests
3. Coagulopathy (hypofibrinogenemia)
4. Decreased erythrocyte sedimentation rate
5. Hypertriglyceridemia
6. Hyponatremia
7. Hypoalbuminemia
8. Hyperferritinemia
9. Elevated sCD25 and sCD163

Clinical Features*

1. Nonremitting fever
2. Hepatomegaly
3. Splenomegaly
4. Lymphadenopathy
5. Hemorrhages
6. Central nervous system dysfunction (headache, seizures, lethargy, coma, disorientation)

Histopathologic Features*

1. Macrophage hemophagocytosis in the bone marrow aspirate
2. Increased CD163 staining of the bone marrow

Proposed Criteria for MAS in sJIA †

- Serum ferritin >684 ng/mL *and*
- Any 2 of the following:
    - Thrombocytopenia (≤181 × 10^9 /L)
    - Elevated liver enzymes (aspartate transaminase >48 U/L)
    - Hypertriglyceridemia (>156 mg/dL)
    - Hypofibrinogenemia (≤360 mg/dL)

† From Ravelli A, Minoia F, Davì S, et al: 2016 Classification criteria for macrophage activation syndrome complicating systemic juvenile idiopathic arthritis: a European League Against Rheumatism/American College of Rheumatology/Paediatric Rheumatology International Trials Organisation collaborative initiative, *Arthritis Rheumatol* 68:566-576, 2016.

Bone mineral metabolism and skeletal maturation are adversely affected in children with JIA, regardless of subtype. Children with JIA have decreased bone mass (osteopenia), which appears to be associated with increased disease activity. Increased levels of cytokines such as TNF-α and IL-6, both key regulators in bone metabolism, have deleterious effects on bone within the joint as well as systemically in the axial and appendicular bones. Abnormalities of skeletal maturation become most prominent during the pubertal growth spurt.

Diagnosis

JIA is a clinical diagnosis without any diagnostic laboratory tests. The meticulous clinical exclusion of other diseases and many mimics is therefore essential. Laboratory studies, including tests for ANA and RF, are only supportive or prognostic, and their results may be normal in patients with JIA (see Tables 180.1 , 180.3 , and 180.4).

Differential Diagnosis

The differential diagnosis for arthritis is broad and a careful, thorough investigation for other underlying etiology is imperative (Table 180.7). History, physical examination, laboratory tests, and radiography may help exclude other possible causes. Arthritis can be a presenting manifestation for any of the multisystem rheumatic diseases of childhood, including systemic lupus erythematosus (see Chapter 183), juvenile dermatomyositis (see Chapter 184), sarcoidosis (see Chapter 190), and the vasculitic syndromes (see Chapter 192). In scleroderma (see Chapter 185), limited ROM caused by sclerotic skin overlying a joint may be confused with sequelae from chronic inflammatory arthritis. **Acute rheumatic fever** is characterized by exquisite joint pain and tenderness, remittent fever, and migratory polyarthritis. **Autoimmune hepatitis** can also be associated with an acute arthritis.

Table 180.7

Conditions Causing Arthritis or Extremity Pain

Rheumatic and Inflammatory Diseases

Juvenile idiopathic arthritis

Systemic lupus erythematosus
Juvenile dermatomyositis
Polyarteritis nodosa
Scleroderma
Sjögren syndrome
Behçet disease
Overlap syndromes
Antineutrophilic cytoplasmic antibody (ANCA)–associated vasculitis
Sarcoidosis
Kawasaki syndrome
Henoch-Schönlein purpura
Chronic recurrent multifocal osteomyelitis

Seronegative Spondyloarthropathies

Juvenile ankylosing spondylitis
Inflammatory bowel disease
Psoriatic arthritis
Reactive arthritis associated with urethritis, iridocyclitis, and mucocutaneous lesions

Infectious Illnesses

Bacterial arthritis (septic arthritis, *Staphylococcus aureus, Kingella kingae*, pneumococcal, gonococcal, *Haemophilus influenzae*)
Lyme disease
Viral illness (parvovirus, rubella, mumps, Epstein-Barr, hepatitis B, chikungunya)
Fungal arthritis
Mycobacterial infection
Spirochetal infection
Endocarditis

Reactive Arthritis

Acute rheumatic fever

Reactive arthritis (postinfectious caused by *Shigella*, *Salmonella*, *Yersinia*, *Chlamydia*, or meningococcus)
Serum sickness
Toxic synovitis of the hip
Postimmunization

Immunodeficiencies

Hypogammaglobulinemia
Immunoglobulin A deficiency
Common variable immunodeficiency disease (CVID)
Human immunodeficiency virus (HIV)

Congenital and Metabolic Disorders

Gout
Pseudogout
Mucopolysaccharidoses
Thyroid disease (hypothyroidism, hyperthyroidism)
Hyperparathyroidism
Vitamin C deficiency (scurvy)
Hereditary connective tissue disease (Marfan syndrome, Ehlers-Danlos syndrome)
Fabry disease
Farber disease
Amyloidosis (familial Mediterranean fever)

Bone and Cartilage Disorders

Trauma
Patellofemoral syndrome
Hypermobility syndromes
Osteochondritis dissecans
Avascular necrosis (including Legg-Calvé-Perthes disease)
Hypertrophic osteoarthropathy
Slipped capital femoral epiphysis

- Osteolysis
- Benign bone tumors (including osteoid osteoma)
- Langerhans cell histiocytosis
- Rickets

Neuropathic Disorders

- Peripheral neuropathies
- Carpal tunnel syndrome
- Charcot joints

Neoplastic Disorders

- Leukemia
- Neuroblastoma
- Lymphoma
- Bone tumors (osteosarcoma, Ewing sarcoma)
- Histiocytic syndromes
- Synovial tumors

Hematologic Disorders

- Hemophilia
- Hemoglobinopathies (including sickle cell disease)

Miscellaneous Disorders

- Autoinflammatory diseases
- Recurrent multifocal osteomyelitis
- Pigmented villonodular synovitis
- Plant-thorn synovitis (foreign body arthritis)
- Myositis ossificans
- Eosinophilic fasciitis
- Tendinitis (overuse injury)
- Raynaud phenomenon

Hemophagocytic syndromes

Pain Syndromes

Fibromyalgia
Growing pains
Depression (with somatization)
Complex regional pain syndrome

Many infections are associated with arthritis, and a recent history of infectious symptoms may help make a distinction. Viruses, including parvovirus B19, rubella, Epstein-Barr virus, hepatitis B virus, and HIV, can induce a transient arthritis. Arthritis may follow enteric infections (see Chapter 182). **Lyme disease** should be considered in children with oligoarthritis living in or visiting endemic areas (see Chapter 249). Although a history of tick exposure, preceding flulike illness, and subsequent rash should be sought, these are not always present. Monoarticular arthritis unresponsive to antiinflammatory treatment may be the result of chronic mycobacterial or other infection, such as *Kingella kingae* , and the diagnosis is established by synovial fluid analysis (PCR) or biopsy. Acute onset of fever and a painful, erythematous, hot joint suggests septic arthritis (see Chapter 705). Isolated hip pain with limited ROM suggests suppurative arthritis, osteomyelitis (see Chapter 704), toxic synovitis, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and chondrolysis of the hip (see Chapter 698).

Lower-extremity arthritis and tenderness over insertion of ligaments and tendons, especially in a boy, suggests ERA (see Chapter 181). **Psoriatic arthritis** can manifest as limited joint involvement in an unusual distribution (e.g., small joints of hand and ankle) years before onset of cutaneous disease. **Inflammatory bowel disease** may manifest as oligoarthritis, usually affecting joints in the lower extremities, as well as gastrointestinal symptoms, elevations in ESR, and microcytic anemia.

Many conditions present solely with arthralgia (i.e., joint pain). Hypermobility may cause joint pain, especially in the lower extremities. Growing pains should be suspected in a child age 4-12 yr complaining of leg pain in the evening with normal investigative studies and no morning symptoms. Nocturnal pain that awakens the child also alerts to the possibility of a malignancy. An adolescent with missed school days may suggest a diagnosis of fibromyalgia (see Chapter 193).

Children with **leukemia** or **neuroblastoma** may have joint or bone pain resulting from malignant infiltration of the bone, synovium, or more often the bone marrow, sometimes months before demonstrating lymphoblasts on peripheral blood smear. Physical examination may reveal no tenderness, a deeper pain with palpation of the bone, or pain out of proportion to exam findings. Malignant pain often awakens the child from sleep and may cause cytopenias. Because platelets are an acute-phase reactant, a high ESR with leukopenia and a low normal platelet count may also be a clue to underlying leukemia. In addition, the characteristic quotidian fever of sJIA is absent in malignancy. Bone marrow examination is necessary for diagnosis. Some diseases, such as cystic fibrosis, diabetes mellitus, and the glycogen storage diseases, have associated arthropathies (see Chapter 194). Swelling that extends beyond the joint can be a sign of lymphedema or Henoch-Schönlein purpura (see Chapter 192.1). A peripheral arthritis indistinguishable from JIA occurs in the humoral immunodeficiencies (see Chapter 150), such as common variable immunodeficiency and X-linked agammaglobulinemia. Skeletal dysplasias associated with a degenerative arthropathy are diagnosed from their characteristic radiologic abnormalities.

Systemic onset of JIA often presents as a fever of unknown origin (see Chapter 204). Important considerations in the differential diagnosis include infections (endocarditis, brucellosis, cat scratch disease, Q fever, mononucleosis), autoinflammatory disease (see Chapter 188) malignancy (leukemia, lymphoma, neuroblastoma) and HLH (see Chapter 534.2).

Laboratory Findings

Hematologic abnormalities often reflect the degree of systemic or articular inflammation, with elevated white blood cell (WBC) and platelet counts and a microcytic anemia. Inflammation may also cause elevations in ESR and C-reactive protein, although it is not unusual for both to be normal in children with JIA.

Elevated ANA titers are present in 40–85% of children with oligoarticular or polyarticular JIA, but are rare with sJIA. ANA seropositivity is associated with increased risk of **chronic uveitis** in JIA. Approximately 5–15% of patients with polyarticular JIA are seropositive for RF. Anti–cyclic citrullinated peptide antibody, as with RF, is a marker of more aggressive disease. Both ANA and RF seropositivity can occur in association with transient events, such as viral infection.

Children with sJIA usually have striking elevations in inflammatory markers and WBC and platelet counts. Hemoglobin levels are low, typically 7-10 g/dL, with indices consistent with anemia of chronic disease. The ESR is usually high, except in MAS. Although immunoglobulin levels tend to be high, ANA and RF are uncommon. Ferritin values are typically elevated and can be markedly increased in MAS (>10,000 ng/mL). In the setting of MAS, all cell lines have the potential to decline precipitously because of the consumptive process. A low or normal WBC count and/or platelet count in a child with active sJIA should raise concerns for MAS.

Early radiographic changes of arthritis include soft tissue swelling, periarticular osteopenia, and periosteal new-bone apposition around affected joints (Fig. 180.13). Continued active disease may lead to subchondral erosions, loss of cartilage, with varying degrees of bony destruction, and fusion. Characteristic radiographic changes in cervical spine, most frequently in the neural arch joints at C2-C3 (see Fig. 180.9), may progress to atlantoaxial subluxation. MRI is more sensitive than radiography to detect early changes (Fig. 180.14).

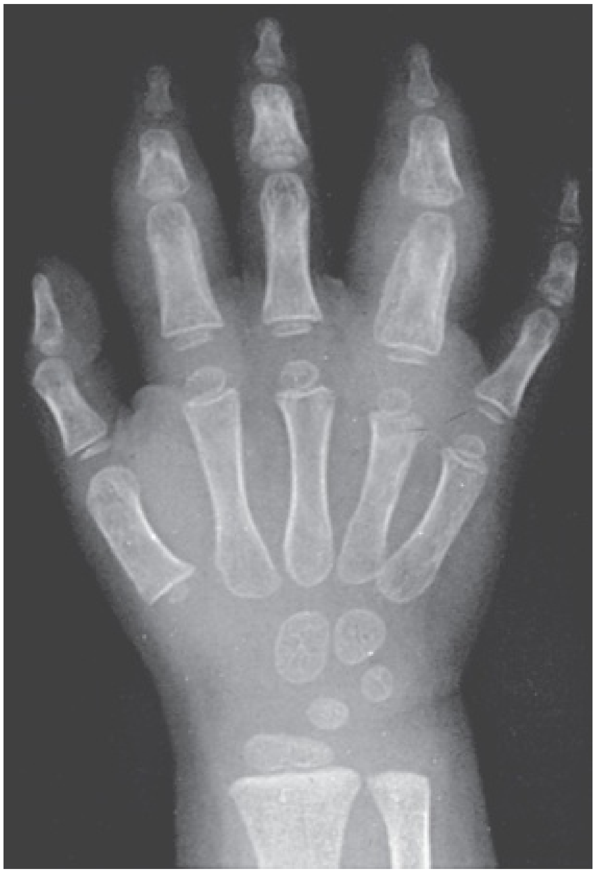

FIG. 180.13 Early (6 mo duration) radiographic changes of juvenile idiopathic arthritis. Soft-tissue swelling and periosteal new bone formation appear adjacent to the 2nd and 4th proximal interphalangeal joints.

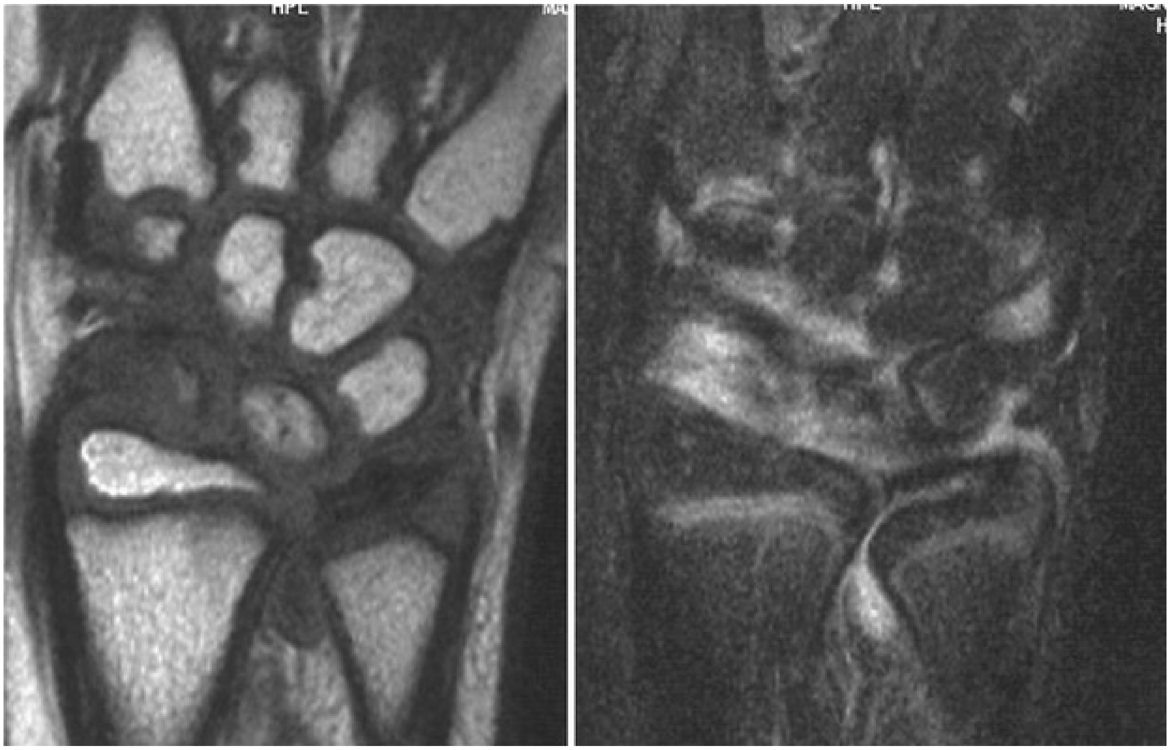

FIG. 180.14 MRI of the wrist in a child with wrist arthritis. *Left,* Image shows multiple erosions of carpal bones. *Right,* Image obtained after administration of gadolinium contrast agent reveals uptake consistent with active synovitis.

Treatment

The goals of treatment are to achieve disease remission, prevent or halt joint damage, and foster normal growth and development. All children with JIA need individualized treatment plans, and management is tailored according to disease subtype and severity, presence of poor prognostic indicators, and response to medications. Disease management also requires monitoring for potential medication toxicities (see Chapter 179).

Children with oligoarthritis often show partial response to nonsteroidal antiinflammatory drugs (NSAIDs), with improvement in inflammation and pain (Table 180.8). Those who have no or partial response after 4-6 wk of treatment with NSAIDs, or who have functional limitations such as joint contracture or leg-length discrepancy, benefit from injection of intraarticular corticosteroids. *Triamcinolone hexacetonide* is a long-lasting preparation that provides a prolonged response. A substantial fraction of patients with oligoarthritis show no response to NSAIDs and injections, and therefore require treatment with disease-modifying antirheumatic drugs (DMARDs), including methotrexate, and, if no response, TNF inhibitors.

Table 180.8

Pharmacologic Treatment of Juvenile Idiopathic Arthritis (JIA)

TYPICAL MEDICATIONS	TYPICAL DOSES	JIA SUBTYPE	SIDE EFFECT(S)
NONSTEROIDAL ANTIINFLAMMATORY DRUGS			
Naproxen	15 mg/kg/day PO divided bid (maximum dose 500 mg bid)	Polyarthritis Systemic Oligoarthritis	Gastritis, renal and hepatic toxicity, pseudoporphyria
Ibuprofen	40 mg/kg/day PO divided tid (maximum dose 800 mg tid)	Same as above	Same as above
Meloxicam	0.125 mg/kg PO once daily (maximum dose 15 mg daily)	Same as above	Same as above
DISEASE-MODIFYING ANTIRHEUMATIC DRUGS			
Methotrexate	0.5-1 mg/kg PO or SC weekly (maximum dose 25 mg/wk)	Polyarthritis Systemic Persistent or extended oligoarthritis	Nausea, vomiting, oral ulcerations, hepatic toxicity, blood count dyscrasias, immunosuppression, teratogenicity
Sulfasalazine	Initial 12.5 mg/kg PO daily; increase by 10 mg/kg/day Maintenance: 40-50 mg/kg divided bid (maximum dose 2 g/day)	Polyarthritis	GI upset, allergic reaction, pancytopenia, renal and hepatic toxicity, Stevens-Johnson syndrome
Leflunomide*	10-20 mg PO daily	Polyarthritis	GI upset, hepatic toxicity, allergic rash, alopecia (reversible), teratogenicity (needs washout with cholestyramine)
BIOLOGIC AGENTS			
Anti–Tumor Necrosis Factor-α			
Etanercept	0.8 mg/kg SC weekly or 0.4 mg/kg SC twice weekly (maximum dose 50 mg/wk)	Polyarthritis Systemic Persistent or extended oligoarthritis	Immunosuppressant, concern for malignancy, demyelinating disease, lupus-like reaction, injection site reaction
Infliximab*	3-10 mg/kg IV q4-8 wk	Same as above	Same as above, infusion reaction
Adalimumab	10 to <15 kg: 10 mg SC every other week 15 to <30 kg: 20 mg SC every other week >30 kg: 40 mg SC every other week	Same as above	Same as above
Anticytotoxic T-Lymphocyte–Associated Antigen-4 Immunoglobulin			
Abatacept	<75 kg: 10 mg/kg/dose IV q4wk 75-100 kg: 750 mg/dose	Polyarthritis	Immunosuppressant, concern for malignancy, infusion reaction

	IV q4wk >100 kg: 1,000 mg/dose IV q4wk SC once weekly: 10 to <25 kg: 50 mg ≥25 to <50 kg: 87.5 mg ≥50 kg: 125 mg		
Anti-CD20			
Rituximab*	750 mg/m^2 IV 2 wk × 2 (maximum dose 1,000 mg)	Polyarthritis	Immunosuppressant, infusion reaction, progressive multifocal encephalopathy
Interleukin-1 Inhibitors			
Anakinra*	1-2 mg/kg SC daily (maximum dose 100 mg/day)	Systemic	Immunosuppressant, GI upset, injection site reaction
Canakinumab	15-40 kg: 2 mg/kg/dose SC q8wk >40 kg: 150 mg SC q8wk	Systemic	Immunosuppressant, headache, GI upset, injection site reaction
Rilonacept*	2.2 mg/kg/dose SC weekly (maximum dose 160 mg)	Systemic	Immunosuppressant, allergic reaction, dyslipidemia, injection site reaction
Interleukin-6 Receptor Antagonist			
Tocilizumab	IV q2 wk: <30 kg: 12 mg/kg/dose q2wk >30 kg: 8 mg/kg/dose q2wk (maximum dose 800 mg)	Systemic Polyarthritis	Immunosuppressant, hepatic toxicity, dyslipidemia, cytopenias, GI upset, infusion reaction
	SC: <30 kg: 162 mg/dose q3wk ≥30 kg: 162 mg/dose q2wk	Polyarthritis	

* Not indicated by the U.S. Food and Drug Administration for use in JIA as of 2018.

bid, Twice daily; GI, gastrointestinal; IV, intravenous; PO, oral; q, every; SC, subcutaneous; tid, 3 times daily.

NSAIDs alone rarely induce remission in children with polyarthritis or sJIA. *Methotrexate* is the oldest and least toxic of the DMARDs available for adjunctive therapy. It may take 6-12 wk to see the effects of methotrexate. Failure of methotrexate monotherapy warrants the addition of a biologic DMARD. Biologic medications that inhibit proinflammatory cytokines, such as TNF-α, IL-1, and IL-6, demonstrated excellent disease control. TNF-α antagonists (e.g., *etanercept, adalimumab*) are used to treat children with an inadequate response to methotrexate, with poor prognostic factors, or with severe disease onset. Early aggressive therapy with a combination of methotrexate and a TNF-α antagonist may result in earlier achievement of clinically inactive disease. *Abatacept*, a selective inhibitor of T-cell activation, and *tocilizumab*, an IL-6 receptor antagonist, have demonstrated efficacy in and are approved for treatment of polyarticular JIA (Table 180.8).

TNF inhibition is not as effective for the systemic symptoms found in sJIA. When systemic symptoms dominate, systemic corticosteroids are started followed by the initiation of IL-1 or IL-6 antagonist therapy, which often induces a dramatic and rapid response. Patients with severe disease activity may go directly to anakinra. *Canakinumab,* an IL-1β inhibitor, and tocilizumab are FDA-approved treatments for sJIA in children older than 2 yr (Table 180.8). Standardized consensus treatment plans to guide therapy for sJIA outline 4 treatment plans based on glucocorticoids, methotrexate, anakinra, or tocilizumab, with optional glucocorticoid use in the latter 3 plans as clinically indicated.

With the advent of newer DMARDs, the use of systemic corticosteroids can often be avoided or minimized. Systemic corticosteroids are recommended only for management of severe systemic illness, for *bridge therapy* during the wait for therapeutic response to a DMARD, and for control of uveitis. Steroids impose risks of severe toxicities, including Cushing syndrome, growth retardation, and osteopenia, and they do not prevent joint destruction.

Oral Janus kinase (JAK) inhibitors (tofacitinib, ruxolitinib) inhibit JAK signaling pathways involved in immune activation and inflammation. *Tofacitinib* is FDA approved for adults with rheumatoid arthritis.

Management of JIA must include periodic slit-lamp ophthalmologic examinations to monitor for asymptomatic uveitis (Figs. 180.15 and 180.16 ; see Table 180.4). Optimal treatment of uveitis requires collaboration between the ophthalmologist and rheumatologist; initial management may include mydriatics and corticosteroids used topically, systemically, or through periocular injection. DMARDs allow for a decrease in exposure to steroids, and methotrexate and TNF-α inhibitors (adalimumab and infliximab) are effective in treating severe uveitis.

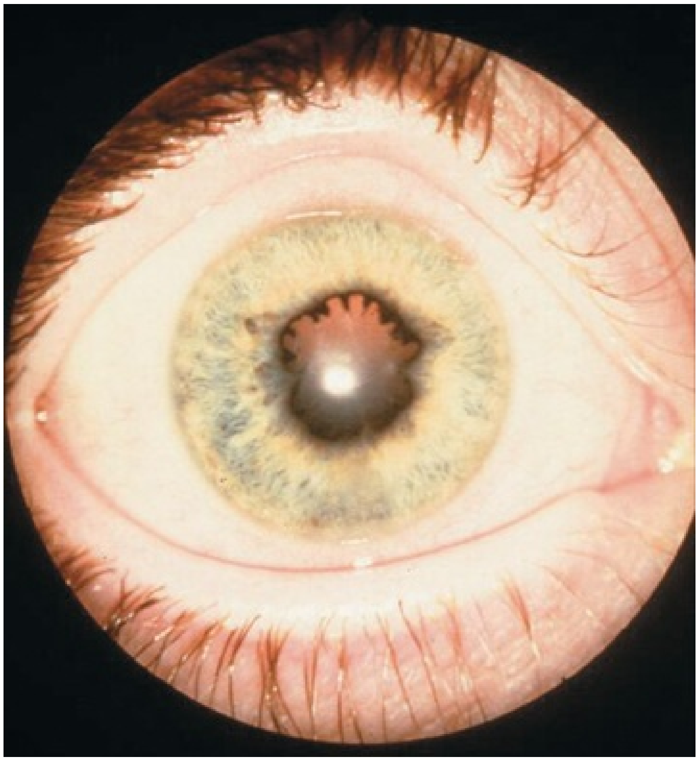

FIG. 180.15 Chronic anterior uveitis demonstrating posterior synechiae and absence of significant scleral inflammation. (From Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley & Firestein's textbook of rheumatology,* ed 10, Philadelphia, 2017, Elsevier, Fig 107-5, p 1838.)

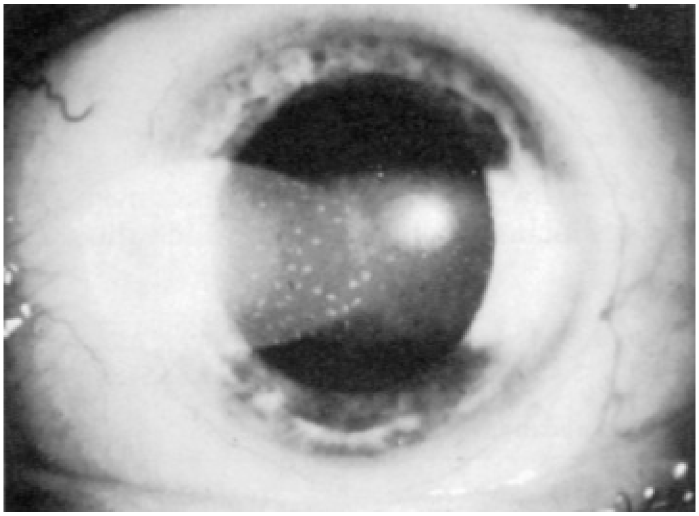

FIG. 180.16 Slit-lamp examination shows “flare” in the fluid of the anterior chamber (caused by increased protein content) and keratic precipitates on the posterior surface of the cornea, representing small collections of inflammatory cells. (Courtesy of Dr. H.J. Kaplan. From Petty RE,

Rosenbaum JT: Uveitis in juvenile idiopathic arthritis. In Cassidy JT, Petty RE, Laxer RM, et al, editors, *Textbook of pediatric rheumatology,* ed 6, Philadelphia, 2011, Saunders, Fig 20-3, p 309.)

Dietary evaluation and counseling to ensure appropriate calcium, vitamin D, protein, and caloric intake are important for children with JIA. Physical therapy and occupational therapy are invaluable adjuncts to any treatment program. A social worker and nurse clinician can be important resources for families, to recognize stresses imposed by a chronic illness, to identify appropriate community resources, and to aid compliance with the treatment protocol.

Prognosis

Although the course of JIA in an individual child is unpredictable, some prognostic generalizations can be made on the basis of disease type and course. Studies analyzing management of JIA in the pre–TNF-α era indicate that up to 50% of patients with JIA have active disease persisting into early adulthood, often with severe limitations of physical function.

Children with persistent oligoarticular disease fare well, with a majority achieving disease remission. Those with extended oligoarticular disease have a poorer prognosis. Children with oligoarthritis, particularly girls who are ANA positive and with onset of arthritis before 6 yr of age, are at greatest risk for development of chronic uveitis. There is no association between the activity or severity of arthritis and uveitis. Persistent, uncontrolled anterior uveitis (see Fig. 180.15) can cause posterior synechiae, cataracts, glaucoma, and band keratopathy, with resultant blindness. Morbidity can be averted with early diagnosis and implementation of systemic therapy.

The child with polyarticular JIA often has a more prolonged course of active joint inflammation and requires early and aggressive therapy. Predictors of severe and persistent disease include young age at onset, RF seropositivity or rheumatoid nodules, presence of anti–cyclic citrullinated peptide antibodies, and many affected joints. Disease involving the hip and hand/wrist is also associated with a poorer prognosis and may lead to significant functional impairment.

Systemic JIA is often the most difficult to control in terms of both articular inflammation and systemic manifestations. Poorer prognosis is related to polyarticular distribution of arthritis, fever lasting >3 mo, and increased inflammatory markers, such as platelet count and ESR, for >6 mo. IL-1 and IL-6 inhibitors have changed the management and improved the outcomes for children with severe and prolonged systemic disease.

Orthopedic complications include leg length discrepancy and flexion contractures, particularly of the knees, hips, and wrists. Discrepancies in leg length can be managed with a shoe lift on the shorter side to prevent secondary scoliosis. Joint contractures require aggressive medical control of arthritis, often in conjunction with intraarticular corticosteroid injections, appropriate splinting, and stretching of the affected tendons. Popliteal cysts may require no treatment if they are small or respond to intraarticular corticosteroids in the anterior knee.

Psychosocial adaptation may be affected by JIA. Studies indicate that, compared with controls, a significant number of children with JIA have problems with lifetime adjustment and employment. Disability not directly associated with arthritis may continue into young adulthood in as many as 20% of patients, together with continuing chronic pain syndromes at a similar frequency. Psychological complications, including problems with school attendance and socialization, may respond to counseling by mental health professionals.

CHAPTER 181

Ankylosing Spondylitis and Other Spondyloarthritides

Pamela F. Weiss, Robert A. Colbert

The diseases collectively referred to as *spondyloarthritides* include **ankylosing spondylitis (AS)** , arthritis associated with inflammatory bowel disease (IBD) or psoriasis, and reactive arthritis following gastrointestinal (GI) or genitourinary (GU) infections (Table 181.1 and Table 181.2). **Spondyloarthritis** is more common in adults, but all forms can present during childhood with varying symptoms and signs. Many children with spondyloarthritis are classified in the **juvenile idiopathic arthritis (JIA)** categories of **enthesitis-related arthritis (ERA)** or psoriatic arthritis. Children and adolescents with spondyloarthritis who may not meet JIA criteria include arthritis associated with IBD, juvenile ankylosing spondylitis (JAS), and reactive arthritis.

Table 181.1

Overlapping Characteristics of the Spondyloarthritides*

CHARACTERISTIC	JUVENILE ANKYLOSING SPONDYLITIS	JUVENILE PSORIATIC ARTHRITIS	INFLAMMATORY BOWEL DISEASE	REACTIVE ARTHRITIS
Enthesitis	+++	+	+	++
Axial arthritis	+++	++	++	+
Peripheral arthritis	+++	+++	+++	+++
HLA-B27 positive	+++	+	++	+++
Antinuclear antibody positive	−	++	−	−
Rheumatoid factor positive	−	−	−	−
SYSTEMIC DISEASE:

Chlamydia pneumoniae
Chlamydia psittaci

From Kim PS, Klausmeier TL, Orr DP: Reactive arthritis: a review, *J Adolesc*

Health 44:309–315, 2009 (Table 2, p 311).

Epidemiology

JIA is diagnosed in 90 per 100,000 U.S. children every year (see Chapter 180). ERA accounts for 10–20% of JIA, and has a mean age at onset of 12 yr. In India, ERA is the most common category of JIA, accounting for 35% of cases. Unlike other JIA categories, males are affected more often than females, accounting for 60% of ERA cases. AS occurs in 0.2–0.5% of adults, with approximately 15% of cases beginning in childhood. These disorders can be familial, largely as a result of the influence of human leukocyte antigen (**HLA**)-**B27** , which is found in 90% of JAS and 50% of ERA patients compared to 7% of healthy individuals. Approximately 20% of children with ERA have a family history of HLA-B27–associated disease, such as reactive arthritis, AS, or IBD with sacroiliitis.

Etiology and Pathogenesis

Spondyloarthritides are complex diseases in which susceptibility is largely genetically determined. Only 30% of heritability has been defined, with HLA-B27 responsible for two thirds of the total, and >100 additional genetic loci accounting for only one third. Genes that influence interleukin (IL)-23 responses (e.g., *CARD9* , *IL23R, JAK2, TYK2* , *STAT3*) and the function of HLA-B27 *(ERAP1)* are particularly important. Unusual properties of HLA-B27, such as its tendency to misfold and form abnormal cell surface structures, may have a role. Infection with certain GI or GU pathogens can trigger reactive arthritis (see Table 181.2 and Chapter 182). Altered gut microbiota and an abnormal immune response to normal microbiota may also play a role in pathogenesis. Inflamed joints and entheses in spondyloarthritis contain T and B cells, macrophages, osteoclasts, proliferating fibroblasts, and osteoblasts, with activation of the IL-23/IL-17 pathway. Bone loss and osteoproliferation in and around vertebral bodies and facet joints in long-standing AS contribute to significant morbidity.

Clinical Manifestations and Diagnosis

Clinical manifestations that help distinguish spondyloarthritis from other forms of juvenile arthritis include arthritis of the axial skeleton (sacroiliac joints) and hips, enthesitis (inflammation at the site of tendon, ligament, or joint capsule attachment to bone), symptomatic eye inflammation (acute anterior uveitis), and GI inflammation (even in the absence of IBD) (Tables 181.1 and 181.3).

Table 181.3

Assessment in Spondyloarthritis International Society (ASAS) Classification Criteria for Spondyloarthritis (SpA)

AXIAL SpA			**PERIPHERAL SpA**
In patients with ≥3 mo back pain and age at onset <45 yr			In patients with peripheral symptoms ONLY
Sacroiliitis on imaging * *plus* ≥1 SpA feature(s)	*or*	**HLA-B27** *plus* ≥2 other SpA features	**Arthritis** *or* **enthesitis** *or* **dactylitis** *plus*
SpA features • Inflammatory back pain (IBP) • Arthritis • Enthesitis (heel) • Uveitis • Dactylitis • Psoriasis • Crohn disease/ulcerative colitis • Good response to NSAIDs • Family history for SpA • HLA-B27 • Elevated CRP			≥1 SpA feature(s) • Uveitis • Psoriasis • Crohn disease/ulcerative colitis • Preceding infection • HLA-B27 • Sacroiliitis on imaging* *or* ≥2 other SpA features • Arthritis • Enthesitis • Dactylitis • IBP ever • Family history for SpA

* Active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA. Definite radiographic sacroiliitis according to modified NY criteria.

CRP, C-reactive protein; NSAIDs, nonsteroidal antiinflammatory drugs.

Adapted from Rudwaleit M, van der Heijde D, Landewé R, et al: The development of Assessment of Spondyloarthritis International Society classification criteria for axial spondyloarthritis. Part II. Validation and final selection, Ann Rheum Dis 68(6):777–783, 2009; and The Assessment of Spondyloarthritis International Society classification criteria for peripheral spondyloarthritis and for spondyloarthritis in general, Ann Rheum Dis 70(1):25–31, 2011.

Enthesitis-Related Arthritis

Children have ERA if they have *either* arthritis and enthesitis *or* arthritis or enthesitis, with at least 2 of the following characteristics: (1) sacroiliac joint tenderness or inflammatory lumbosacral pain, (2) presence of HLA-B27, (3) onset of arthritis in a male older than 6 yr, (4) acute anterior uveitis, and (5) a family history of an HLA-B27–associated disease (ERA, sacroiliitis with IBD, reactive arthritis, or acute anterior uveitis) in a first-degree relative. Patients with psoriasis (or a family history of psoriasis in a first-degree relative), a positive–rheumatoid factor (RF) test result, or systemic arthritis are excluded from this group. During the 1st 6 mo of disease the arthritis is typically asymmetric and involves ≤4 joints. most frequently the knees, ankles, and hips. Inflammation of the small joints of the foot, or *tarsitis,* is highly suggestive of ERA. Enthesitis is typically symmetric and typically affects the lower limbs. Up to 40% of children develop clinical or radiographic evidence of sacroiliac joint arthritis as part of their disease; approximately 20% have evidence of sacroiliac joint arthritis at diagnosis. When the sacroiliac or other axial joints are involved, children may experience **inflammatory back pain** (Table 181.4), hip pain, and alternating buttock pain. Patients may also experience pain with palpation of the lower back or with pelvic compression. The risk of sacroiliac joint arthritis is highest in children who are HLA-B27 positive and have an elevated C-reactive protein (CRP). Untreated sacroiliitis may, but does not always, evolve into AS; additional risk factors for progression are unclear.

Table 181.4

Symptoms Characteristic of Inflammatory Back Pain

Pain at night with morning stiffness (and improvement on arising)
No improvement with rest
Improvement with exercise
Insidious onset
Good response to nonsteroidal antiinflammatory drugs

Psoriatic Arthritis

Psoriatic arthritis accounts for approximately 5% of JIA. Common clinical features of psoriatic arthritis are nail pitting (Fig. 181.1), onycholysis, and dactylitis (sausage-like swelling of fingers or toes).

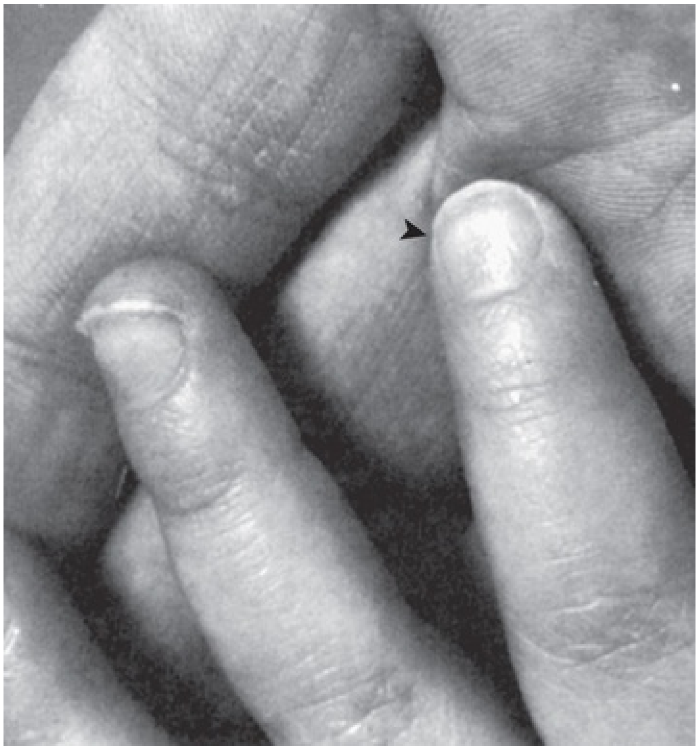

FIG. 181.1 Nail pitting *(arrowhead)* and "sausage digit" (dactylitis) of the left index finger of a girl with juvenile psoriatic arthritis. (From Petty RE, Malleson P: Spondyloarthropathies of childhood, *Pediatr Clin North Am* 33:1079–1096, 1986.)

Children have psoriatic arthritis if they have arthritis and psoriasis *or* arthritis and at least 2 of the following: (1) dactylitis, (2) nail pitting or onycholysis, and (3) psoriasis in a first-degree relative. The presence of psoriasis aids in diagnosis but is not required. Disease onset peaks during the preschool and early adolescent years. Children with onset during the preschool years are more often female, antinuclear antibody (ANA) positive, and at risk for asymptomatic ocular inflammation. Disease onset during adolescence is equally common among males and females. In the majority of children the arthritis is asymmetric and affects ≤4 joints at presentation. Large (knees and ankles) and small (fingers and toes) joints may be involved. Although distal interphalangeal joint involvement is uncommon, it is highly suggestive of the diagnosis. Enthesitis is detectable in 20–60% of patients and seems to be more frequent in those who present at an older age. Axial (sacroiliac) and root (hip) joints may be affected in up to 30% of children; the risk of axial arthritis is highest in those who are HLA-B27 positive.

Juvenile Ankylosing Spondylitis

JAS frequently begins with oligoarthritis and enthesitis. The arthritis occurs predominantly in the lower extremities and often involves the hips. In comparison to adult-onset AS, axial disease and inflammatory back pain are less frequent at disease onset, whereas enthesitis and peripheral arthritis are more common. AS is diagnosed according to the modified New York (NY) criteria if there is sufficient radiographic evidence of sacroiliitis (sacroiliitis of grade 2 or greater bilaterally or at least grade 3 unilaterally) and if the patient meets at least 1 clinical criterion involving inflammatory back pain, limitation of motion in the lumbar spine (Fig. 181.2), or limitation of chest expansion. JAS is present if the patient is <16 yr old. Juvenile-*onset* AS is frequently used to describe adult AS when the symptoms began before 16 yr of age, but full criteria were not met until later.

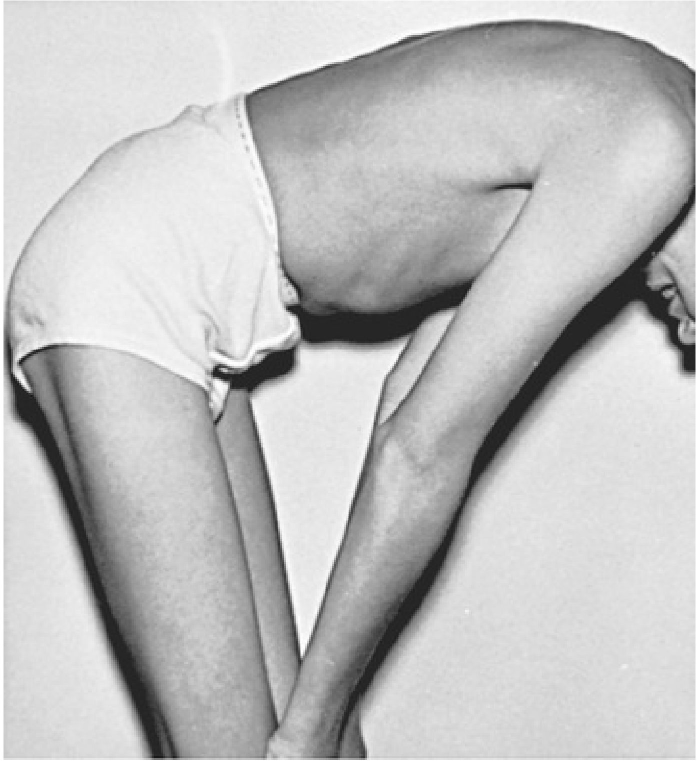

FIG. 181.2 Loss of lumbodorsal spine mobility in a boy with ankylosing spondylitis. The lower spine remains straight when the patient bends forward.

To fulfill the modified NY criteria for AS, patients must have radiographic changes in the sacroiliac joints as well as clinical sequelae of axial disease. Because radiographic sacroiliitis can take many years to develop in adults and even longer in children, and clinical sequelae may lag further behind, criteria to identify preradiographic axial spondyloarthritis were developed by the **Assessment of SpondyloArthritis International Society** . To meet criteria for axial spondyloarthritis (SpA), patients must have at least 3 mo of back pain and sacroiliitis on imaging (acute inflammation on MRI or definite radiographic sacroiliitis by NY criteria) plus 1 feature of SpA (inflammatory back pain, arthritis, enthesitis [heel], uveitis, dactylitis, psoriasis, Crohn disease/ulcerative colitis, good response to nonsteroidal antiinflammatory drugs [NSAIDs], family history for SpA, HLA-B27, or elevated C-reactive protein). Alternatively, patients can fulfill axial SpA criteria if they are HLA-B27 positive and have at least 2 SpA features. These criteria have low sensitivity and specificity in the pediatric population but, in the absence of alternate pediatric criteria, may be useful as a guide to evaluating preradiographic axial SpA.

Arthritis With Inflammatory Bowel Disease

The presence of erythema nodosum, pyoderma gangrenosum, oral ulcers, abdominal pain, diarrhea, fever, weight loss, or anorexia in a child with chronic arthritis should raise suspicion of IBD. Two patterns of arthritis complicate IBD. **Polyarthritis** affecting large and small joints is most common and often reflects the activity of the intestinal inflammation. Less frequently, **arthritis of the axial skeleton** , including the sacroiliac joints, occurs. As with psoriatic arthritis, the presence of HLA-B27 is a risk factor for the development of axial disease. The severity of axial involvement is independent of the activity of the GI inflammation.

Laboratory Findings

Laboratory evidence of systemic inflammation with elevation of the erythrocyte sedimentation rate (ESR) and/or CRP value is variable in most spondyloarthritides and may or may not be present at the onset of disease. RF and ANAs are absent, except in children with psoriatic arthritis, as many as 50% of whom are ANA positive. HLA-B27 is present in approximately 90% of children with JAS, compared with 7% of healthy individuals, but is less frequent in ERA and other SpA types.

Imaging

Conventional radiographs detect chronic bony changes and damage but not active inflammation. Early radiographic changes in the sacroiliac joints include indistinct margins and erosions that can result in joint space widening. **Sclerosis** typically starts on the iliac side of the joint (Fig. 181.3). Peripheral joints may exhibit periarticular **osteoporosis** , with loss of sharp cortical margins in areas of enthesitis, which may eventually show erosions or bony spurs (enthesophytes). Squaring of the corners of the vertebral bodies and syndesmophyte formation resulting in the classic "bamboo spine" characteristic of advanced AS is rare in early disease, particularly in childhood. CT, like radiographs, can detect chronic bony changes but not active inflammation and has the disadvantage of more radiation exposure. The gold standard for early visualization of sacroiliitis is evidence of bone marrow edema adjacent to the joint on MRI with fluid-sensitive sequences such as short-T1 inversion recovery (STIR). Gadolinium does not add value to the study of the sacroiliac joints if STIR is used. MRI will reveal abnormalities before the plain radiograph. Whole body MRI is also used to evaluate the axial skeleton in adults with early disease because it can detect vertebral lesions in addition to sacroiliac changes.

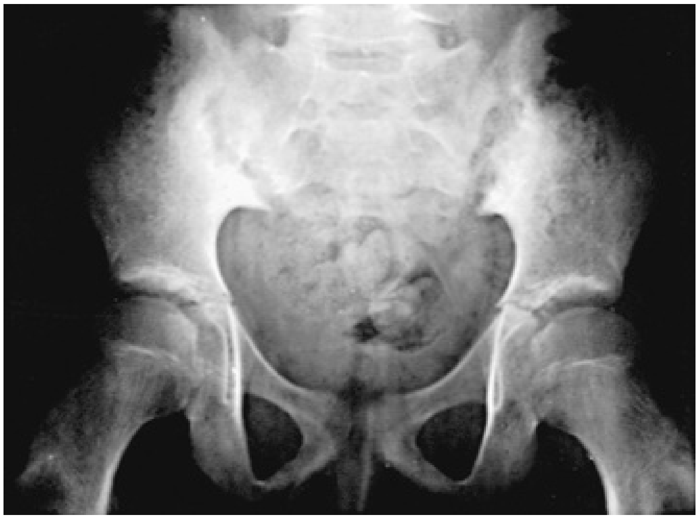

FIG. 181.3 Well-developed sacroiliitis in a boy with ankylosing spondylitis. Both sacroiliac joints show extensive sclerosis, erosion of joint margins, and apparent widening of the joint space.

Differential Diagnosis

The onset of arthritis following a recent history of diarrhea or symptoms of urethritis or conjunctivitis may suggest **reactive arthritis** (see Chapter 182). Lower back pain can be caused by suppurative arthritis of the sacroiliac joint, osteomyelitis of the pelvis or spine, osteoid osteoma of the posterior elements of the spine, pelvic muscle pyomyositis, or malignancies. In addition, mechanical conditions such as spondylolysis, spondylolisthesis, and Scheuermann disease should be considered. Back pain secondary to **fibromyalgia** usually affects the soft tissues of the upper back in a symmetric pattern and is associated with well-localized tender points and sleep disturbance (see Chapter 193.3). Legg-Calvé-Perthes disease (avascular necrosis of the femoral head), slipped capital femoral epiphysis, and chondrolysis may also manifest as pain over the inguinal ligament and loss of internal rotation of the hip joint, but without other SpA features, such as involvement of other entheses and/or joints. Radiography or MRI is critical for distinguishing these conditions.

Treatment

The goals of therapy are to control inflammation, minimize pain, preserve function, and prevent ankylosis (fusion of adjacent bones) using a combination of antiinflammatory medications, physical therapy, and education. Treatment regimens for SpA include monotherapy or combination therapy with NSAIDs, disease-modifying antirheumatic drugs (DMARDs), or biologic agents. NSAIDs, such as naproxen (15-20 mg/kg/day), are frequently used initially and may slow the progression of structural damage (syndesmophyte formation and growth) if used continually. With relatively mild disease, intraarticular corticosteroids (e.g., triamcinolone acetonide/hexacetonide) may also help to control peripheral joint inflammation. However, for moderate disease and JAS, it is typically necessary to add a second-line agent. DMARDs such as sulfasalazine (up to 50 mg/kg/day; maximum 3 g/day) or methotrexate (10 mg/m^2) may be beneficial for peripheral arthritis, but these medications have not been shown to improve axial disease in adults. Tumor necrosis factor (TNF) inhibitors (e.g., etanercept, infliximab, adalimumab) have been efficacious in reducing symptoms and improving function in adults with AS, and there is evidence that similar responses are seen in children. It remains unclear whether TNF inhibitors have an impact on structural damage in established AS, underscoring the need for earlier recognition and better therapies. Drugs that target IL-17 and IL-23/IL-12 (secukinumab and ustekinumab, respectively) also reduce clinical disease activity in adults with AS, but have not been studied in children.

Physical therapy and low-impact exercise should be included in the treatment program for all children with spondyloarthritis. Exercise to maintain range of motion in the back, thorax, and affected joints should be instituted early in the disease course. Custom-fitted insoles and heel cups are particularly useful in management of painful entheses around the feet, and the use of pillows to position the lower extremities while the child is in bed can be helpful.

Prognosis

Observational studies suggest that ongoing disease activity for >5 yr in juvenile spondyloarthritis predicts disability. Disease remission occurs in <20% of children with spondyloarthritis 5 yr after diagnosis. Factors associated with disease progression include tarsitis, HLA-B27 positivity, hip arthritis within the 1st 6 mo, and disease onset after age 8. Important questions, such as which patients with ERA will go on to have JAS/AS, have yet to be addressed. Outcomes for JAS compared with adult-onset AS suggest that hip disease requiring replacement is more common in children but axial disease is more severe in adults.

CHAPTER 182

Reactive and Postinfectious Arthritis

Pamela F. Weiss, Robert A. Colbert

In addition to causing arthritis by means of direct microbial infection (i.e., septic arthritis; see Chapter 705), microbes activate innate and adaptive immune responses, which can lead to the generation and deposition of immune complexes as well as antibody or T cell–mediated cross-reactivity with self. In addition, microbes may influence the immune system in ways that promote immune-mediated inflammatory diseases such as systemic lupus erythematosus (SLE), inflammatory bowel disease (IBD), juvenile idiopathic arthritis (JIA), and spondyloarthritis. **Reactive arthritis** and **postinfectious arthritis** are defined as joint inflammation caused by a sterile inflammatory reaction following a recent infection. We use *reactive arthritis* to refer to arthritis that occurs following enteropathic or urogenital infections and *postinfectious arthritis* to describe arthritis that occurs after infectious illnesses not classically considered in the reactive arthritis group, such as infection with group A streptococcus or viruses. In some patients, nonviable components of the initiating organism have been demonstrated in affected joints, and the presence of viable, yet nonculturable, bacteria within the joint remains an area of investigation.

The course of reactive arthritis is variable and may remit or progress to a chronic spondyloarthritis, including ankylosing spondylitis (see Chapter 181). In postinfectious arthritis the pain or joint swelling is usually transient, lasting <6 wk, and does not necessarily share the typical spondyloarthritis pattern of joint involvement. The distinction between postinfectious arthritis and reactive arthritis is not always clear, either clinically or pathophysiologically.

Pathogenesis

Reactive arthritis typically follows enteric infection with *Salmonella* species, *Shigella flexneri, Yersinia enterocolitica, Campylobacter jejuni* , or genitourinary (GU) tract infection with *Chlamydia trachomatis* . *Escherichia coli* and *Clostridium difficile* are also causative enteric agents, although less common (see Table 181.2). Acute **rheumatic fever** caused by group A streptococcus (see Chapters 182 and 210.1), arthritis associated with infective endocarditis (see Chapter 464), and the tenosynovitis associated with *Neisseria gonorrhoeae* are similar in some respects to reactive arthritis.

Approximately 75% of patients with reactive arthritis are HLA-B27 positive. Incomplete elimination of bacteria and bacterial products, such as DNA, has been proposed as a factor in reactive arthritis. A relationship with clinical characteristics of specific infectious disorders is not present. In postinfectious arthritis, several viruses (rubella, varicella-zoster, herpes simplex, cytomegalovirus) have been isolated from the joints of patients. Antigens from other viruses (e.g., hepatitis B, adenovirus) have been identified in immune complexes from joint tissue.

Patients with reactive arthritis who are HLA-B27 positive have an increased frequency of acute and symptomatic uveitis and other extraarticular features. In addition, HLA-B27 is a risk factor for persistent gastrointestinal (GI) inflammation following enteric infections, even after resolution of the initial infection, and significantly increases the risk that the individual will develop chronic spondyloarthritis. Nevertheless, reactive arthritis also occurs in HLA-B27–negative patients, emphasizing the importance of other genes in disease susceptibility.

Clinical Manifestations and Differential Diagnosis

Symptoms of reactive arthritis begin approximately 3 days to 6 wk following infection. The classic triad of arthritis, urethritis, and conjunctivitis is relatively uncommon in children. The arthritis is typically asymmetric, oligoarticular, with a predilection for lower extremities. Dactylitis may occur, and enthesitis is common, affecting as many as 90% of patients (Fig. 182.1). Cutaneous manifestations can occur and may include circinate balanitis, ulcerative vulvitis, erythematous oral macules or plaques or erosions, erythema nodosum, paronychia, painful erosions or pustules on fingertips, and keratoderma blennorrhagica, which is similar in appearance to pustular psoriasis (Fig. 182.2).

Systemic symptoms may include fever, malaise, and fatigue. Less common features may include conjunctivitis, optic neuritis, aortic valve involvement, sterile pyuria, and polyneuropathy. Early in the disease course, markers of inflammation—erythrocyte sedimentation rate (ESR), C-reactive protein, and platelets—may be greatly elevated. The clinical manifestations may last for weeks to months.

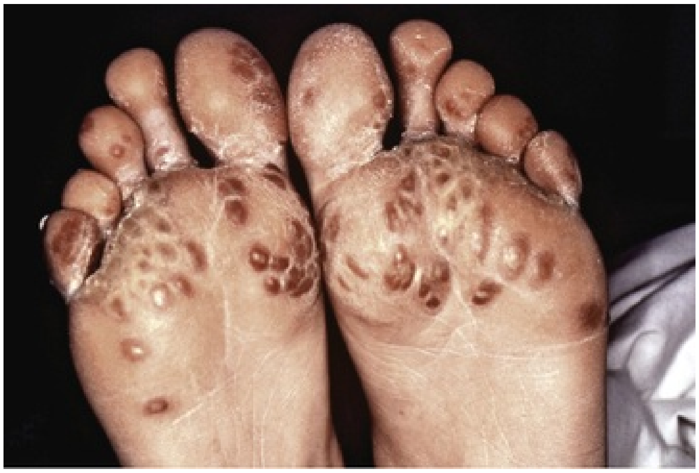

FIG. 182.2 Keratoderma blennorrhagica. (Courtesy of Dr. M.F. Rein and Centers for Disease Control and Prevention Public Health Image Library,

1976. Image #6950.)

Familiarity with other causes of postinfectious arthritis is vital when a diagnosis of reactive arthritis is being considered. Numerous viruses are associated with postinfectious arthritis and may result in particular patterns of joint involvement (Table 182.1). Rubella and hepatitis B virus typically affect the small joints, whereas mumps and varicella often involve large joints, especially the knees. The **hepatitis B arthritis–dermatitis syndrome** is characterized by urticarial rash and a symmetric migratory polyarthritis resembling that of serum sickness. Rubella-associated arthropathy may follow natural rubella infection and, infrequently, rubella immunization. It typically occurs in young women, with an increased frequency with advancing age, and is uncommon in preadolescent children and in males. Arthralgia of the knees and hands usually begins within 7 days of onset of the rash or 10-28 days after immunization. Parvovirus B19, which is responsible for erythema infectiosum (fifth disease), can cause arthralgia, symmetric joint swelling, and morning stiffness, particularly in adult women and less frequently in children. Arthritis occurs occasionally during cytomegalovirus infection and may occur during varicella infections but is rare after Epstein-Barr virus infection. Varicella may also be complicated by suppurative arthritis, usually secondary to group A streptococcus infection. HIV is associated with an arthritis that resembles psoriatic arthritis more than JIA (see Chapter 180).

Adapted from Infectious arthritis and osteomyelitis. In Petty RE, Laxer R, Lindsley CB, et al: *Textbook of pediatric rheumatology*, ed 7, Philadelphia, 2015, Saunders Elsevier.

Poststreptococcal arthritis may follow infection with either group A or group G streptococcus. It is typically oligoarticular, affecting lower-extremity joints, and mild symptoms can persist for months. Poststreptococcal arthritis differs from rheumatic fever, which typically manifests with painful migratory polyarthritis of brief duration. Because valvular lesions have occasionally been documented by echocardiography after the acute illness, some clinicians consider poststreptococcal arthritis to be an incomplete form of acute rheumatic fever (see Chapter 210.1). Certain HLA-DRB1 types may predispose children to development of either poststreptococcal arthritis (HLA-DRB1*01) or acute rheumatic fever (HLA-DRB1*16).

Transient synovitis (toxic synovitis) , another form of postinfectious arthritis, typically affects the hip, often after an upper respiratory tract infection (see Chapter 698.2). Boys 3-10 yr of age are most often affected and have acute onset of severe pain in the hip (groin), with referred pain to the thigh or knee, lasting approximately 1 wk. ESR and white blood cell count are usually normal. Radiologic or ultrasound examination may confirm widening of the joint space secondary to an effusion. Aspiration of joint fluid is often necessary to exclude septic arthritis and typically results in dramatic clinical improvement. The trigger is presumed to be viral, although responsible microbes have not been identified.

Nonsuppurative arthritis has been reported in children, usually adolescent boys, in association with **s** evere truncal acne. Patients often have fever and persistent infection of the pustular lesions. **Pyogenic (sterile) arthritis, pyoderma gangrenosum, and acne (cystic) syndrome** , an autosomal dominant disorder caused by a mutation in the *PSTPIP1* gene, is a difficult-to-treat but rare autoinflammatory disorder that has responded to anakinra or anti–tumor necrosis factor antibody therapy in a few patients. Recurrent episodes of erosive arthritis begin in childhood; cystic acne and the painful ulcerating lesions of pyoderma gangrenosum begin during adolescence. Recurrent episodes may also be associated with a sterile myopathy and may last for several months.

Infective endocarditis can be associated with arthralgia, arthritis, or signs suggestive of vasculitis, such as Osler nodes, Janeway lesions, and Roth spots. Postinfectious arthritis, perhaps because of immune complexes, also occurs in children with *N. gonorrhoeae*, *Neisseria meningitidis*, *Haemophilus influenzae* type b, and *Mycoplasma pneumoniae* infections.

Diagnosis

A recent GU or GI infection may suggest the diagnosis of reactive arthritis, but there is no diagnostic test. A complete blood count, acute-phase reactants, complete metabolic panel, and urinalysis may be helpful to exclude other etiologies. Although stool or urogenital tract cultures can be performed in an attempt to isolate it, the triggering organism is not typically found at the time arthritis presents. Imaging findings are nonspecific or normal. Documenting previous streptococcal infection with antibody testing (anti-streptolysin O and anti-DNAse B) may help to diagnose postinfectious arthritis. Serum sickness associated with the antibiotic treatment of preceding infection must be excluded.

Because the preceding infection can be remote or mild and often not recalled by the patient, it is also important to rule out other causes of arthritis. Acute and painful arthritis affecting a single joint suggests septic arthritis, mandating joint aspiration. Osteomyelitis may cause pain and an effusion in an adjacent joint but is more often associated with focal bone pain and tenderness at the site of infection. Arthritis affecting a single joint, particularly the knee, may also be secondary to Lyme disease in endemic areas. The diagnosis of postinfectious arthritis is often established by exclusion and after the arthritis has resolved. Arthritis associated with GI symptoms or abnormal liver function test results may be triggered by infectious or autoimmune hepatitis. Arthritis or spondyloarthritis may occur in children with IBD, such as Crohn disease or ulcerative colitis (see Chapter 362.1). Parvovirus infection, macrophage activation (hemophagocytic) syndrome, and leukemia should be strongly considered when 2 or more blood cell lines are low or progressively decrease in a child with arthritis. Persistent arthritis (>6 wk) suggests the possibility of a chronic rheumatic disease, including JIA (see Chapters 180) and systemic lupus erythematosus (see Chapter 183).

Treatment

Specific treatment is unnecessary for most cases of reactive or postinfectious arthritis. Nonsteroidal antiinflammatory drugs (NSAIDs) are often needed for management of pain and functional limitation. Unless ongoing *Chlamydia* infection is suspected, attempts to treat the offending organism are not warranted. If swelling or arthralgia recurs, further evaluation may be necessary to exclude active infection or evolving rheumatic disease. Intraarticular corticosteroid injections may be given for refractory or severely involved joints once acute infection has been ruled out. Systemic corticosteroids or disease-modifying antirheumatic drugs (DMARDs) are rarely indicated but may be considered for chronic disease. Participation in physical activity should be encouraged, and physical therapy may be needed to maintain normal function and prevent muscle atrophy. For postinfectious arthritis caused by streptococcal disease, current recommendations include penicillin prophylaxis for at least 1 yr. Long-term prophylaxis is often recommended, but the duration is controversial and may need to be individualized.

Complications and Prognosis

Postinfectious arthritis following viral infections usually resolves without complications unless it is associated with involvement of other organs, such as **encephalomyelitis** . Children with reactive arthritis after enteric infections occasionally experience IBD months to years after onset. Both **uveitis** and **carditis** have been reported in children diagnosed with reactive arthritis. Reactive arthritis, especially after bacterial enteric infection or GU tract infection with *C. trachomatis*, has the potential for evolving to chronic arthritis, particularly spondyloarthritis (see Chapter 181). The presence of HLA-B27 or significant systemic features increases the risk of chronic disease.

CHAPTER 183

Systemic Lupus Erythematosus

Rebecca E. Sadun, Stacy P. Ardoin, Laura E. Schanberg

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease characterized by multisystem inflammation and the presence of circulating autoantibodies directed against self-antigens. SLE occurs in both children and adults, disproportionately affecting females of reproductive age. Although nearly every organ may be affected, most frequently involved are the skin, joints, kidneys, blood-forming cells, blood vessels, and central nervous system. Systemic signs of inflammation such as fever and lymphadenopathy can also be seen. Compared with adults, children and adolescents with SLE have more severe disease and more widespread organ involvement.

Etiology

The pathogenesis of SLE remains largely unknown, but several factors likely influence risk and severity of disease, including genetics, hormonal milieu, and environmental exposures. A genetic predisposition to SLE is suggested by the association with specific genetic abnormalities, including congenital deficiencies of C1q, C2, and C4, as well as several polymorphisms (e.g., interferon regulatory factor 5, protein tyrosine phosphatase N22), and familial clustering of SLE or other autoimmune disease. In addition, certain human leukocyte antigen (HLA) types (including HLA-B8, HLA-DR2, and HLA-DR3) occur with increased frequency in patients with SLE. Although SLE clearly has a genetic component, its occurrence is sporadic in families and its concordance incomplete (estimated at 2–5% among dizygotic twins and 25–60% among monozygotic twins), suggesting **nonmendelian genetics** as well as involvement of epigenetic and environmental factors. Patients with SLE often have family members, especially mothers and sisters, with SLE or other autoimmune diseases.

Because SLE preferentially affects females, especially during their reproductive years, it is suspected that hormonal factors are important in pathogenesis. Of individuals with SLE, 90% are female, making **female sex** the strongest risk factor for SLE. Estrogens are likely to play a role in SLE, and both in vitro and animal model studies suggest that estrogen exposure promotes B-cell autoreactivity. Estrogen-containing oral contraceptives do not appear to induce flares in quiescent SLE, although the risk of flares may be increased in postmenopausal women receiving hormone replacement therapy.

Environmental exposures that may trigger the development of SLE remain largely unknown; certain viral infections, including Epstein-Barr virus (EBV), may play a role in susceptible individuals, and ultraviolet light exposure is known to trigger SLE disease activity. Environmental influences also may induce epigenetic modifications to DNA, increasing the risk of SLE and drug-induced lupus. In mouse models, drugs such as procainamide and hydralazine can promote lymphocyte hypomethylation, causing a lupus-like syndrome.

Epidemiology

The reported prevalence of SLE in children and adolescents (1-6/100,000) is lower than that in adults (20-70/100,000). Prevalence of SLE is highest among blacks, Asians, Hispanics, Native Americans, and Pacific Islanders for both adult and pediatric populations. SLE predominantly affects females, with reported 2-5:1 ratio before puberty, 9:1 ratio during reproductive years, and return to near-prepubertal ratios in the postmenopausal period. Childhood SLE is rare before 5 yr of age and is usually diagnosed in adolescence, with a median age at diagnosis of 11-12 yr. Up to 20% of all individuals with SLE are diagnosed before age 16 yr. Some define pediatric-onset lupus as onset of symptoms before age 16, and others as onset before age 18.

Pathology

Histologic features most suggestive of SLE include findings in the kidney and skin. Renal manifestations of SLE are classified histologically according to the criteria of the International Society of Nephrology (see Chapter 538.2). The finding of diffuse proliferative glomerulonephritis (class IV) significantly increases risk for renal morbidity. Renal biopsies are helpful to establish the diagnosis of SLE and to stage disease. Immune complexes are typically found with “full house” deposition of immunoglobulin and complement.

The characteristic **discoid rash** depicted in Figure 183.1*D* is characterized on biopsy by hyperkeratosis, follicular plugging, and infiltration of mononuclear cells into the dermal-epidermal junction (DEJ). The histopathology of photosensitive rashes can be nonspecific, but immunofluorescence examination of both affected and nonaffected skin may reveal deposition of immune complexes within the DEJ. This finding is called the **lupus band test** , which is specific for SLE.

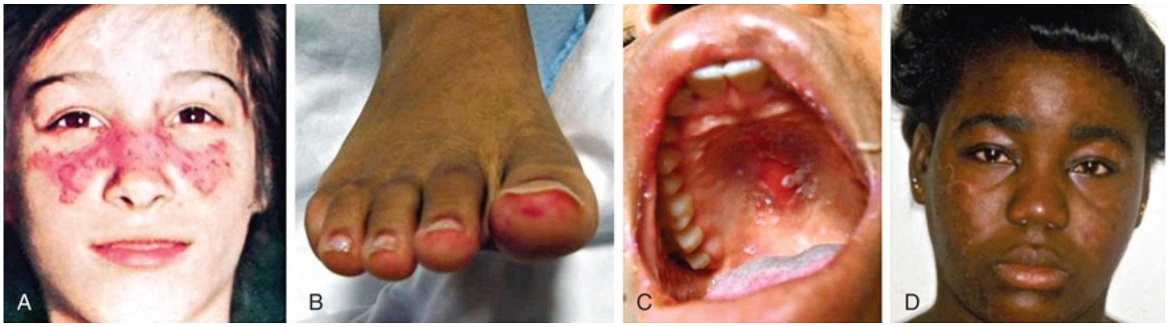

FIG. 183.1 Mucocutaneous manifestations of SLE. A, Malar rash; B, vasculitic rash on toes; C, oral mucosal ulcers; D, discoid rash in malar distribution.

Pathogenesis

A hallmark of SLE is the generation of **autoantibodies** directed against self-antigens, particularly nucleic acids. These intracellular antigens are ubiquitously expressed but are usually inaccessible and cloistered within the cell. During cell necrosis or apoptosis, the antigens are released. SLE skin cells are highly susceptible to damage from ultraviolet (UV) light, and the resulting cell death leads to release of cell contents, including nucleic antigens. Individuals with SLE may have greatly increased levels of apoptosis or significantly impaired ability to clear cell debris, causing prolonged exposure to nucleic antigens in the bloodstream and increased opportunity for recognition by immune cells, leading to B-cell stimulation and autoantibody production. Circulating autoantibodies form immune complexes and deposit in tissues, leading to local complement activation, initiation of a proinflammatory cascade, and, ultimately, tissue damage. Antibodies to **double-stranded (ds) DNA** can form immune complexes, deposit in glomeruli, and initiate inflammation leading to glomerulonephritis. However, many individuals with SLE have circulating antibodies to dsDNA but do not have nephritis, suggesting that autoantibodies are not the only pathway leading to end-organ damage in SLE.

Both the innate and the adaptive arms of the immune system have been implicated in the dysregulation of the immune system seen in SLE. High levels of interferon (IFN)-α production by plasmacytoid dendritic cells (DCs) promote expression of other proinflammatory cytokines and chemokines, maturation of monocytes into myeloid DCs, promotion of autoreactive B and T cells, and loss of self-tolerance. Almost 85% of patients with SLE exhibit this cytokine profile, known as the **type I interferon signature** . Other cytokines with increased expression in SLE include interleukin (IL)-1, IL-2, IL-6, IL-10, IL-12, IL-17, IL-21, anti–tumor necrosis factor-α, and IFN-γ, and B-lymphocyte stimulator (**BLyS**), also known as B-cell activating factor (**BAFF**). Both B and T cells demonstrate functional impairments in SLE. In active SLE, B-cell populations have impaired tolerance and increased autoreactivity, enhancing their ability to produce autoantibodies after exposure to self-antigen. In addition, cytokines such as BLyS/BAFF may promote abnormal B-cell number and function. T-cell abnormalities in SLE include increased numbers of memory T cells and decreased number and function of T-regulatory cells. SLE T cells display aberrant signaling and increased autoreactivity. As a result, they are resistant to attrition by normal apoptosis pathways. In addition, a neutrophil signature can be identified in 65% of adult SLE patients and has recently been recognized as a potential biomarker for active lupus nephritis.

Clinical Manifestations

Any organ system can be involved in SLE, so the potential clinical manifestations are myriad (Tables 183.1 and 183.2). The presentation of SLE in childhood or adolescence differs somewhat from that seen in adults. The most common presenting complaints of children with SLE include fever, fatigue, hematologic abnormalities, arthralgia, and arthritis. Arthritis is usually present in the 1st yr of diagnosis; arthritis may be painful or painless swelling, often with stiffness in the morning, and is usually a **symmetric polyarthritis** affecting large and small joints. Tenosynovitis is often present, but joint erosions or other radiographic changes are rare.

Table 183.1

Potential Clinical Manifestations of Systemic Lupus Erythematosus

TARGET ORGAN	POTENTIAL CLINICAL MANIFESTATIONS
Constitutional	Fatigue, anorexia, weight loss, fever, lymphadenopathy
Musculoskeletal	Arthritis, myositis, tendonitis, arthralgias, myalgias, avascular necrosis, osteoporosis
Skin	Malar rash, discoid (annular) rash, photosensitive rash, cutaneous vasculitis (petechiae, palpable purpura, digit ulcers, gangrene, urticaria), livedo reticularis, periungual capillary abnormalities, Raynaud phenomenon, alopecia, oral and nasal ulcers, panniculitis, chilblains, alopecia
Renal	Hypertension, proteinuria, hematuria, edema, nephrotic syndrome, renal failure
Cardiovascular	Pericarditis, myocarditis, conduction system abnormalities, Libman-Sacks endocarditis
Neuropsychiatric	Seizures, psychosis, cerebritis, stroke, transverse myelitis, depression, cognitive impairment, headaches, migraines, pseudotumor, peripheral neuropathy (mononeuritis multiplex), polyneuropathy, myasthenia gravis, chorea, optic neuritis, cranial nerve palsies, plexopathy, acute confusional states, dural sinus thrombosis, aseptic meningitis, depression, psychosis, anxiety disorder
Pulmonary	Pleuritis, interstitial lung disease, pulmonary hemorrhage, pulmonary hypertension, pulmonary embolism
Hematologic	Immune-mediated cytopenias (hemolytic anemia, thrombocytopenia or leukopenia), anemia of chronic inflammation, hypercoagulability, thrombocytopenic thrombotic microangiopathy
Gastroenterology	Hepatosplenomegaly, pancreatitis, vasculitis affecting bowel, protein-losing enteropathy, peritonitis
Ocular	Retinal vasculitis, scleritis, episcleritis, papilledema, dry eyes, optic neuritis
Other	Macrophage activation syndrome

Table 183.2

Frequency of Clinical Features of Children and Adolescents With Systemic Lupus Erythematosus

CLINICAL FEATURE*	WITHIN 1 YR OF DIAGNOSIS (%)	ANY TIME (%)
Fever	35-90	37-100
Lymphadenopathy	11-45	13-45
Hepatosplenomegaly	16-42	19-43
Weight loss	20-30	21-32
Arthritis	60-88	60-90
Myositis	<5	<5
Any skin involvement	60-80	60-90
Malar rash	22-68	30-80
Discoid rash	<5	<5
Photosensitivity	12-45	17-58
Mucosal ulceration	25-32	30-40
Alopecia	10-30	15-35
Other rashes	40-52	42-55
Nephritis	20-80	48-100
Neuropsychiatric disease	5-30 †	15-95 ‡

Psychosis	5-12	8-18
Seizures	5-15	5-47
Headache	5-22	10-95
Cognitive dysfunction	6-15	12-55
Acute confusional state	5-15	8-35
Peripheral nerve involvement	<5	<5
Cardiovascular disease	5-30	25-60
Pericarditis	12-20	20-30

[*] Not all reports commented on all features or incidence in 1st yr.

[†] Had highest prevalence of central nervous system disease but did not describe incidence in 1st yr.

[‡] Headache reported in 95% of patients.

From Petty RE, Laxer RM, Lindsley CB, Wedderburn LR, editors: *Textbook of pediatric rheumatology,* ed 7, Philadelphia, 2016, Elsevier (Table 23.5, p 291).

Renal disease in SLE is often asymptomatic, underscoring the need for careful monitoring of blood pressure and urinalyses; in adolescents, SLE can present with **nephrotic syndrome** and/or **renal failure** with the predominant symptoms being edema, fatigue, changes in urine color, and nausea/vomiting. Because SLE symptoms and findings may develop serially over several years, and not all may be present simultaneously, the diagnosis may require longitudinal follow up. SLE is often characterized by periods of flare and disease quiescence but may follow a more smoldering disease course. The **neuropsychiatric complications** of SLE may occur with or without apparently active SLE, posing a particularly difficult diagnostic challenge in adolescents, who are already at high risk for mood disorders (Fig. 183.2). Long-term complications of SLE and its therapy, including accelerated atherosclerosis and osteoporosis, become clinically evident in young to middle adulthood. SLE is a disease that evolves over time in each affected individual, and new manifestations arise even many years after diagnosis.

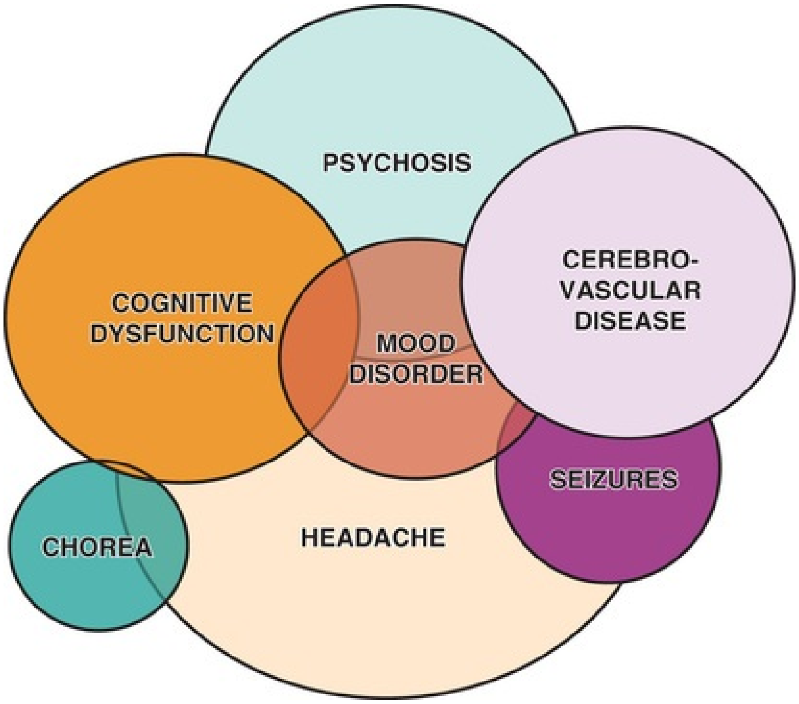

FIG. 183.2 **Overlapping neuropsychiatric symptoms in pediatric SLE. Patients with pediatric SLE typically have >1 neuropsychiatric symptom—in particular for seizures. (From Silverman E, Eddy A: Systemic lupus erythematosus. In Cassidy JT, Petty RE, Laxer RM, et al, editors, *Textbook of pediatric rheumatology,* ed 6, Philadelphia, 2011, Saunders Elsevier, Fig 21-17, p 329.)**

Diagnosis

The diagnosis of SLE requires a comprehensive clinical and laboratory assessment revealing characteristic multisystem disease and excluding other etiologies, including infection and malignancy. Presence of 4 of the 11 **American College of Rheumatology (ACR)** 1997 revised classification criteria for SLE simultaneously or cumulatively over time establishes the diagnosis (Table 183.3). Of note, although a positive antinuclear antibody (ANA) test result is not required for the diagnosis of SLE, ANA-negative lupus is extremely rare. ANA is very sensitive for SLE (95–99%), but it is not very specific (50%). The ANA may be positive many years before a diagnosis of SLE is established. However, most asymptomatic, ANA-positive patients do not have SLE or other autoimmune disease.

Table 183.3

American College of Rheumatology (ACR)

1997 Revised Classification Criteria for Systemic Lupus Erythematosus*

- Malar rash
- Discoid rash
- Photosensitivity
- Oral or nasal ulcers
- **Arthritis**
  - Nonerosive, ≥2 joints
- **Serositis**
  - Pleuritis, pericarditis, or peritonitis
- **Renal manifestations** †
  - Consistent renal biopsy
  - Persistent proteinuria or renal casts
- Seizure or psychosis
- **Hematologic manifestations** †
  - Hemolytic anemia
  - Leukopenia (<4,000 leukocytes/mm^3)
  - Lymphopenia (<1,500 leukocytes/mm^3)
  - Thrombocytopenia (<100,000 thrombocytes/mm^3)
- **Immunologic abnormalities** †
  - Positive anti–double-stranded DNA or anti-Smith antibody
  - False-positive rapid plasma reagin test result, positive lupus anticoagulant test result, or elevated anticardiolipin IgG or IgM antibody
- Positive antinuclear antibody test result

---

* The presence of 4 of 11 criteria establishes the diagnosis of SLE. These criteria were developed for classification in clinical trials and not for clinical diagnosis.

† Each of these criteria counts as a single criterion whether 1 or more definitions are satisfied.

Adapted from Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus, *Arthritis*

Rheum 40:1725, 1997.

Antibodies against dsDNA and **anti-Smith** are specific for SLE (98%) but not as sensitive (40–65%). **Hypocomplementemia** , although common in SLE, is not one of the ACR classification criteria; however, hypocomplementemia has been added to updated criteria validated by the **Systemic Lupus International Collaborating Clinics (SLICC)** in 2012 (Table 183.4). Other differences in the SLICC criteria include the addition of nonscarring alopecia, additional cutaneous and neurologic manifestations of lupus, and a positive direct Coombs test in the absence of hemolytic anemia. The SLICC criteria have been validated in pediatric SLE and have been shown to have higher sensitivity (93% vs 77%) but lower specificity (85% vs 99%) than the ACR criteria.

Table 183.4

Systemic Lupus International Collaborating Clinics (SLICC) Classification Criteria for Systemic Lupus Erythematosus*

Clinical Criteria

Acute cutaneous lupus

Malar rash, bullous lupus, toxic epidermal necrolysis variant of SLE, maculopapular lupus rash, photosensitive lupus rash, or subacute cutaneous lupus

Chronic cutaneous lupus

Classic discoid rash, lupus panniculitis, mucosal lupus, lupus erythematous tumidus, chilblains lupus, discoid lupus/lichen planus overlap

Oral or nasal ulcers

Nonscarring alopecia

Synovitis (≥2 joints)

Serositis

Pleurisy or pericardial pain ≥1 day, pleural effusion or rub, pericardial effusion or rub, ECG evidence of pericarditis

Renal

Presence of red blood cell casts or urine protein/creatinine ratio representing >500 mg protein/24 hr

Neurologic

Seizures, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, or acute confusional state

Hemolytic anemia

Leukopenia (<4,000/mm^3) or lymphopenia (<1,000/mm^3)

Thrombocytopenia (<100,000/mm^3)

Immunologic Criteria

Positive antinuclear antibody

Positive double-stranded DNA antibody

Positive anti-Smith antibody

Antiphospholipid antibody positivity

Positive lupus anticoagulant, false-positive test for rapid plasma regain, medium- to high-titer anticardiolipin antibody level (IgA, IgG, IgM), or positive anti–β_2 -glycoprotein-1 antibody (IgA, IgG, IgM)

Low complement

Low C3, C4, or CH_{50} level

Positive direct Coombs test

---

[*] The presence of 4 criteria (including at least 1 clinical and 1 immunologic criterion) establishes the diagnosis of SLE. Biopsy-proven lupus nephritis with positive ANA or anti–double-stranded DNA also satisfies the diagnosis of SLE. These criteria were developed for classification in clinical trials and not for clinical diagnosis.

Adapted from Petri M: Derivation and validation of the Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus, *Arthritis Rheum* 64(8):2677–2686, 2012.

Differential Diagnosis

Multiorgan disease is the hallmark of SLE. Given its wide array of potential clinical manifestations, SLE is in the differential diagnosis of many clinical scenarios, including unexplained fevers, joint pain or arthritis, rash, cytopenias, nephritis, nephrotic syndrome, pleural or pericardial effusions or other cardiopulmonary abnormalities, and new-onset psychosis, movement disorders, or seizures. For patients ultimately diagnosed with pediatric SLE, the initial differential diagnosis often includes infections (sepsis, EBV, parvovirus B19, endocarditis), malignancies (leukemia, lymphoma), poststreptococcal glomerulonephritis, other rheumatologic conditions (juvenile idiopathic arthritis, vasculitides), and drug-induced lupus.

Drug-induced lupus refers to the presence of SLE manifestations triggered by exposure to specific medications, including hydralazine, minocycline, many anticonvulsants, sulfonamides, and antiarrhythmic agents (Table 183.5). In individuals prone to SLE, these agents may act as a trigger for true SLE, but more often these agents provoke a reversible lupus-like syndrome. Unlike SLE, drug-induced lupus affects males and females equally. A genetic predisposition toward slow drug acetylation may increase the risk of drug-induced lupus. Circulating **antihistone antibodies** are often present in drug-induced SLE; these antibodies are only detected in up to 20% of individuals with SLE. Hepatitis, which is rare in SLE, is more common in drug-induced lupus. Individuals with drug-induced lupus are less likely to demonstrate antibodies to dsDNA, hypocomplementemia, and significant renal or neurologic disease. In contrast to SLE, manifestations of drug-induced lupus typically resolve after withdrawal of the offending medication; however, complete recovery may take several months to years, requiring treatment with hydroxychloroquine, NSAIDs, and/or corticosteroids.

Table 183.5

Medications Associated With Drug-Induced Lupus

Definite Association

Minocycline, procainamide, hydralazine, isoniazid, penicillamine, diltiazem, interferon-α, methyldopa, chlorpromazine, etanercept, infliximab, adalimumab

Probable Association

Phenytoin, ethosuximide, carbamazepine, sulfasalazine, amiodarone, quinidine, rifampin, nitrofurantoin, β-blockers, lithium, captopril, interferon-γ, hydrochlorothiazide, glyburide, docetaxel, penicillin, tetracycline, statins, gold, valproate, griseofulvin, gemfibrozil, propylthiouracil

Laboratory Findings

A positive ANA test is present in 95–99% of SLE patients. ANA has poor specificity for SLE, however, because up to 20% of healthy individuals also have a positive ANA test result, making the ANA a poor screen for SLE when used in isolation. High titers are more suggestive of underlying autoimmune disease, but ANA titers do not correlate with disease activity, so repeating ANA titers after diagnosis is not helpful. Antibodies to dsDNA are specific for SLE, and in many individuals, anti-dsDNA levels correlate with disease activity, particularly in those with significant nephritis. Anti-Smith antibody, although found specifically in patients with SLE, does not correlate with disease activity. Serum levels of total hemolytic complement (CH_{50}), C3, and C4 are typically decreased in active disease and often improve with treatment. Table 183.6 lists autoantibodies found in SLE along with their clinical associations. Hypergammaglobulinemia is a common but nonspecific finding. Inflammatory markers, particularly erythrocyte sedimentation rate, are often elevated in active disease. C-reactive protein (CRP) correlates less well with disease activity; significantly elevated CRP values often reflect infection, whereas chronic mild elevation may indicate increased cardiovascular risk.

Table 183.6

Autoantibodies Typically Associated With Systemic Lupus Erythematosus

ANTIBODY	CLINICAL ASSOCIATION
Anti–double-stranded DNA	Specific for the diagnosis of SLE Correlates with disease activity, especially nephritis, in some with SLE
Anti-Smith antibody	Specific for the diagnosis of SLE
Antiribonucleoprotein (anti-RNP) antibody	Increased risk for Raynaud phenomenon, insterstitial lung disease, and pulmonary hypertension

Anti-Ro antibody (anti-SSA antibody) Anti-La antibody (anti-SSB antibody)	Associated with sicca syndrome May suggest diagnosis of Sjögren syndrome Increased risk of neonatal lupus in offspring (congenital heart block) May be associated with cutaneous and pulmonary manifestations of SLE May be associated with isolated discoid lupus
Antiphospholipid antibodies (including anticardiolipin antibodies)	Increased risk for venous and arterial thrombotic events
Antihistone antibodies	Present in a majority of patients with drug-induced lupus May be present in SLE

Antiphospholipid antibodies , which increase clotting risk, can be found in up to 66% of children and adolescents with SLE. Antiphospholipid laboratory findings include the presence of anticardiolipin or anti–β_2 -glycoprotein antibodies, prolonged phospholipid-dependent coagulation test results (partial thromboplastin time, dilute Russell viper-venom time), and circulating **lupus anticoagulant** (which confirms that a prolonged PPT is not corrected with mixing studies). When an arterial or venous clotting event occurs in the presence of an antiphospholipid antibody, **antiphospholipid antibody syndrome** is diagnosed, which can occur in the context of SLE (secondary) or independent of SLE (primary) (see Chapter 479).

Treatment

Treatment of SLE is tailored to the individual and is based on specific disease manifestations and medication tolerability. For all patients, sunscreen and avoidance of prolonged direct sun exposure and other UV light may help control disease and should be reinforced at every visit with the patient. *Hydroxychloroquine* is recommended for all individuals with SLE when tolerated. In addition to treating mild SLE manifestations such as rash and mild arthritis, hydroxychloroquine prevents SLE flares, improves lipid profiles, and may improve mortality and renal outcomes. Potential toxicities include retinal deposition and subsequent vision impairment; therefore, annual ophthalmology exams are recommended for patients taking hydroxychloroquine, including automated visual field testing as well as spectral-domain optical coherence tomography (SD-OCT). Given that risk factors for ocular toxicity include duration of use and dose, hydroxychloroquine in SLE should never be prescribed at doses >6.5 mg/kg (maximum 400 mg daily), and newer ophthalmology guidelines recommend limiting maintenance dosing to 4-5 mg/kg.

Corticosteroids are a treatment mainstay for significant manifestations of

SLE and work quickly to improve acute deterioration; side effects often limit patient adherence, especially in adolescence, and potential toxicities are worrisome. It is important to limit dose and length of exposure to corticosteroids whenever possible. Potential consequences of corticosteroid therapy include growth disturbance, weight gain, striae, acne, hyperglycemia, hypertension, cataracts, avascular necrosis, and osteoporosis. The optimal dosing of corticosteroids in children and adolescents with SLE remains unknown; severe disease is often treated with high doses of intravenous (IV) methylprednisolone (e.g., 30 mg/kg/day to a maximum of 1,000 mg/day for 3 days, sometimes followed by a period of weekly pulses) and/or high doses of oral prednisone (1-2 mg/kg/day). As disease manifestations improve, corticosteroid dosages are gradually tapered over months. For most patients it is necessary to introduce a steroid-sparing immunosuppressive medication to limit cumulative steroid exposure.

Steroid-sparing immunosuppressive agents for the treatment of pediatric SLE include methotrexate, leflunomide, azathioprine, mycophenolate mofetil (MMF), tacrolimus, cyclophosphamide, rituximab, and belimumab. Methotrexate, leflunomide, and azathioprine are often used to treat persistent moderate disease, including arthritis, significant cutaneous or hematologic involvement, and pleural disease. Cyclophosphamide, MMF, and azathioprine are appropriate for the treatment of lupus nephritis, whereas MMF and rituximab are often used for significant hematologic manifestations, including severe leukopenia, hemolytic anemia, or thrombocytopenia.

Cyclophosphamide , usually administered intravenously, is reserved for the most severe, potentially life-threatening SLE manifestations, such as renal, neurologic, and cardiopulmonary disease. Although cyclophosphamide is highly effective in controlling disease, the potential toxicities are significant, including cytopenias, infection, hemorrhagic cystitis, premature gonadal failure, and increased risk of future malignancy. Attention to adequate hydration can attenuate the risk of hemorrhagic cystitis. Fortunately, young girls are at much lower risk of gonadal failure than older women, and the use of gonadotropin-releasing hormone agonists, such as leuprolide acetate, may help prevent gonadal failure.

The **Childhood Arthritis Rheumatology Research Alliance (CARRA)** consensus treatment plan for induction therapy of newly diagnosed **proliferative lupus nephritis** (class IV) is specific to the pediatric SLE population. The treatment is considered necessary for class IV lupus nephritis but also appropriate for certain patients with class III, V, or VI lupus nephritis. The CARRA treatment plans advise 6 mo of induction therapy with either cyclophosphamide (given per NIH Protocol as 500-1000 mg/m^2 IV monthly) or MMF (600 mg/m^2 , up to 1500 mg, twice daily), used in combination with 1 of 3 standardized glucocorticoid regimens. For patients who fail to achieve a partial response in 6 mo, it is appropriate to switch agents. For adult-weight adolescents, the cyclophosphamide dosing regimen used in the **Euro-Lupus Nephritis Trial** can be considered instead of the above 6 mo therapy to reduce toxicity from cyclophosphamide exposure. Per this protocol, a fixed dose of 500 mg is given every 2 wk for 3 mo; this regimen is thought to reduce adverse effects while maintaining comparable efficacy for lupus nephritis in adults, but has not been studied specifically in pediatric lupus. Oral medication adherence is very poor in pediatric SLE, which must be considered when weighing the benefits of an IV infusion vs a twice-daily oral medication such as MMF. Maintenance therapy of lupus nephritis consists of cyclophosphamide every 3 mo, or MMF, or azathioprine, typically for 36 mo after completion of induction therapy.

Clinical trial data on the use of *rituximab* in SLE with treatment-resistant glomerulonephritis has been largely disappointing, but results from the LUNAR study suggest a possible benefit for subpopulations of SLE patients. The U.S. Food and Drug Administration (FDA) has approved the use of *belimumab* , a monoclonal antibody against BLyS/BAFF, for the treatment of lupus in adults; when added to standard SLE therapy, belimumab improves multiple markers of disease severity. Other therapies being studied for treatment of lupus include rigerimod (a polypeptide corresponding to a sequence of the snRNP protein) and anifrolumab (monoclonal antibody to IFN-α receptor), all with encouraging phase II results.

Given the lifelong nature of SLE, optimal care of children and adolescents with this disease also involves preventive practices. Because of the enhanced risk of atherosclerosis in SLE, attention to cholesterol levels, smoking status, body mass index, blood pressure, and other traditional cardiovascular risk factors is warranted. Even though the **Atherosclerosis Prevention in Pediatric Lupus Erythematosus (APPLE)** study failed to support placing all children with SLE on a statin, post hoc analyses suggest that statins should be considered for primary prevention of atherosclerotic disease in certain clinical circumstances, particularly pubertal patients with an elevated CRP.

SLE patients with antiphospholipid antibody syndrome (antiphospholipid antibodies *and* a history of clot) are treated with long-term anticoagulation to prevent thrombotic events. For SLE patients who are antiphospholipid antibody positive without a history of clot, many pediatric rheumatologists prescribe aspirin (81 mg daily).

For all SLE patients, adequate intake of calcium and vitamin D is necessary to prevent future osteoporosis, particularly as vitamin D levels are lower in pediatric SLE patients compared to age-matched healthy controls. Studies suggest a link between hypovitaminosis D and SLE susceptibility, with a possible emerging role for vitamin D in immunomodulation.

Infections, particularly pneumococcal disease, frequently complicate SLE, so routine immunization is recommended, including the annual influenza vaccination. In addition, pediatric SLE patients age 6 or older should receive an additional pneumococcal 13 vaccination, followed by the pneumococcal 23 vaccination at least 2 mo later. It is important to note that many of the immunosuppressants used in SLE contraindicate live vaccines. Prompt attention to febrile episodes should include an evaluation for serious infections. Because pediatric SLE patients are at high risk for developing anxiety and depression, screening for depression is also essential. Peer support and cognitive-behavioral therapy interventions reduce pain and enhance resilience in pediatric SLE.

It should be remembered that pregnancy can worsen SLE, and obstetric complications are common. In addition, many medications used to treat SLE are teratogenic, so it is important to counsel adolescent girls about these risks and facilitate access to appropriate contraceptive options. Hydroxychloroquine is recommended throughout the pregnancy of all SLE patients, and other medications may need to be adjusted.

Complications

Within the first several years of diagnosis, the most common causes of death in SLE patients are infection and complications of glomerulonephritis and neuropsychiatric disease (Table 183.7). Over the long-term, the most common causes of mortality are complications of atherosclerosis and malignancy. The increased risk of premature atherosclerosis in SLE is not explained by traditional risk factors and is partly a result of the chronic immune dysregulation and inflammation associated with SLE. Increased malignancy rates may be caused by immune dysregulation as well as exposure to medications with carcinogenic potential.

Table 183.7

Morbidity in Childhood Lupus

SYSTEM	MORBIDITY
Renal	Hypertension, dialysis, transplantation
Central nervous	Organic brain syndrome, seizures, psychosis, neurocognitive dysfunction
Cardiovascular	Atherosclerosis, myocardial infarction, cardiomyopathy, valvular disease
Immune	Recurrent infection, functional asplenia, malignancy
Musculoskeletal	Osteopenia, compression fractures, avascular necrosis
Ocular	Cataracts, glaucoma, retinal detachment, blindness
Endocrine	Diabetes, obesity, growth failure, infertility, fetal wastage

From Cassidy JT, Petty RE: *Textbook of pediatric rheumatology,* ed 6, Philadelphia, 2011, Elsevier Saunders.

Prognosis

The severity of pediatric SLE is notably worse than the typical course for adult-onset SLE. However, because of advances in the diagnosis and treatment of SLE, survival has improved dramatically over the past 50 yr. Currently, the 5 yr survival rate for pediatric SLE is approximately 95%, although the 10 yr survival rate remains 80–90%. Given their long burden of disease, children and adolescents with SLE face high risks of future morbidity and mortality from the disease and its complications, as well as medication side effects (see Table 183.7). Given the complex and chronic nature of SLE, it is optimal for children and adolescents with SLE to be treated by pediatric rheumatologists in a multidisciplinary clinic with access to a full complement of pediatric subspecialists.

Keywords

NLE
congenital heart block
hydrops fetalis
IVIG

Neonatal lupus erythematosus (NLE), an entity distinct from SLE, is one of the few rheumatic disorders manifesting in the neonate. NLE is not an autoimmune disease of the fetus but instead results from passively acquired autoimmunity, when maternal immunoglobulin G autoantibodies cross the placenta and enter the fetal circulation. In contrast to SLE, neonatal lupus is not characterized by ongoing immune dysregulation, although infants with neonatal lupus may be at some increased risk for development of future autoimmune disease. The vast majority of NLE cases are associated with maternal **anti-Ro** (also known as anti-SSA), **anti-La** antibodies (also known as anti-SSB), or **anti-RNP** (antiribonucleoprotein) autoantibodies. Despite the clear association with maternal autoantibodies, their presence alone is not sufficient to cause disease, because only 2% of offspring born to mothers with anti-Ro and anti-La antibodies develop neonatal lupus. Siblings of infants with NLE have a 15–20% chance of developing NLE. Neonatal lupus seems to be independent of maternal health since many mothers are asymptomatic and only identified to have anti-Ro/anti-La antibodies subsequent to the diagnosis of NLE. Half the infants with NLE are born to the mothers with a defined rheumatic disease, such as Sjögren syndrome or SLE.

Clinical manifestations of neonatal lupus include a characteristic annular or macular rash typically affecting the face (especially the periorbital area), trunk, and scalp (Fig. 183.3). The rash can be present at birth but more often appears within the first 6-8 wk of life, after exposure to UV light, and typically lasts 3-4 mo. Infants may also have cytopenias and hepatitis, each occurring in approximately 25% of cases, but the most feared complication is **congenital heart block** .

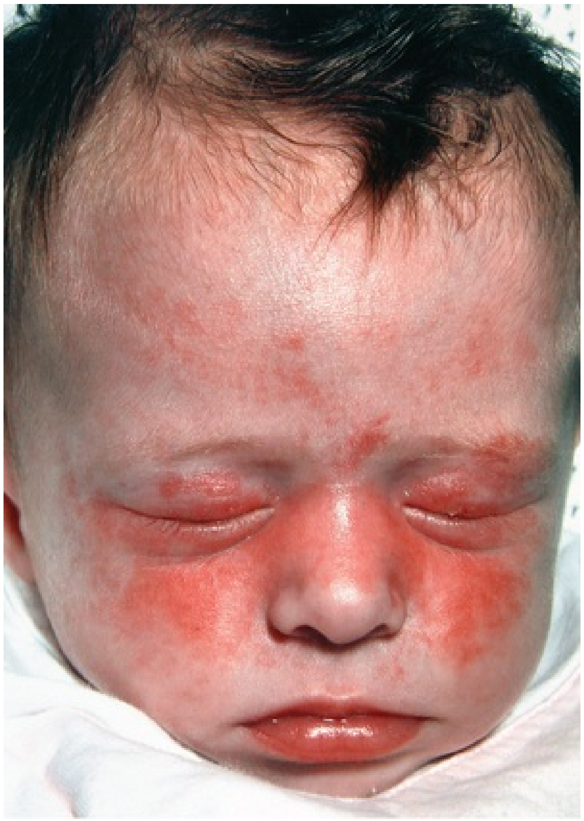

FIG. 183.3 Neonatal lupus syndrome. Typical rash, often photosensitive with a malar distribution, appearing as plaques with erythema and scaling. (Reproduced, with written parental permission, from Pain C, Beresford MW: Neonatal lupus syndrome, *Paediatr Child Health* 17:223–227, 2007.)

Conduction system abnormalities range from prolongation of the PR interval to complete heart block, with development of progressive cardiomyopathy in the most severe cases. The noncardiac manifestations of NLE are usually reversible, whereas third-degree congenital heart block is permanent. Conduction system abnormalities can be detected in utero by fetal echocardiogram beginning at 16 wk gestational age. Neonatal lupus cardiac disease has a mortality rate of approximately 20%. Cardiac NLE can manifest as heart block, cardiomyopathy, valvular dysfunction, and endocardial fibroelastosis. Fetal bradycardia from heart block can lead to **hydrops fetalis** .

In vitro studies suggest that during cardiac development via apoptosis, Ro and La antigens may be exposed on the surface of cardiac cells in the proximity of the atrioventricular node, making the antigens accessible to maternal autoantibodies. Binding incites a local immune response, resulting in fibrosis within the conduction system as well as more extensive disease in fatal cases. In the skin, exposure to ultraviolet light results in cell damage and the subsequent exposure of Ro and La antigens, inducing a similar local inflammatory response that produces the characteristic rash.

Although the scant clinical trial data have been mixed, fluorinated corticosteroids (dexamethasone or betamethasone), intravenous immune globulin (IVIG) at 1–2 g/kg maternal weight, plasmapheresis, hydroxychloroquine, and terbutaline (combined with steroids) have been used in pregnant women with anti-Ro or anti-La antibodies to prevent occurrence or progression of fetal cardiac abnormalities.

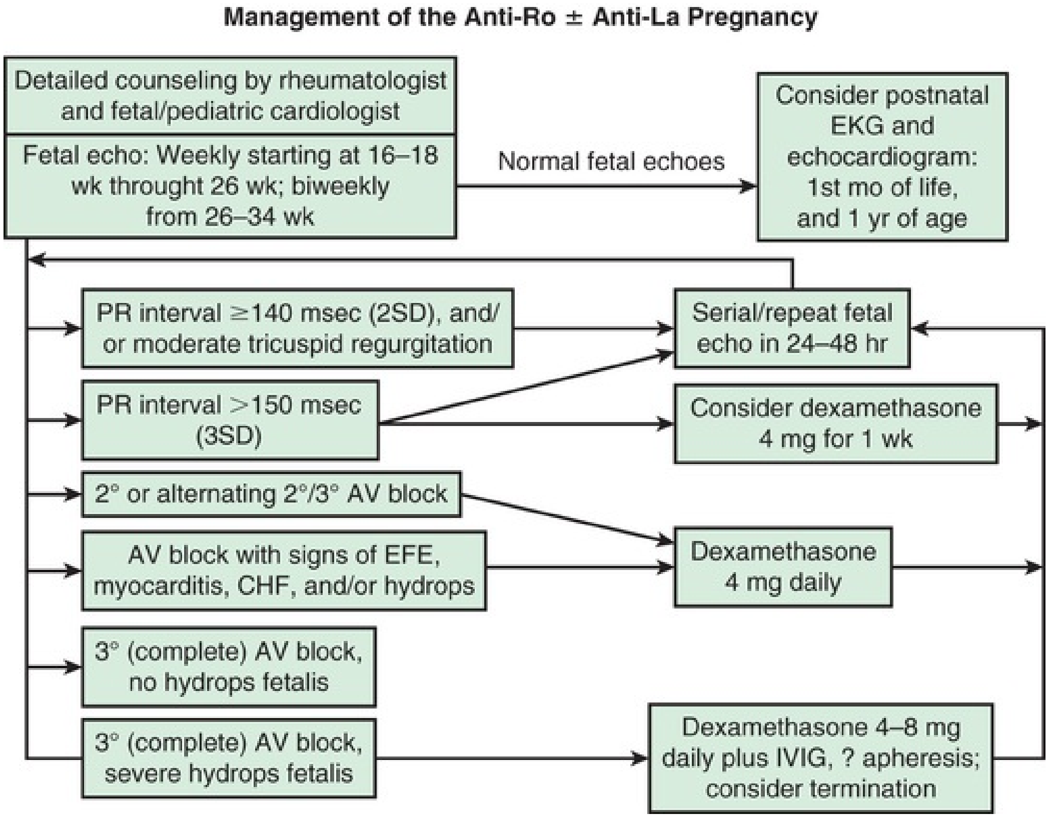
Most encouraging are retrospective cohort studies suggesting maternal treatment with *hydroxychloroquine* may reduce the frequency and recurrence of congenital heart block. In a case control study of women with lupus and known anti-Ro autoantibodies, maternal use of hydroxychloroquine decreased the rate of cardiac disease (odds ratio 0.28). This was confirmed in an expanded international study in which the recurrence rate of cardiac disease was 64% lower in pregnant women given hydroxychloroquine than controls (7.5% vs 21.2%). All clinical data on the use of hydroxychloroquine in pregnancy point to safety; prospective clinical studies are examining efficacy in the prevention of recurrent congenital heart block in pregnant women known to be anti-Ro and/or anti-La positive.

In utero, fluorinated corticosteroids seem to improve cases of hydrops fetalis. Furthermore, the addition of β-agonist therapy to increase fetal heart rate, used in combination with corticosteroids or IVIG, may help prevent hydrops in cases of severe fetal heart block. However, recent data from the **Research Registry for Neonatal Lupus** suggest that dexamethasone is not efficacious in preventing progression of isolated third-degree block, influencing the need for pacing after birth, or overall survival.

Significant conduction system abnormalities after birth are treated with cardiac pacing and occasionally IVIG and corticosteroids, whereas severe cardiomyopathy may require cardiac transplantation. If the conduction defect is not addressed, affected children are at risk for exercise intolerance, arrhythmias, and death. With cardiac pacing, children with conduction system disease in the absence of cardiomyopathy have an excellent prognosis.

Noncardiac manifestations are typically transient and are conservatively managed, often with supportive care alone. Topical corticosteroids can be used to treat moderate to severe NLE rash. Cytopenias may improve over time, but severe cases occasionally require IVIG. Supportive care is usually appropriate for hepatic and neurologic manifestation. As the neonate clears maternal autoantibodies over the 1st 6 mo of life, these inflammatory manifestations gradually resolve.

Because maternal autoantibodies gain access to the fetus through the placenta via FcRn at about 12 wk of gestation, all pregnant women with circulating anti-Ro and/or anti-La antibodies, or those with a history of offspring with NLE or congenital heart block, are monitored by a pediatric cardiologist, with screening fetal echocardiography performed weekly from 16-26 wk of gestation and then biweekly through 34 wk. The period of greatest vulnerability is usually 18-24 wk. If fetal bradycardia is found during in utero monitoring, and if fetal echocardiography confirms a conduction defect, screening for maternal anti-Ro and anti-La antibodies is warranted. Figure 183.4 presents a proposed management algorithm.



Management of the Anti-Ro ± Anti-La Pregnancy
Detailed counseling by rheumatologist and fetal/pediatric cardiologist
Fetal echo: Weekly starting at 16–18 wk throught 26 wk; biweekly from 26–34 wk
Normal fetal echoes
Consider postnatal EKG and echocardiogram: 1st mo of life, and 1 yr of age
PR interval ≥140 msec (2SD), and/or moderate tricuspid regurgitation
Serial/repeat fetal echo in 24–48 hr
PR interval >150 msec (3SD)
Consider dexamethasone 4 mg for 1 wk
2° or alternating 2°/3° AV block
AV block with signs of EFE, myocarditis, CHF, and/or hydrops
Dexamethasone 4 mg daily
3° (complete) AV block, no hydrops fetalis
3° (complete) AV block, severe hydrops fetalis
Dexamethasone 4–8 mg daily plus IVIG, ? apheresis; consider termination

FIG. 183.4 Algorithm for the management of the anti-Ro ± anti-La pregnancy. All such pregnancies should include counseling and serial fetal echocardiograms. AV, Atrioventricular; CHF, congestive heart failure; EFE, endocardial fibroelastosis; SD, standard deviations.

Juvenile Dermatomyositis

Angela Byun Robinson, Ann M. Reed

Juvenile dermatomyositis (JDM) is the most common inflammatory myositis in children, distinguished by proximal muscle weakness and a characteristic rash. Inflammatory cell infiltrates result in *vascular inflammation,* the underlying pathology in this disorder.

Etiology

Evidence suggests that the etiology of JDM is multifactorial, based on genetic predisposition and an unknown environmental trigger. Human leukocyte antigen (HLA) alleles such as B8, DRB1*0301, DQA1*0501, and DQA1*0301 are associated with increased susceptibility to JDM in selected populations. Maternal microchimerism may play a part in the etiology of JDM by causing graft-versus-host disease (GVHD) or autoimmune phenomena. Persistent maternal cells have been found in blood and tissue samples of children with JDM. An increased number of these maternal cells are positive for HLA-DQA1*0501, which may assist with transfer or persistence of chimeric cells. Specific cytokine polymorphisms in tumor necrosis factor (TNF)-α promoter and variable-number tandem repeats of the interleukin (IL)-1 receptor antagonist may increase genetic susceptibility. These polymorphisms are common in the general population. A history of infection in the 3 mo before disease onset is usually reported; multiple studies have failed to produce a causative organism. Constitutional signs and upper respiratory symptoms predominate, but one third of patients report preceding gastrointestinal (GI) symptoms. Group A streptococcus, upper respiratory infections, GI infections, coxsackievirus B, toxoplasma, enteroviruses, parvovirus B19, and multiple other organisms have been postulated as possible pathogens in the etiology of JDM. Despite these concerns, results of serum antibody testing and polymerase chain reaction amplification of the blood and muscle tissue for multiple infectious diseases have not been revealing. Environmental factors may also play a contributing role, with geographic and seasonal clustering reported. Short-term increases in UV index prior to onset of disease have been reported; however, no clear theory of etiology has emerged.

Epidemiology

The incidence of JDM is approximately 3 cases/1 million children/yr, without racial predilection. Peak age of onset is 4-10 yr. A 2nd peak of dermatomyositis onset occurs in late adulthood (45-64 yr), but adult-onset dermatomyositis appears to be a distinctly separate entity in prognosis and etiology. In the United States the ratio of girls to boys with JDM is 2 : 1. Multiple cases of myositis in a single family are rare, but familial autoimmune disease may be increased in families with children who have JDM than in families of healthy children. Reports of seasonal association have not been confirmed, although clusters of cases may occur.

Pathogenesis

Interferon (IFN) upregulates genes critical in immunoregulation and major histocompatibility complex (MHC) class I expression, activates natural killer (NK) cells, and supports dendritic cell (DC) maturation. Upregulation of gene products controlled by type I IFNs occurs in patients with dermatomyositis, potentially correlating with disease activity and holding promise as clinical biomarkers.

It appears that children with genetic susceptibility to JDM (HLA-DQA1*0501, HLA-DRB*0301) may have prolonged exposure to maternal chimeric cells and/or an unknown environmental trigger. Once triggered, an inflammatory cascade with type I IFN response leads to upregulation of MHC class I expression and maturation of DCs. Overexpression of MHC class I upregulates adhesion molecules, which influence migration of lymphocytes, leading to inflammatory infiltration of muscle. In an autoregulatory feedback loop, muscle inflammation increases the type I IFN response, regenerating the cycle of inflammation. Cells involved in the inflammatory cascade include NK cells (CD56), T-cell subsets (CD4, CD8, Th17), monocytes/macrophages (CD14), and plasmacytoid DCs. Neopterin, IFN-inducible protein 10, monocyte chemoattractant protein, myxovirus resistance protein, and von Willebrand factor products, as well as other markers of vascular inflammation, may be elevated in patients with JDM who have active inflammation.

Clinical Manifestations

Children with JDM present with either rash, insidious onset of weakness, or both. Fevers, dysphagia or dysphonia, arthritis, muscle tenderness, and fatigue are also commonly reported at diagnosis (Tables 184.1 and 184.2).

Table 184.1

Diagnostic Criteria for Juvenile Dermatomyositis

Classic rash	Heliotrope rash of the eyelids Gottron papules
Plus 3 of the following:	
Weakness	Symmetric Proximal
Muscle enzyme elevation (≥1)	Creatine kinase Aspartate transaminase Lactate dehydrogenase Aldolase
Electromyographic changes	Short, small polyphasic motor unit potentials Fibrillations Positive sharp waves Insertional irritability Bizarre, high-frequency repetitive discharges
Muscle biopsy	Necrosis Inflammation

Data from Bohan A, Peter JB: Polymyositis and dermatomyositis (2nd of 2 parts), *N Engl J Med* 292:403–407, 1975.

Table 184.2

Clinical Features of Juvenile Dermatomyositis During Disease Course

FEATURE	%
Muscle weakness	90-100
Dysphagia or dysphonia	13-40
Muscle atrophy	10
Muscle pain and tenderness	30-75

Skin lesions	85-100
Heliotrope rash of eyelids	66-95
Gottron papules	57-95
Erythematous rash of malar/facial area	42-100
Periungual (nail fold) capillary changes	80-90
Photosensitive rash	5-42
Ulcerations	22-30
Calcinosis	12-30
Lipodystrophy	11-14
Raynaud phenomenon	2-15
Arthritis and arthralgia	22-58
Joint contractures	26-27
Fever	16-65
Gastrointestinal signs and symptoms	8-37
Restrictive pulmonary disease	4-32
Interstitial lung disease	1-7
Cardiac involvement	0-3

From Rider LG, Lindsley CB, Cassidy JT: Juvenile dermatomyositis. In Cassidy JT, Petty RE, Laxer RM, et al, editors: *Textbook of pediatric rheumatology,* ed 6, Philadelphia, 2011, Saunders (Table 24.20, p 410).

Rash develops as the first symptom in 50% of patients and appears concomitant with weakness only 25% of the time. Children often exhibit extreme photosensitivity to ultraviolet (UV) light exposure with generalized erythema in sun-exposed areas. If seen over the chest and neck, this erythema is known as the **shawl sign** . Erythema is also commonly seen over the knees and elbows. The characteristic **heliotrope rash** is a blue-violet discoloration of the eyelids that may be associated with periorbital edema (Fig. 184.1). Facial erythema crossing the nasolabial folds is also common, in contrast to the malar rash without nasolabial involvement typical of systemic lupus erythematosus (SLE). Classic **Gottron papules** are bright-pink or pale, shiny, thickened or atrophic plaques over the proximal interphalangeal joints and distal interphalangeal joints and occasionally on the knees, elbows, small joints of the toes, and ankle malleoli (Fig. 184.2). The rash of JDM is sometimes mistaken for eczema or psoriasis. Rarely, a thickened erythematous and scaly rash develops in children over the palms (known as **mechanic's hands**) and soles along the flexor tendons, which is associated with anti–Jo-1 antibodies.

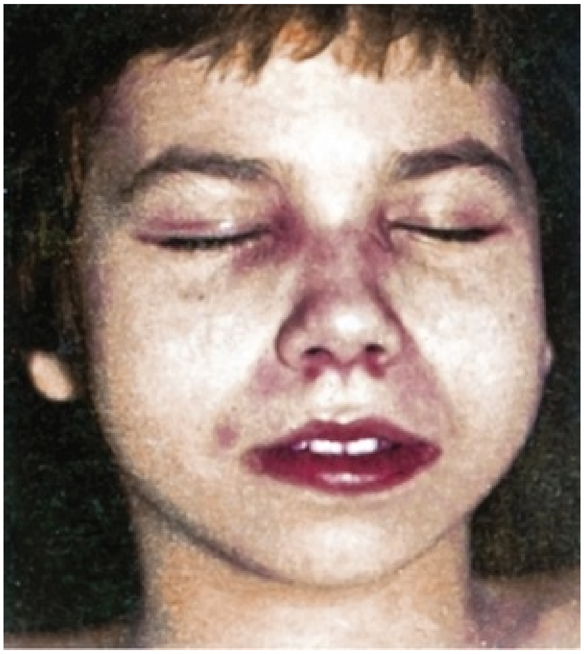

FIG. 184.1 The facial rash of juvenile dermatomyositis. There is erythema over the bridge of the nose and malar areas with violaceous (heliotropic) discolorations of the upper eyelids.

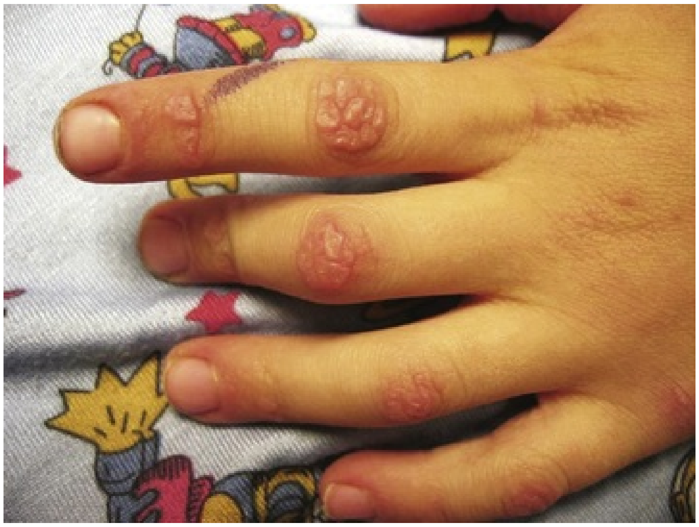

FIG. 184.2 The rash of juvenile dermatomyositis. The skin over the metacarpal and proximal interphalangeal joints may be hypertrophic and pale red (Gottron papules).

Evidence of small-vessel inflammation is often visible in the nail folds and gums as individual capillary loops that are thickened, tortuous, or absent (Fig. 184.3*C*). Telangiectasias may be visible to the naked eye but are more easily visualized under capillaroscopy or with a magnifier (e.g., ophthalmoscope). Severe vascular inflammation causes cutaneous ulcers on toes, fingers, axillae, or epicanthal folds.

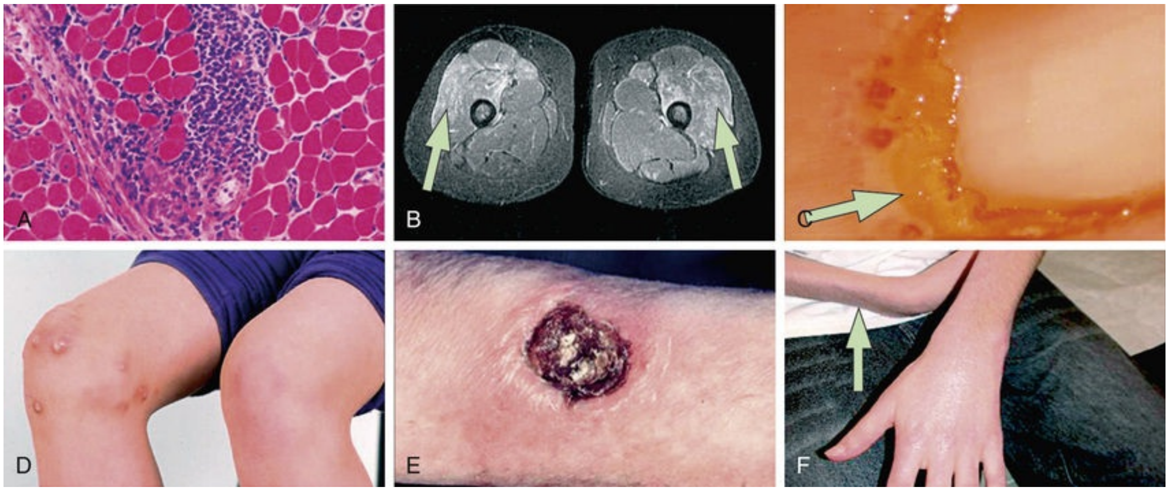

FIG. 184.3 Features of juvenile dermatomyositis. A, Perivascular and perifascicular inflammatory infiltrates with necrotic fibers, perifascicular atrophy, and regeneration in a muscle biopsy. B, MRI is a sensitive indicator of myositis. Inflamed areas appear bright on short-tau inversion recovery–weighted images *(arrows).* C, Capillaries are most often abnormal when viewed at the nail fold. Typical changes of dilation with adjacent dropout *(arrow)* is seen. D, About 30% of juvenile dermatomyositis (JDM) patients have dystrophic calcinosis. E, Cutaneous ulceration with central necrosis, crust, and surrounding erythema at the elbow of 10-year-old boy with severe JDM. F, Lipoatrophy of the forearm *(arrow)* in a boy with JDM. (From Feldman BM, Rider LG, Reed AM, Pachman LM: Juvenile dermatomyositis and other idiopathic inflammatory myopathies of childhood, *Lancet* 371:2201–2212, 2008, Fig 3, p 2205.)

Weakness associated with JDM is often insidious and difficult to differentiate from fatigue at onset. It is typically symmetric, affecting proximal muscles such as the neck flexors, shoulder girdle, and hip flexors. Parents may report difficulty climbing stairs, combing hair, and getting out of bed. Examination reveals inability to perform a sit-up, head lag in a child after infancy, and **Gower sign** (use of hands on thighs to stand from a sitting position). Patients with JDM may roll to the side rather than sit straight up from lying to compensate for truncal weakness. Approximately half of children exhibit muscle tenderness as a result of muscle inflammation.

Esophageal and respiratory muscles are also affected, resulting in aspiration or respiratory failure. It is essential to assess for dysphonia or nasal speech, palatal elevation with gag, dysphagia, and gastroesophageal reflux by means of history, physical examination, and swallow study, if symptoms are present. Respiratory muscle weakness can be a medical emergency and lead to respiratory failure.

Children with respiratory muscle weakness do *not* manifest typical symptoms of impending respiratory failure with increased work of breathing, instead demonstrating **hypercarbia** rather than hypoxemia.

Diagnosis

Diagnosis of dermatomyositis requires the presence of characteristic rash as well as at least 3 signs of muscle inflammation and weakness (see Table 184.1). Diagnostic criteria developed in 1975 predate the use of MRI and have not been validated in children. Diagnosis is often delayed because of the insidious nature of disease onset.

Electromyography (EMG) shows signs of myopathy (increased insertional activity, fibrillations, sharp waves) as well as muscle fiber necrosis (decreased action potential amplitude and duration). Nerve conduction studies are typically normal unless severe muscle necrosis and atrophy are present. It is important that EMG be performed in a center with experience in pediatric EMG and its interpretation. Muscle biopsy is typically indicated when diagnosis is in doubt or for grading disease severity (Fig. 184.3*A*). Biopsy of involved muscle reveals focal necrosis and phagocytosis of muscle fibers, fiber regeneration, endomysial proliferation, inflammatory cell infiltrates and vasculitis, and tubuloreticular inclusion bodies within endothelial cells. Findings of lymphoid structures and vasculopathy may portend more severe disease.

Some children present with classic rash but no apparent muscle weakness or inflammation; this variation is called **amyopathic JDM** or **dermatomyositis sine myositis** . It is unclear whether these children have isolated skin disease or mild undetected muscle inflammation, risking progression to more severe muscle involvement with long-term sequelae such as calcinosis and lipodystrophy if untreated.

Differential Diagnosis

Differential diagnosis depends on the presenting symptoms. If the presenting complaint is solely weakness without rash or atypical disease, other causes of myopathy should be considered, including polymyositis, infection-related myositis (influenza A and B, coxsackievirus B, and other viral illnesses), muscular dystrophies (e.g., Duchenne, Becker), myasthenia gravis, Guillain-

Barré syndrome, endocrinopathies (hyperthyroidism, hypothyroidism, Cushing syndrome, Addison disease, parathyroid disorders), mitochondrial myopathies, TNF receptor–associated periodic syndrome (TRAPS), and metabolic disorders (glycogen and lipid storage diseases). Infections associated with prominent muscular symptoms include trichinosis, *Bartonella* infection, toxoplasmosis, and staphylococcal pyomyositis. Blunt trauma and crush injuries may lead to transient rhabdomyolysis with myoglobinuria. Myositis in children may also be associated with vaccinations, drugs, growth hormone, and GVHD. The rash of JDM may be confused with eczema, dyshidrosis, psoriasis, erythema nodosa, malar rash from SLE, capillary telangiectasias from Raynaud phenomenon, and other rheumatic diseases. Muscle inflammation is also seen in children with SLE, juvenile idiopathic arthritis, mixed connective tissue disease, inflammatory bowel disease, and antineutrophil cytoplasmic antibody–positive vasculitides. Necrotizing immune-mediated myopathies are characterized by muscle necrosis without lymphocytic infiltration. Antibodies to signal recognition particle (SRP) or 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) distinguish two types from each other and from JDM. Table 184.3 compares other juvenile idiopathic inflammatory myositis disorders: JDM, juvenile polymyositis, and juvenile connective tissue myositis.

Table 184.3

Frequency of Manifestations of Juvenile Dermatomyositis, Juvenile Polymyositis, and Overlap Myositis

Manifestation	**FREQUENCY AT ONSET (%)**		
	JDM	**JPM**	**Overlap Myositis**
Progressive proximal muscle weakness	82-100	100	100
Easy fatigue	80-100	85	84
Gottron papules	57-91	0	74-80
Heliotrope rash	66-87	0	40-59
Erythematous rash of malar/facial area	42-100	0-6	20-51
Periungual nailfold capillary changes	35-91	33	67-80
Muscle pain or tenderness	25-83	61-66	55
Weight loss	33-36	52	53
Falling episodes	40	59	29
Arthritis	10-65	0-45	69-80
Fever	16-65	0-41	0-49
Lymphadenopathy	8-75	0-12	20-22
Dysphagia or dysphonia	15-44	39	40
Joint contractures	9-55	17-42	57-60
V- or shawl-sign rashes	19-29	3-6	8-14

Dyspnea on exertion	5-43	17-42	40
Gastrointestinal symptoms	5-37	9-33	6-53
Photosensitive rashes	5-51	0-6	22-40
Raynaud phenomenon	9-28	0-24	41-60
Edema	11-34	15	20
Gingivitis	6-30	9	0-37
Cutaneous ulceration	5-30	3	20-22
Calcinosis	3-34	6	24
Cardiac involvement	2-13	36	19
Interstitial lung disease	5	15	26
Lipodystrophy	4-14	3	0-6
Gastrointestinal bleeding or ulceration	3-4	3	4-10

JDM, Juvenile dermatomyositis; JPM, juvenile polymyositis.

From Rider LG, Lindsley CB, Miller FW: Juvenile Dermatomyositis. IN Petty RE, Laxer RM, Lindsley CB, Wedderburn L, editors: *Textbook of pediatric rheumatology,* ed 7, Philadelphia, 2016, Elsevier, Table 26.4.

Laboratory Findings

Elevated serum levels of muscle-derived enzymes (creatine kinase [CK], aldolase, aspartate transaminase, alanine transaminase [ALT], lactate dehydrogenase) reflect muscle inflammation. Not all enzyme levels rise with inflammation in a specific individual; ALT is usually elevated on initial presentation, whereas CK level may be normal. The erythrocyte sedimentation rate (ESR) is often normal, and the rheumatoid factor (RF) test result is typically negative. There may be anemia consistent with chronic disease. Antinuclear antibody (ANA) is present in >80% of children with JDM. Serologic testing results are divided into 2 groups: **myositis-associated antibodies (MAAs)** and **myositis-specific antibodies (MSAs)** . MAAs are associated with JDM, but are not specific and can be seen in both overlap conditions and other rheumatic diseases. MSAs are specific for myositis. Presence of MAAs such as SSA, SSB, Sm, ribonucleoprotein (RNP), and double-stranded (ds) DNA may increase the likelihood of overlap disease or connective tissue myositis. Antibodies to Pm/Scl identify a small, distinct subgroup of myopathies with a protracted disease course, often complicated by pulmonary interstitial fibrosis and cardiac involvement. Similar to what is seen in adults, the presence of MSAs in JDM such as anti–Jo-1, anti–Mi-2, anti-p155/140, anti-NXP2, and other myositis-specific autoantibodies help define distinct clinical subsets and may predict the development of complications, although differences remain in certain aspects such as malignancy between adults and children. Anti-p155/140 antibodies also known as TIF-1-γ are reported in 23–30% of children with JDM and are associated with photosensitive rashes, ulceration, and lipodystrophy. Unlike in adults, this antibody is not associated with malignancy in children with JDM. Anti-MJ antibodies, also known as NXP2, are reported in 12–23% of children with JDM and are associated with cramps, muscle atrophy, contractures, and dysphonia. Anti-MDA5 antibodies have been recently reported in 7–33% of children with JDM, and are concerning for development of interstitial lung disease.

Radiographic studies aid both diagnosis and medical management. MRI using T2-weighted images and fat suppression (Fig. 184.3*B*) identifies active sites of disease, reducing sampling error and increasing the sensitivity of muscle biopsy and EMG, results of which are nondiagnostic in 20% of cases if the procedures are not directed by MRI. Extensive rash and abnormal MRI findings may be found despite normal serum levels of muscle-derived enzymes. Muscle biopsy often demonstrates evidence of disease activity and chronicity that is not suspected from the levels of the serum enzymes alone.

A contrast swallow study may document palatal dysfunction and risk of aspiration. Pulmonary function testing detects a restrictive defect consistent with respiratory weakness and reduced diffusion capacity of carbon monoxide from alveolar fibrosis associated with other connective tissue diseases. Serial measurement of vital capacity or negative inspiratory force can document changes in respiratory weakness, especially in an inpatient setting. **Calcinosis** is seen easily on radiographs, along the fascial planes and within muscles (Figs. 184.3*D, E* and 184.4).

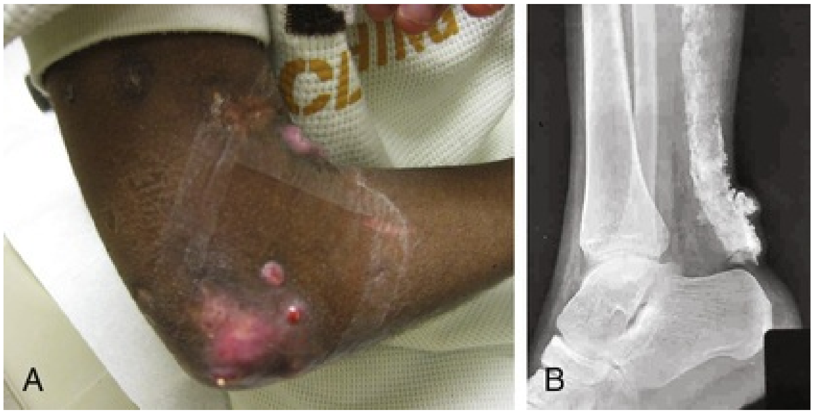

FIG. 184.4 Calcifications in dermatomyositis. A, Skin effects of calcification. B, Radiographic evidence of calcification.

Treatment

The aid of an experienced pediatric rheumatologist is invaluable in outlining an appropriate course of treatment for a child with JDM. Before the advent of corticosteroids, one third of patients spontaneously improved, a third had a chronic, lingering course, and a third died from the disease. Corticosteroids have altered the course of disease, lowering morbidity and mortality. *Methotrexate* decreases the length of treatment with corticosteroids, thereby reducing morbidity from steroid toxicity. Intravenous (IV) gamma globulin is frequently used as an adjunct for treatment of severe disease and can be given at 2 g/kg (maximum 70 g) every 2 wk for 3 doses, then every 4 wk as needed. Consensus treatment plans for guiding treatment of North American children with JDM are available from the **Childhood Arthritis and Rheumatology Research Alliance** online through PubMed.

Corticosteroids are still the mainstay of treatment. In a clinically stable child without debilitating weakness, oral prednisone at 2 mg/kg/day (maximum 60 mg daily) is usually started. Children with GI involvement have decreased absorption of oral corticosteroids and require IV administration. In more severe cases with respiratory or oropharyngeal weakness, high-dose pulse methylprednisolone is used (30 mg/kg/day for 3 days, maximum dose 1 g/day) with ongoing weekly or monthly IV dosing along with daily oral corticosteroids as needed. Corticosteroid dosage is slowly tapered over 12 mo, after indicators of inflammation (muscle enzymes) normalize and strength improves.

Weekly oral, IV, or subcutaneous methotrexate (the lesser of 1 mg/kg or 15 mg/m^2 , maximum 40 mg) is often used as a steroid-sparing agent in JDM. The concomitant use of methotrexate halves the cumulative dosage of steroids needed for disease control. Risks of methotrexate include immunosuppression, blood count dyscrasias, chemical hepatitis, pulmonary toxicity, nausea/vomiting, and teratogenicity. Folic acid is typically given with methotrexate starting at a dose of 1 mg daily to reduce toxicity and side effects of folate inhibition (oral ulcers, nausea, anemia). Children who are taking immunosuppressive medications such as methotrexate should avoid live-virus vaccination, although inactivated influenza vaccination is recommended yearly. An international trial found the combination of methotrexate plus corticosteroids to perform better than corticosteroids alone and with fewer side effects than corticosteroids plus cyclosporine A.

Hydroxychloroquine has little toxicity risk and is used as a secondary disease-modifying agent to reduce rash and maintain remission. Typically, it is administered at doses of 4-6 mg/kg/day orally in either tablet or liquid form. Ophthalmologic follow-up 1-2 times per year to monitor for rare retinal toxicity is recommended. Other side effects include hemolysis in patients with glucose-6-phosphate deficiency, GI intolerance, and skin/hair discoloration.

The use of *rituximab* in a trial of steroid-dependent patients with resistant inflammatory myopathies, including JDM, did not meet the primary study end-point showing a difference in time to improvement between individuals given rituximab at baseline or at 8 wk, but overall, 83% of all patients met the definition of improvement in the trial. Reports of the use of other biologic agents are based on case reports with mixed results.

Other medications for severe unresponsive disease include intravenous immune globulin, mycophenolate mofetil, cyclosporine, and cyclophosphamide. Children with pharyngeal weakness may need nasogastric or gastrostomy feedings to avoid aspiration, whereas those with GI vasculitis require full bowel rest. Rarely, children with severe respiratory weakness require ventilator therapy and even tracheostomy until the respiratory weakness improves.

Physical therapy and **occupational therapy** are integral parts of the treatment program, initially for passive stretching early in the disease course and then for direct reconditioning of muscles to regain strength and range of motion. Therapy may improve strength muscle measures and cardiovascular fitness. Bed rest is not indicated, because weight bearing improves bone density and prevents contractures. Social work and psychology services may facilitate adjustment to the frustration of physical impairment in a previously active child and aid with sleep disturbances associated with rheumatic disease.

All children with JDM should avoid sun exposure and apply high-SPF (sun protection factor) sunscreen daily, even in winter and on cloudy days. Vitamin D and calcium supplements are indicated for all children undergoing long-term corticosteroid therapy to reduce drug-induced osteopenia and osteoporosis.

Complications

Most complications from JDM are related to prolonged and severe weakness from muscle atrophy to cutaneous calcifications and scarring or atrophy to lipodystrophy. Secondary complications from medical treatments are also common. Children with acute and severe weakness are at risk for aspiration pneumonia and respiratory failure and occasionally require nasogastric feeding and mechanical ventilation until weakness improves. Rarely, **vasculitis** of the GI tract develops in children with severe JDM. Crampy abdominal pain and occult GI bleeding may indicate bowel wall vasculitis and lead to ischemia, GI bleeding, and perforation if not treated with complete bowel rest and aggressive treatment for the underlying inflammation. Surgery should be avoided if possible, because the GI vasculitis is diffuse and not easily amenable to surgical intervention. Contrast-enhanced CT may show dilation or thickening of the bowel wall, intraluminal air, or evidence of bowel necrosis.

Involvement of the cardiac muscle with pericarditis, myocarditis, and conduction defects with arrhythmias has been reported, as well as reduced diastolic and systolic function related to ongoing disease activity.

Lipodystrophy and **calcinosis** are thought to be associated with long-standing or undertreated disease (Fig. 184.3, *D-F*). Dystrophic deposition of calcium phosphate, hydroxyapatite, or fluoroapatite crystals occurs in subcutaneous plaques or nodules, resulting in painful ulceration of the skin with extrusion of crystals or calcific liquid. Calcification is found in up to 40% of large cohorts of children with JDM. Pathologic calcifications may be related to severity of disease and prolonged delay to treatment and potentially to genetic polymorphisms of TNF-α-308. Calcium deposits tend to form in subcutaneous tissue and along muscle. Some ulcerate through the skin and drain a soft calcific liquid, and others manifest as hard nodules along extensor surfaces or embedded along muscle. Draining lesions serve as a nidus for cellulitis or osteomyelitis. Nodules cause skin inflammation that may mimic cellulitis. Spontaneous regression of calcium deposits may occur, but there is no evidence-based recommendation for treatment of calcinosis. Some experts recommend aggressive treatment of underlying myositis. Others have recommended bisphosphonates, TNF inhibitors, and sodium thiosulfate, but no evidence-based trials have been conducted for this condition.

Lipodystrophy manifests in 10–40% of patients with JDM and can be difficult to recognize. Lipodystrophy results in progressive loss of subcutaneous and visceral fat, typically over the face and upper body, and may be associated with a metabolic syndrome similar to polycystic ovarian syndrome with insulin resistance, hirsutism, acanthosis, hypertriglyceridemia, and abnormal glucose tolerance. Lipodystrophy may be generalized or localized.

Children receiving prolonged corticosteroid therapy are prone to complications such as cessation of linear growth, weight gain, hirsutism, adrenal suppression, immunosuppression, striae, cushingoid fat deposition, mood changes, osteoporosis, cataracts, avascular necrosis, and steroid myopathy. Families should be counseled on the effects of corticosteroids and advised to use medical alert identification and to consult a nutritionist regarding a low-salt, low-fat diet with adequate vitamin D and calcium supplementation.

An association with malignancy at disease onset is observed in adults with dermatomyositis but very rarely in children.

Prognosis

The mortality rate in JDM has decreased since the advent of corticosteroids, from 33% to currently approximately 1%; little is known about the long-term consequences of persistent vascular inflammation. The period of active symptoms has decreased from about 3.5 yr to <1.5 yr with more aggressive immunosuppressive therapy; the vascular, skin, and muscle symptoms of children with JDM generally respond well to therapy. At 7 yr of follow-up, 75% of patients have little to no residual disability, but 25% continue to have chronic weakness and 40% have chronic rash. Up to one-third may need long-term medications to control their disease. Children with JDM appear able to repair inflammatory damage to vasculature and muscle, but there is some emerging concern about long-term effects on cardiovascular risk.

CHAPTER 185

Scleroderma and Raynaud Phenomenon

Heather A. Van Mater, C. Egla Rabinovich

Juvenile scleroderma encompasses a range of conditions unified by the presence of fibrosis of the skin. Juvenile scleroderma is divided into 2 major categories, **juvenile localized scleroderma** (**JLS** , also known as **morphea**), which is largely limited to the skin, and **juvenile systemic sclerosis** (**JSSc**), with multisystem organ involvement. Localized disease is the predominant type seen in pediatric populations (>95%), but systemic sclerosis is associated with mortality and severe multiorgan morbidity.

Etiology and Pathogenesis

The etiology of scleroderma is unknown, but the mechanism of disease appears to be a combination of a vasculopathy, autoimmunity, immune activation, and fibrosis. Triggers, including trauma, infection, and, possibly, subclinical graft-versus-host reaction from persistent maternal cells (*microchimerism*), injure vascular endothelial cells, resulting in increased expression of adhesion molecules. These molecules entrap platelets and inflammatory cells, resulting in vascular changes with manifestations such as Raynaud phenomenon and pulmonary hypertension. Inflammatory cells infiltrate the area of initial vascular damage, causing further vascular damage and resulting in thickened artery walls and reduction in capillary numbers. Macrophages and other inflammatory cells then migrate into affected tissues and secrete cytokines that induce fibroblasts to reproduce and synthesize excessive amounts of collagen, resulting in fibrosis and subsequent lipoatrophy, dermal fibrosis, with loss of sweat glands and hair follicles. In late stages the entire dermis may be replaced by compact collagen fibers.

Autoimmunity is believed to be a key process in the pathogenesis of both localized and systemic scleroderma, given the high percentage of affected children with autoantibodies. Children with localized disease often have a positive antinuclear antibody (ANA) test result (42%), and 47% of this subgroup have antihistone antibodies. Children with JSSc have higher rates of ANA positivity (80.7%) and may have anti–Scl-70 antibody (34%, antitopoisomerase I). The relationship between specific autoantibodies and the various forms of scleroderma is not well understood, and all antibody test results may be negative, especially in JLS.

Classification

Localized scleroderma is distinct from systemic scleroderma and rarely progresses to systemic disease. The category of JLS includes several subtypes differentiated by both the distribution of the lesions and the depth of involvement (Tables 185.1 and 185.2). Up to 15% of children have a combination of 2 or more subtypes.

Table 185.1

Classification of Pediatric Scleroderma (Morphea)

Localized Scleroderma

Plaque Morphea

- Confined to dermis, occasionally superficial panniculus
- Well-circumscribed circular area of induration, often a central waxy, ivory-colored area surrounded by a violaceous halo; unilateral

Generalized Morphea

- Involves dermis primarily, occasionally panniculus
- Defined as confluence of individual morphea plaques or lesions in ≥3 anatomic sites; more likely to be bilateral

Bullous Morphea

Bullous lesions that can occur with any of the subtypes of morphea

Linear Scleroderma

Linear lesions can extend through the dermis, subcutaneous tissue, and muscle to underlying bone; more likely unilateral

Limbs/trunk:

- One or more linear streaks of the extremities or trunk
- Flexion contracture occurs when lesion extends over a joint; limb length discrepancies

En coup de sabre:

- Involves the scalp and/or face; lesions can extend into the central nervous system, resulting in neurologic sequelae, most commonly seizures and headaches

Parry-Romberg syndrome:

- Hemifacial atrophy without a clearly definable en coup de sabre lesion; can also have neurologic involvement

Deep Morphea

Involves deeper layers, including panniculus, fascia, and muscle; more likely to be bilateral

Subcutaneous morphea:

- Primarily involves the panniculus or subcutaneous tissue
- Plaques are hyperpigmented and symmetric

Eosinophilic fasciitis:

- Fasciitis with marked blood eosinophilia
- Fascia is the primary site of involvement; typically involves extremities
- Classic description is “peau d'orange” or orange peel texture, but early disease manifests as edema (see Fig. 185.2)

Morphea profunda:

- Deep lesion extending to fascia and sometimes muscle, but may be limited to a single plaque, often on trunk

Disabling pansclerotic morphea of childhood:

Generalized full-thickness involvement of skin on the trunk, face and extremities, sparing fingertips and toes

Systemic Sclerosis

Diffuse

Most common type in childhood

Symmetric thickening and hardening of the skin (sclerosis) with fibrous and degenerative changes of viscera

Limited

Rare in childhood

Previously known as CREST (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) syndrome

Table 185.2

Provisional Criteria for Classification of Juvenile Systemic Sclerosis (JSSc)

Major Criterion (Required)*

Proximal skin sclerosis/induration of the skin proximal to metacarpophalangeal or metatarsophalangeal joints

Minor Criteria (at Least 2 Required)

Cutaneous: Sclerodactyly

Peripheral vascular: Raynaud phenomenon, nail fold capillary abnormalities (telangiectasias), digital tip ulcers

Gastrointestinal: Dysphagia, gastroesophageal reflux

Cardiac: Arrhythmias, heart failure

Renal: Renal crisis, new-onset arterial hypertension

Respiratory: Pulmonary fibrosis (high-resolution CT/radiography), decreased diffusing capacity for carbon monoxide, pulmonary arterial hypertension

Neurologic: Neuropathy, carpal tunnel syndrome

Musculoskeletal: Tendon friction rubs, arthritis, myositis

Serologic: Antinuclear antibodies—SSc-selective autoantibodies (anticentromere, antitopoisomerase I [Scl-70], antifibrillarin, anti-PM/Scl, antifibrillin, or anti-RNA polymerase I or III

---

[*] Diagnosis requires at least 1 major and at least 2 minor criteria.

From Zulian F, Woo P, Athreya BH, et al: The Pediatric Rheumatology European Society/American College of Rheumatology/European League against Rheumatism provisional classification criteria for juvenile systemic sclerosis, *Arthritis Rheum* 57:203–212, 2007.

Epidemiology

Juvenile scleroderma is rare, with an estimated prevalence of 1 in 100,000 children. LS is much more common than SSc in children, by a 10 : 1 ratio, with **linear scleroderma** being the most common subtype. LS is predominantly a pediatric condition, with 65% of patients diagnosed before age 18 yr. After age 8 yr the female/male ratio for both LS and SSc is approximately 3 : 1, whereas in patients younger than 8 yr, there is no sex predilection.

Clinical Manifestations

Localized Scleroderma

The onset of scleroderma is generally insidious, and manifestations vary according to disease subtype. The initial skin manifestations of localized disease usually include erythema or a bluish hue seen around an area of waxy induration; subtle erythema may be the only presenting sign (Fig. 185.1). Edema and erythema are followed by indurated, hypopigmented or hyperpigmented atrophic lesions (Fig. 185.2). LS varies in size from a few centimeters to the entire length of the extremity, with varying depth. Patients may present with arthralgias, synovitis, or flexion contractures (Fig. 185.3). Children also experience limb length discrepancies as a result of growth impairment caused by involvement of muscle and bone. Children with **en coup de sabre** may have symptoms unique to central nervous system (CNS) involvement, such as seizures, hemifacial atrophy, ipsilateral uveitis, and learning/behavioral changes (Fig. 185.4). Up to 25% of children with LS have extracutaneous manifestations, most frequently arthritis (47%) and neurologic symptoms (17%) associated with en coup de sabre.

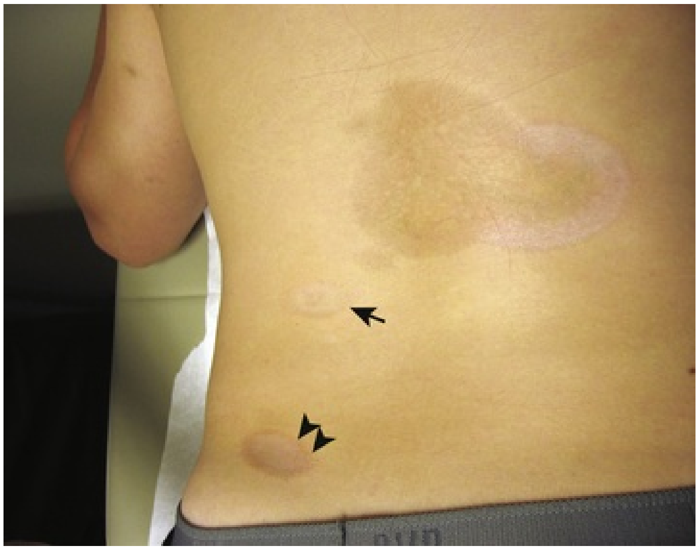

FIG. 185.1 **Boy with generalized morphea. Note the active circular lesion *(arrowheads)* with a surrounding rim of erythema. The largest lesion has areas of postinflammatory hyperpigmentation and depression with an area of erythema on the right. The small lesion *(arrow)* demonstrates depression caused by lipoatrophy.**

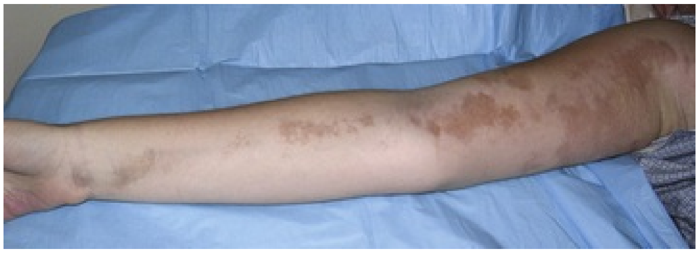

FIG. 185.2 Inactive linear scleroderma demonstrating hyperpigmented lesion with areas of normal skin (skip lesions).

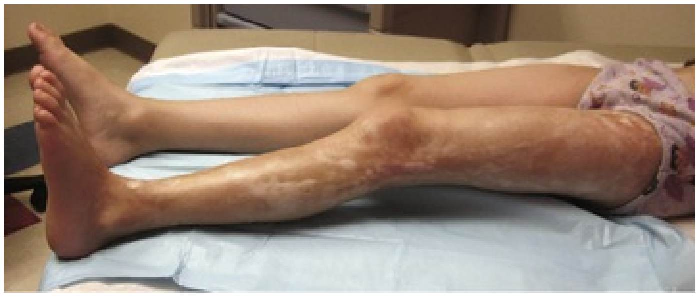

FIG. 185.3 Child with untreated linear scleroderma resulting in knee contracture, immobility of ankle, chronic skin breakdown of scar on the lateral knee, and areas of hypopigmentation and hyperpigmentation. The affected leg is 1 cm shorter.

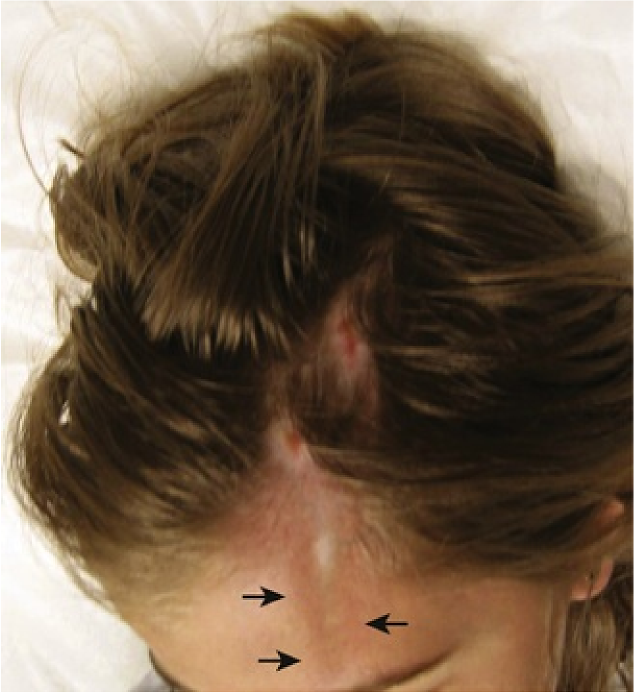

FIG. 185.4 **Child with en coup de sabre lesion on scalp extending down to forehead. Before treatment, the skin on the scalp was bound down with chronic skin breakdown. Note the area of hypopigmentation extending down the forehead *(arrows).***

Systemic Scleroderma

SSc also has an insidious onset with a prolonged course characterized by periods of remission and exacerbation, ending in either remission or, more often, chronic disability and death.

The **skin manifestations** of SSc include an early phase of edema that spreads proximally from the dorsum of the hands and fingers and includes the face. An eventual decrease in edema is followed by induration and fibrosis of skin, ultimately resulting in loss of subcutaneous fat, sweat glands, and hair follicles. Later, atrophic skin becomes shiny and waxy in appearance. As lesions spread proximally, flexion contractures develop at the elbows, hips, and knees associated with secondary muscle weakness and atrophy. In the face, this process results in a small oral stoma with decreased mouth aperture. Skin ulceration over pressure points, such as the elbows, may be associated with subcutaneous calcifications. Severe **Raynaud phenomenon** causes ulceration of the fingertips with subsequent loss of tissue pulp and tapered fingers (**sclerodactyly**) (Fig. 185.5). Resorption of the distal tufts of the distal phalanges may occur (**acroosteolysis**). Hyperpigmented postinflammatory changes surrounded by atrophic depigmentation gives a salt-and-pepper appearance to skin. Over years, remodeling of lesions sometimes results in focal improvement in skin thickening.

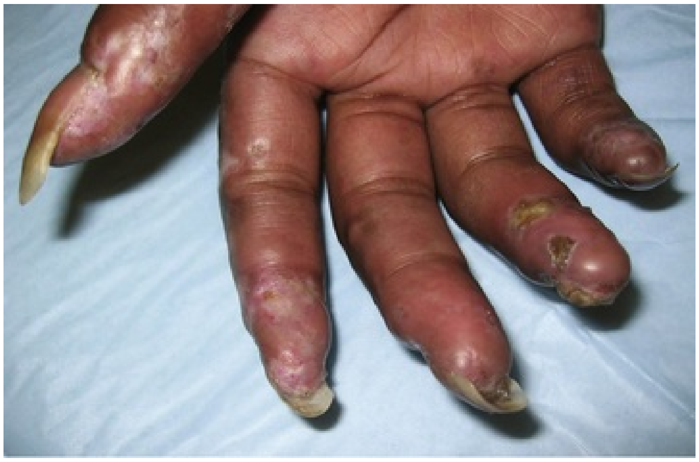

FIG. 185.5 Sclerodactyly and finger ulcerations in a patient with systemic sclerosis who is poorly compliant with treatment.

Pulmonary disease is the most common visceral manifestation of SSc and includes both arterial and interstitial involvement (alveolitis). Symptoms range from asymptomatic disease to exercise intolerance, dyspnea at rest, and right-sided heart failure. **Pulmonary arterial hypertension** is a poor prognostic sign, developing because of lung disease or independently as part of the vasculopathy. Clinical manifestations of pulmonary arterial hypertension in children appear late in the course, are subtle, and include cough and dyspnea on exertion. Pulmonary evaluation should include pulmonary function tests (PFTs) such as diffusion capacity of carbon monoxide (DLCO), bronchoalveolar lavage (BAL), and high-resolution chest computed tomography (HRCT). PFTs reveal decreased vital capacity and decreased DLCO , whereas neutrophilia or eosinophilia on BAL suggest active alveolitis. Chest CT is much more sensitive than chest radiographs, which are often normal, showing typical basilar ground-glass abnormalities, reticular linear opacities, nodules, honeycombing, and mediastinal adenopathy.

Gastrointestinal tract disease is seen in 25% of children with SSc. Common manifestations include esophageal and intestinal dysmotility resulting in dysphagia, reflux, dyspepsia, gastroparesis, bacterial overgrowth, dilated bowel loops and pseudoobstruction, and dental caries, as well as malabsorption and failure to thrive. **Renal** arterial disease can cause chronic or severe episodic hypertension; unlike adult disease, renal crisis is rare. **Cardiac** fibrosis is associated with arrhythmias, ventricular hypertrophy, and decreased cardiac function. Mortality from JSSc is usually a result of cardiopulmonary disease. A scoring system helps identify the severity of the multiorgan involvement (Table 185.3).

Table 185.3

Medsger Systemic Sclerosis Severity Scale*

ORGAN SYSTEM	0 (NORMAL)	1 (MILD)	2 (MODERATE)	3 (SEVERE)	4 (END STAGE)
General	Wt loss <5%	Wt loss 5–10%	Wt loss 10–15%	Wt loss 15–20%	Wt loss 20%+
	Hct 37%+	Hct 33–37%	Hct 29–33%	Hct 25–29%	Hct 25%
	Hb 12.3+ g/dL	Hb 11.0-12.2 g/dL	Hb 9.7-10.9 g/dL	Hb 8.3-9.6 g/dL	Hb <8.3 g/dL
Peripheral vascular	No RP; RP not requiring vasodilators	RP requiring vasodilators	Digital pitting scars	Digital tip ulcerations	Digital gangrene
Skin	TSS 0	TSS 1-14	TSS 15-29	TSS 30-39	TSS 40+
Joint/tendon	FTP 0-0.9 cm	FTP 1.0-1.9 cm	FTP 2.0-3.9 cm	FTP 4.0-4.9 cm	FTP 5.0+ cm
Muscle	Normal proximal muscle strength	Proximal weakness, mild	Proximal weakness, moderate	Proximal weakness, severe	Ambulation aids required
Gastrointestinal tract	Normal esophagogram; normal small bowel series	Distal esophageal hypoperistalsis; small bowel series abnormal	Antibiotics required for bacterial overgrowth	Malabsorption syndrome; episodes of pseudoobstruction	Hyperalimentation required
Lung	DLCO	DLCO 70–	DLCO 50–	DLCO <50%	Oxygen required

	80%+ FVC 80%+ No fibrosis on radiograph sPAP <35 mm Hg	79% FVC 70–79% Basilar rales; fibrosis on radiograph sPAP 35-49 mm Hg	69% FVC 50–69% sPAP 50-64 mm Hg	FVC <50% sPAP 65+ mm Hg	
Heart	ECG normal	ECG conduction defect	ECG arrhythmia	ECG arrhythmia requiring therapy	CHF
	LVEF 50%+	LVEF 45–49%	LVEF 40–44%	LVEF 30–40%	LVEF <30%
Kidney	No history of SRC with serum creatinine <1.3 mg/dL	History of SRC with serum creatinine <1.5 mg/dL	History of SRC with serum creatinine 1.5-2.4 mg/dL	History of SRC with serum creatinine 2.5-5.0 mg/dL	History of SRC with serum creatinine >5.0 mg/dL or dialysis required

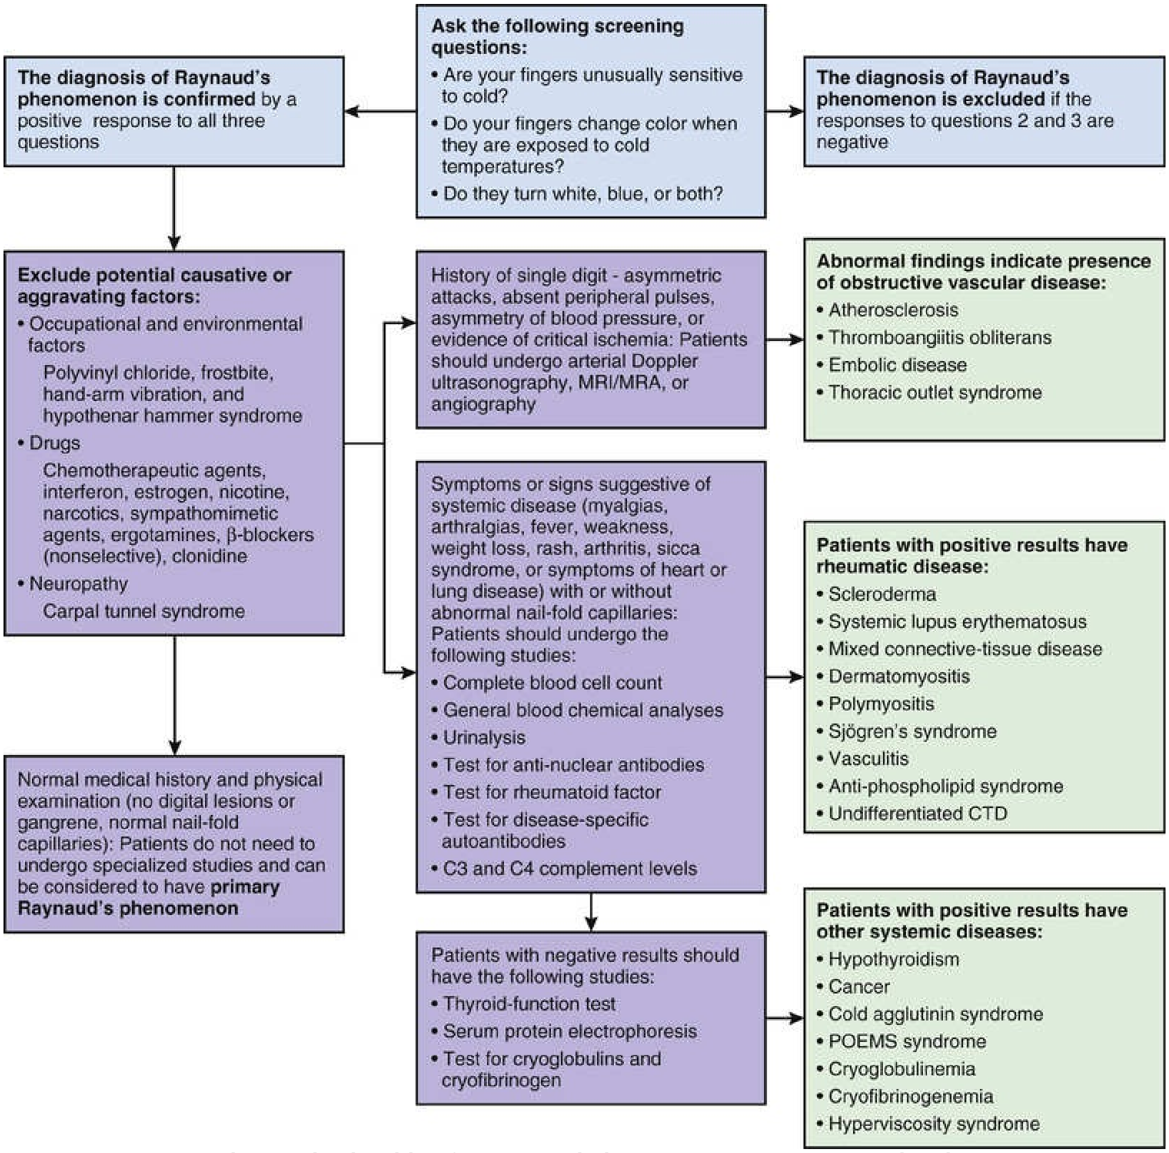
[*] If 2 items are included for a severity grade, only 1 is required for the patient to be scored as having disease of that severity level.

CHF, Congestive heart failure; DLCO , diffusing capacity for carbon monoxide, % predicted; ECG, electrocardiogram; FTP, fingertip-to-palm distance in flexion; FVC, forced vital capacity, % predicted; Hb, hemoglobin; Hct, hematocrit; LVEF, left ventricular ejection fraction; RP, Raynaud phenomenon; sPAP, estimated pulmonary artery pressure by Doppler echo; SRC, scleroderma renal crisis; TSS, total skin score; Wt, weight.

Modified from Medsger TA Jr, Bombardieri S, Czirjak L, et al: Assessment of disease severity and prognosis, *Clin Exp Rheumatol* 21(3 Suppl 29):S51, 2003 (Table 1, p S-43).

Raynaud Phenomenon

Raynaud phenomenon (RP) is the most frequent initial symptom in pediatric systemic sclerosis, present in 70% of affected children months to years before other manifestations. RP refers to the classic triphasic sequence of blanching, cyanosis, and erythema of the digits induced by cold exposure and/or emotional stress. RP is typically independent of an underlying rheumatic disease (Raynaud disease) but can result from rheumatic diseases such as scleroderma, systemic lupus erythematosus (SLE), and mixed connective tissue disease (Fig. 185.6). The color changes are brought about by (1) initial arterial vasoconstriction, resulting in hypoperfusion and pallor (blanching), (2) venous stasis (cyanosis), and (3) reflex vasodilation caused by the factors released from the ischemic phase (erythema). The color change is classically reproduced by immersing the hands in iced water and reversed by warming. During the blanching phase, there is inadequate tissue perfusion in the affected area, associated with pain and paresthesias and resulting in ischemic damage only when associated with a rheumatic disease. The blanching usually affects the distal fingers but may also involve thumbs, toes, ears, and tip of the nose. The affected area is usually well demarcated and uniformly white. *Digital ulcers* associated with RP are indicative of underlying rheumatic disease.



Ask the following screening questions:
- Are your fingers unusually sensitive to cold?
- Do your fingers change color when they are exposed to cold temperatures?
- Do they turn white, blue, or both?

The diagnosis of Raynaud's phenomenon is confirmed by a positive response to all three questions

The diagnosis of Raynaud's phenomenon is excluded if the responses to questions 2 and 3 are negative

Exclude potential causative or aggravating factors:
- Occupational and environmental factors
  Polyvinyl chloride, frostbite, hand-arm vibration, and hypothenar hammer syndrome
- Drugs
  Chemotherapeutic agents, interferon, estrogen, nicotine, narcotics, sympathomimetic agents, ergotamines, β-blockers (nonselective), clonidine
- Neuropathy
  Carpal tunnel syndrome

History of single digit - asymmetric attacks, absent peripheral pulses, asymmetry of blood pressure, or evidence of critical ischemia: Patients should undergo arterial Doppler ultrasonography, MRI/MRA, or angiography

Abnormal findings indicate presence of obstructive vascular disease:
- Atherosclerosis
- Thromboangiitis obliterans
- Embolic disease
- Thoracic outlet syndrome

Symptoms or signs suggestive of systemic disease (myalgias, arthralgias, fever, weakness, weight loss, rash, arthritis, sicca syndrome, or symptoms of heart or lung disease) with or without abnormal nail-fold capillaries: Patients should undergo the following studies:
- Complete blood cell count
- General blood chemical analyses
- Urinalysis
- Test for anti-nuclear antibodies
- Test for rheumatoid factor
- Test for disease-specific autoantibodies
- C3 and C4 complement levels

Patients with positive results have rheumatic disease:
- Scleroderma
- Systemic lupus erythematosus
- Mixed connective-tissue disease
- Dermatomyositis
- Polymyositis
- Sjögren's syndrome
- Vasculitis
- Anti-phospholipid syndrome
- Undifferentiated CTD

Normal medical history and physical examination (no digital lesions or gangrene, normal nail-fold capillaries): Patients do not need to undergo specialized studies and can be considered to have **primary Raynaud's phenomenon**

Patients with negative results should have the following studies:
- Thyroid-function test
- Serum protein electrophoresis
- Test for cryoglobulins and cryofibrinogen

Patients with positive results have other systemic diseases:
- Hypothyroidism
- Cancer
- Cold agglutinin syndrome
- POEMS syndrome
- Cryoglobulinemia
- Cryofibrinogenemia
- Hyperviscosity syndrome

FIG. 185.6 Diagnostic algorithm for Raynaud phenomenon. CTD, Connective tissue disease; MRA, magnetic resonance angiography; POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes. (From Firestein GS, Budd, RC, Gabriel SE, et al, editors: *Kelley & Firestein's textbook of rheumatology,* ed 10, Philadelphia, 2016, Elsevier, Fig 84-3.)

Raynaud disease often begins in adolescence and is characterized by symmetric occurrence, the absence of tissue necrosis and gangrene, and the lack of manifestations of an underlying rheumatic disease. Children have normal nail fold capillaries (absence of periungual telangiectasias). RP should be distinguished from acrocyanosis and chilblains. **Acrocyanosis** is a vasospastic disorder resulting in cool, painless, bluish discoloration in the hands and sometimes feet despite normal tissue perfusion. It may be exacerbated by stimulant medications used to treat attention-deficit disorder. **Chilblains** is a condition with episodic color changes and the development of nodules related to severe cold exposure and spasm-induced vessel and tissue damage; it has been associated with SLE.

Diagnosis

The diagnosis of JLS is based on the distribution and depth of characteristic lesions. Biopsy is helpful to confirm the diagnosis. The diagnosis of JSSc requires proximal sclerosis/induration of the skin as well as the presence of 2 of 20 minor criteria (see Table 185.2).

Differential Diagnosis

The most important condition to differentiate from JLS is JSSc. Contractures and synovitis from juvenile arthritis can be differentiated from those caused by linear scleroderma by the absence of skin changes. Other conditions to consider include chemically induced scleroderma-like disease, diabetic cheiroarthropathy, pseudoscleroderma, and scleredema. **Pseudoscleroderma** comprises a group of unrelated diseases characterized by patchy or diffuse cutaneous fibrosis without the other manifestations of scleroderma. These include phenylketonuria, syndromes of premature aging, and localized idiopathic fibrosis. **Scleredema** is a transient, self-limited disease of both children and adults that has sudden onset after a febrile illness (especially streptococcal infections) and is characterized by patchy sclerodermatous lesions on the neck and shoulders and extending to the face, trunk, and arms.

Laboratory Findings

No laboratory studies are diagnostic of either localized or systemic scleroderma. Although the results of complete blood counts, serum chemistry analyses, and urinalysis are normal, children may have elevated erythrocyte sedimentation rate, eosinophilia, or hypergammaglobulinemia, all of which normalize with treatment. Elevations of muscle enzymes, particularly aldolase, can be seen with muscle involvement. Patients with JSSc may have anemia, leukocytosis, and eosinophilia and autoantibodies (ANA, anti–Scl-70). Imaging studies delineate the affected area and can be used to follow disease progression. MRI is useful in en coup de sabre and Parry-Romberg syndrome (facial hemiatrophy) for determination of CNS or orbital involvement. Infrared thermography uses the temperature variation between areas of active and inactive cutaneous disease to help differentiate active disease from damage. The role of ultrasound to examine lesion activity is evolving. HRCT, PFTs, echocardiography, and manometry are useful tools for diagnosing and monitoring visceral involvement in JSSc.

Treatment

Treatment for scleroderma varies according to the subtype and severity. Superficial morphea may benefit from topical corticosteroids or ultraviolet therapy. For lesions involving deeper structures, systemic therapy is recommended. A combination of *methotrexate* and *corticosteroids* is effective in treating **JLS** by preventing lesion extension and resulting in significant skin softening and improved range of motion of affected joints. The treatment plan for JLS includes (1) weekly subcutaneous (SC) methotrexate at 1 mg/kg (maximum dose 25 mg); (2) weekly SC methotrexate (1 mg/kg; max 25 mg) *plus* either 3 mo of high-dose intravenous (IV) corticosteroids (30 mg/kg; max 1,000 mg) for 3 consecutive days a month *or* weekly corticosteroids at the same dose for 3 mo; or (3) high-dose daily oral corticosteroids (2 mg/kg/day, max 60 mg) with a slow taper over 48 wk. *Mycophenolate mofetil* (MMF) is a second-line agent for recalcitrant disease. Physical and occupational therapy are important adjuncts to pharmacologic treatment. Eosinophilic fasciitis often responds well to corticosteroids and methotrexate.

Treatments for **JSSc** target specific disease manifestations. **RP** is treated with cold avoidance, and pharmacologic interventions are reserved for severe disease. Calcium channel blockers (nifedipine, 30-60 mg sustained-release form daily; amlodipine, 2.5-10 mg daily) are the most common pharmacologic interventions. Additional potential therapies for RP include losartan, prazosin, bosentan, and sildenafil. Angiotensin-converting enzyme (ACE) inhibitors (captopril, enalapril) are recommended for hypertension associated with renal disease. Methotrexate or MMF may be beneficial for skin manifestations. Cyclophosphamide and MMF are used to treat pulmonary alveolitis and prevent fibrosis. Corticosteroids should be used cautiously in SSc because of an association with renal crisis. Adults with SSc have been successfully treated with high-dose cyclophosphamide, antithymocyte globulin, and autologous stem cell transplantation.

The treatment of **RP** begins with avoiding cold stimuli, using hand and foot warmers, and avoiding carrying bags by their handles (impairs circulation). Nifedipine (10-20 mg 3 times daily adult dose) reduces but does not eliminate the number and severity of episodes. Side effects include headache, flushing, and hypotension. Topical nitrates may result in digital vasodilation and may reduce the severity of an episode.

Prognosis

JLS is generally self-limited, with initial inflammatory stage followed by a period of stabilization and then softening, for an average disease duration of 3-5 yr, although there are reports of active disease lasting up to 20 yr. Prolonged disease activity is associated primarily with linear and deep disease subtypes. JLS, especially linear and deep subtypes, can result in significant morbidity, disfigurement, and disability as a result of joint contractures, muscle atrophy, limb shortening, facial asymmetry, and hyper- and hypopigmentation. Death from a en coup de sabre lesion with progressive neurologic decline has been reported.

JSSc has a more variable prognosis. Although many children have a slow, insidious course, others demonstrate a rapidly progressive form with early organ failure and death. Skin manifestations reportedly soften years after disease onset. Overall, the prognosis of JSSc is better than that of the adult form, with 5-, 10-, and 15-year survival rates, respectively, in children of 89%, 80–87%, and 74–87%. The most common cause of death is heart failure caused by myocardial and pulmonary fibrosis.

CHAPTER 186

Behçet Disease

Seza Özen

Behçet disease (BD) is classified as a primary *variable vessel vasculitis* , emphasizing the involvement of any size and type (arterial, venous) of blood vessel. BD is also recognized as an autoinflammatory disease. Originally described with recurrent oral ulcerations, uveitis, and skin abnormalities, the BD spectrum is much broader.

Epidemiology

Behçet disease has a high prevalence in countries along the *Silk Road*, extending from Japan to the eastern Mediterranean. It is increasingly recognized among people of European ancestry. BD has a prevalence of 5-7 per 100,000 adults, which makes it more frequent than the other vasculitides such as granulomatosis polyangiitis (Wegener disease). The increased disease recognition might have had a role in the rising prevalence of BD as well as the immigrations of the 20th century. Prevalence in children is probably not more than 10% of the adult counterparts in eastern Mediterranean countries; boys and girls are equally affected. Family history of BD is present in approximately 20% of the cases. Onset in children is 8-12 yr of age. Newborns of affected mothers have demonstrated symptoms of BD.

Etiology and Pathogenesis

Behçet disease is a polygenic autoinflammatory disorder. Genetic contribution to BD is evident through the well-known association with HLA-B5101, the familial cases, the sibling and twin recurrence rate, the specific frequency of the disease among people along the Silk Road, evidence for genetic anticipation, and genome-wide analysis. Genome wide analysis studies among Turkish and Japanese BD patients confirm the marked association with HLA-B5101. Other significant associations include interleukin (IL)-10 and IL-23R/IL-12Rβ_2 genes. Other possible susceptibility loci in a Turkish cohort demonstrate associations with *STAT4* (a transcription factor in a signaling pathway related to cytokines such as IL-12, type I interferons, and IL-23) and *ERAP1* (an endoplasmic reticulum–expressed aminopeptidase that functions in processing of peptides onto major histocompatibility complex class I).

The autoinflammatory nature of BD is suggested by its episodic nature, the prominent innate immune system activation, the absence of identifiable autoantibodies, and the co-association with the *MEFV* (Mediterranean fever) gene. An infectious agent may be responsible for inducing the aberrant innate immune system attacks in the genetically predisposed host. A number of infectious agents have been implicated and include streptococci, herpes simplex virus type 1, and parvovirus B19.

Clinical Manifestations and Diagnosis

The course of BD is characterized by exacerbations and remissions. There is also marked heterogeneity in disease manifestation (Table 186.1).

Table 186.1

Consensus Classification of Pediatric Behçet Disease

ITEM	DESCRIPTION
Recurrent oral aphthosis	At least three attacks/year
Genital ulceration or aphthosis	Typically with scar
Skin involvement	Necrotic folliculitis, acneiform lesions, erythema nodosum
Ocular involvement	Anterior uveitis, posterior uveitis, retinal vasculitis
Neurologic signs	With the exception of isolated headaches
Vascular signs	Venous thrombosis, arterial thrombosis, arterial aneurysm

From Koné-Paut I, Shahram F, Darce-Bello M, et al, for PEDBD group: Consensus classification criteria for paediatric Behçet's disease from a prospective observational cohort: PEDBD, *Ann Rheum Dis* 75:958–964, 2016.

The mean age of the first symptom is between 8 and 12 yr. The most frequent initial symptom is a painful **oral ulcer** (Fig. 186.1). The oral ulcers are often recurrent, may be single or multiple, range from 2-10 mm, and may be in any location in the oral cavity. They are often very painful. The oral ulcers last 3-10 days and heal without scarring. In contrast, the genital ulcers heal with scars. Genital scars are noted in 60–85% of the patients, usually occur after puberty, and are seen on the labia, scrotum, penis, or the anal area.

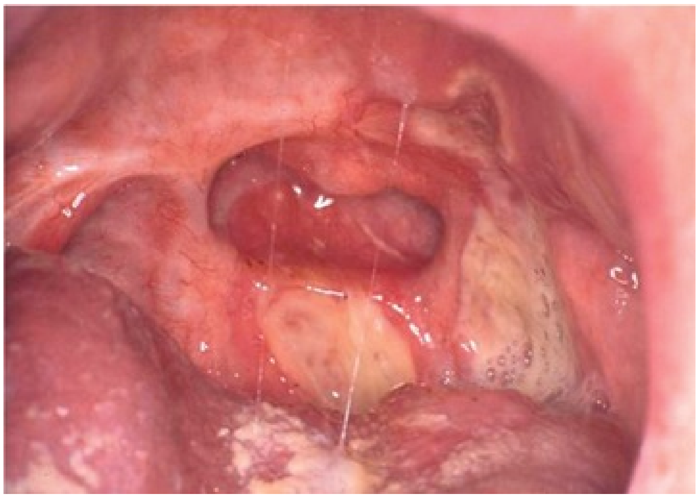

FIG. 186.1 A major aphthous ulcer in a patient with Behçet disease. (From Summers SA, Tilakaratne WM, Fortune F, Ashman N: Renal disease and the mouth. *Am J Med* 120:568-573, 2007.)

Another key feature of BD that has significant morbidity is bilateral eye involvement seen in 30–60% of pediatric patients. The main symptoms of **anterior uveitis** are blurred vision, redness, periorbital or global pain, and photophobia. Although it is often in the form of panuveitis, anterior uveitis may be seen in females. Uveitis in general is more common in males. Vitreitis and retinal vasculitis are the most prominent features of posterior involvement. Complications of uveitis include blindness (unusual with treatment), glaucoma, and cataracts. Retinal vasculitis, retinal detachment, and retrobulbar neuritis (optic neuritis) are less common eye manifestations of BD.

The **skin lesions** of BD range from erythema nodosum (seen in approximately 50% of patients) to papulopustular acneiform lesions (85%), folliculitis, purpura, and ulcers. **Pathergy** (seen in 50%) is another skin feature associated with BD and is a pustular reaction occurring 24-48 hr after a sterile needle puncture or saline injection; it is not pathognomonic of BD.

The **vasculitis** of BD involves both arteries and veins, thrombosis and aneurysm formation, occlusions, or stenosis in arteries of any size. In children, deep venous thrombosis of the lower limbs is the most frequent vasculitic feature. If the hepatic vein is thrombosed, Budd-Chiari syndrome may occur. Pulmonary aneurysms are the most severe feature of pediatric BD, associated with the highest mortality. Coronary artery aneurysms may confuse BD with Kawasaki disease. Microvascular involvement may be noted in the nail bed capillaries.

Central nervous system (CNS) manifestations (approximately 10%) in children include meningoencephalitis (headache, meningismus, cerebrospinal fluid pleocytosis), encephalomyelitis, pseudotumor cerebri, dural sinus thrombosis, and organic psychiatric disorders (psychosis, depression, dementia). **Dural sinus thrombosis** is the most common CNS manifestation in children.

Gastrointestinal (GI) involvement (seen in 10–30%) manifests with abdominal pain, diarrhea, and intestinal ulcerations, most often in the ileocecal region. Gastrointestinal BD may be difficult to distinguish from inflammatory bowel disease. Oligoarticular **arthritis/arthralgia** is present in >50% of patients and can be recurrent, but is nondeforming. Other rare manifestations include orchitis, renal vasculitis, glomerulonephritis, or amyloidosis and cardiac involvement.

The **International Study Group for Behçet Disease** (ISG) criteria are most widely used and require the presence of oral ulcers (at least 3 times per year) along with 2 other major features, including genital ulcers, a positive pathergy test, uveitis, and the characteristic skin lesions (see Table 186.1). If only 1 of the criteria is present along with oral ulcerations, the term *incomplete* or *partial Behçet disease* is applied.

Classification criteria for children have been suggested by the use of an international prospective observational cohort. According to these criteria, BD is diagnosed when 3 of the following criteria are present: recurrent oral aphthosis, genital ulcers, skin involvement (necrotic folliculitis, acneiform lesions, erythema nodosum), ocular involvement, neurologic involvement, and vascular involvement (venous thrombosis, arterial thrombosis, arterial aneurysm). These criteria performed better than the ISG criteria in the pediatric cohort.

There are no specific laboratory tests. Acute-phase reactants are often mildly elevated. The diagnosis relies on the constellation of symptoms and excluding other causes.

Treatment and Prognosis

Azathioprine is highly recommended to treat inflammatory eye disease. Anti–tumor necrosis factor (TNF) treatment and interferon (IFN)-α should be considered for refractory eye disease. For oral and genital ulcers, topical treatment is recommended (sucralfate, corticosteroids). A placebo-controlled study has shown that *apremilast*, an oral phosphodiesterase-4 inhibitor, is effective in treating the oral ulcers of Behçet disease. *Colchicine* is recommended for erythema nodosum or arthritis in males and females and for genital ulcers in females. There is no evidence-based treatment for GI disease, but thalidomide, sulfasalazine, corticosteroids, azathioprine, and anti-TNF agents have been recommended. For CNS disease and vasculitis, corticosteroids, azathioprine, cyclophosphamide, and IFN-α are recommended, and in unresponsive CNS disease, anti-TNF agents. There is no consensus about the benefit of anticoagulation in the management of vein thrombosis in BD.

In patients without major organ involvement, colchicine significantly improves oral and genital ulcers, skin features, and disease activity. In pediatric patients with vascular involvement with venous thrombosis, corticosteroids and azathioprine have been used. In patients with pulmonary arterial or cardiac involvement, cyclophosphamide is typically used initially. Patients treated with anti-TNF drugs have had persistent responses in 90%, 89%, 100%, and 91% of patients with resistant mucocutaneous, ocular, GI, and CNS involvement, respectively.

Mortality in children with BD is low except for the pulmonary aneurysms. However, BD is a chronic disease associated with significant morbidity. Early diagnosis and effective treatment improve the outcome of BD.

CHAPTER 187

Sjögren Syndrome

C. Egla Rabinovich

Sjögren syndrome is a chronic, inflammatory, autoimmune disease characterized by progressive lymphocytic and plasma cell infiltration of the exocrine glands, especially salivary and lacrimal, with potential for systemic manifestations. It is rare in children and predominantly affects middle-age women with classic symptoms of dry eyes (**keratoconjunctivitis sicca**) and dry mouth (**xerostomia**).

Epidemiology

Sjögren syndrome typically manifests at 35-45 yr of age, with 90% of cases among women, but it is underrecognized in children because symptoms often start in childhood. The mean age at diagnosis in children is 9-10 yr; 75% are girls. The disease can occur as an isolated disorder, referred to as **primary** Sjögren syndrome (**sicca complex**), or as a **secondary** Sjögren syndrome in association with other rheumatic disorders, such as systemic lupus erythematosus (SLE), scleroderma, or mixed connective tissue disease, which usually precedes the associated autoimmune disease by years.

Etiology and Pathogenesis

The etiology of Sjögren syndrome is complex and includes genetic predisposition and possibly an infectious trigger. Lymphocytes and plasma cells infiltrate salivary glands, forming distinct periductal and periacinar foci that become confluent and may replace epithelial structure. Several genes regulating apoptosis influence the chronicity of lymphocytic infiltration.

Clinical Manifestations

International classification criteria have been developed for the diagnosis of Sjögren syndrome in adult patients, but these criteria apply poorly to children. Although diagnostic criteria in children have been proposed, they have not been validated (Table 187.1). Recurrent parotid gland enlargement and parotitis are the most common manifestations in children (>70%), whereas **sicca syndrome** (dry mouth, painful mucosa, sensitivity to spicy foods, halitosis, widespread dental caries) predominates in adults. In a cross-sectional study of children with Sjögren syndrome, manifestations included recurrent parotitis (72%), sicca symptoms (38%), polyarthritis (18%), vulvovaginitis (12%), hepatitis (10%), Raynaud phenomenon (10%), fever (8%), renal tubular acidosis (9%), lymphadenopathy (8%), and central nervous system (CNS) involvement (5%).

Table 187.1

Proposed Criteria for Pediatric Sjögren Syndrome*

I. CLINICAL SYMPTOMS

1. Oral: recurrent parotitis or enlargement of parotid gland, dry mouth (xerostomia)
2. Ocular: dry eyes (xerophthalmia) recurrent conjunctivitis without obvious allergic or infectious etiology, keratoconjunctivitis sicca
3. Other mucosal: recurrent vaginitis
4. Systemic: fever, noninflammatory arthralgias, hypokalemic paralysis, abdominal pain

II. IMMUNOLOGIC ABNORMALITIES

Presence of at least 1 of the following antibodies: anti-SSA, anti-SSB, high-titer antinuclear antibody, rheumatoid factor

III. OTHER ABNORMALITIES OR INVESTIGATIONS

1. Biochemical: elevated serum amylase
2. Hematologic: leukopenia, high erythrocyte sedimentation rate
3. Immunologic: polyclonal hyperimmunoglobulinemia
4. Renal: renal tubular acidosis
5. Histologic proof of lymphocytic infiltration of salivary glands or other organs (i.e., liver)

    6. Objective documentation of ocular dryness (rose bengal staining or Schirmer test)
    7. Positive findings of parotid gland scintigraphy

IV. Exclusion of all other autoimmune diseases

---

[*] Diagnosis requires ≥4 criteria.

From Bartunkova J. Primary Sjögren syndrome in children and adolescents: proposal for diagnostic criteria, *Clin Exp Rheumatol* 17:381–386, 1999.

Subjective symptoms of xerostomia complaints are relatively rare in juvenile cases, perhaps indicating that Sjögren syndrome is a slowly progressive disease; however, increased dental caries is seen clinically in children. Serologic markers (antinuclear antibodies [ANAs], antibodies to Ro [SSA] and La [SSB]) and articular manifestations are significantly more common in adults. Reported frequencies of ANAs and SSA and SSB antibodies in children are 78%, 75%, and 65%, respectively, with rheumatoid factor present in 67%. Additional clinical manifestations from a variety of organ involvement patterns include a decreased sense of smell, hoarseness, chronic otitis media, leukocytoclastic vasculitis (purpura), and internal organ exocrine disease involving the lungs (diffuse interstitial lymphocytosis), pancreas, hepatobiliary system, gastrointestinal tract, kidneys (renal tubular acidosis), musculoskeletal (arthritis and arthralgia), hematologic (cytopenias), peripheral nervous system (sensory and autonomic neuropathy), and CNS (optic neuritis, transverse myelitis, meningoencephalitis).

Nonexocrine disease manifestations of Sjögren syndrome may be related to inflammatory vascular disease (skin, muscle and joints, serosal surfaces, CNS, peripheral nervous system), noninflammatory vascular disease (Raynaud phenomenon), mediator-induced disease (hematologic cytopenias, fatigue, fever), and autoimmune endocrinopathy (thyroiditis).

Diagnosis

Clinical presentation of recurrent **parotitis** and or recurrent parotid gland swelling in a child or adolescent is characteristic and should raise the suspicion for Sjögren syndrome. The diagnosis is based on clinical features supported by biopsy of salivary or parotid glands demonstrating foci of lymphocytic infiltration, the current gold standard for diagnosis. Children are more likely to have normal minor salivary gland but abnormal parotid gland biopsies. Supporting laboratory abnormalities include cryoglobulinemia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, positive rheumatoid factor, and detection of SSA and SSB antibodies. Anti–β-fodrin autoantibodies, directed against an apoptotic cleavage product of α-fodrin, are a useful diagnostic marker for juvenile Sjögren syndrome. The **Schirmer test** detects abnormal tear production (≤5 mm of wetting of filter paper strip in 5 min). **Rose bengal staining** detects damaged ocular epithelial conjunctival and corneal cells. Imaging studies, including MRI, technetium (^{99m} Tc) scintigraphy, and sialography, are useful in the diagnostic evaluation for Sjögren syndrome (Fig. 187.1).

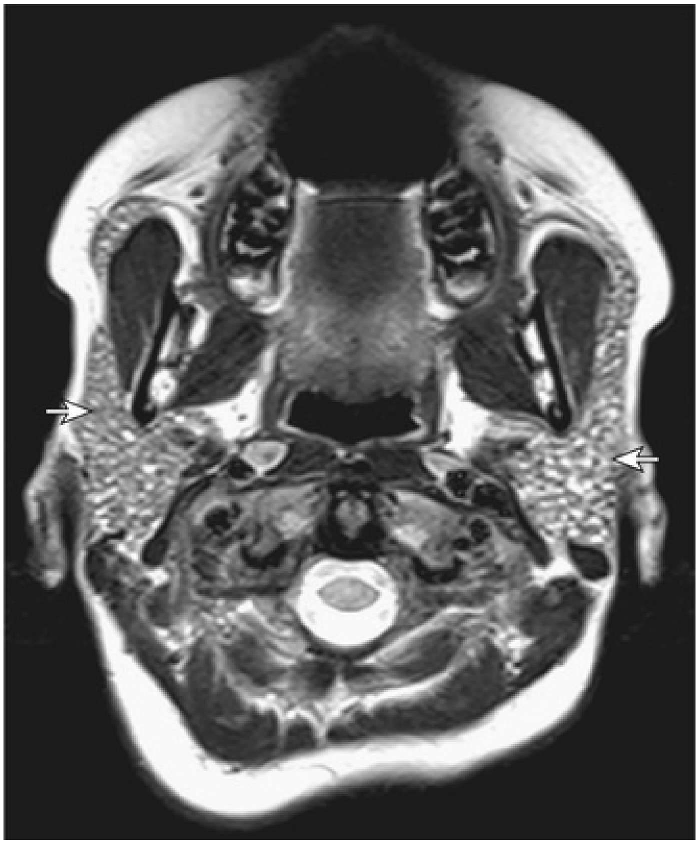

FIG. 187.1 T2-weighted MRI of child with Sjögren syndrome showing parotitis *(arrows).*

Differential Diagnosis

The differential diagnosis of Sjögren syndrome in children includes **juvenile recurrent parotitis** , characterized by intermittent unilateral parotid swelling typically lasting only a few days. It is frequently associated with fever and may undergo remission with puberty. Unlike in Sjögren syndrome, there is a male predominance, juvenile recurrent parotitis is seen in the younger children (3-6 yr), and there is a lack of focal lymphocytic infiltrates on biopsy. Other conditions in the differential diagnosis include eating disorders, infectious parotitis (mumps, streptococcal and staphylococcal infections, Epstein-Barr virus, cytomegalovirus, HIV, parainfluenza, influenza enterovirus), and local trauma to the buccal mucosa. Rarely, polycystic parotid disease, tumors, and sarcoidosis may present with recurrent parotid swelling. In these conditions, sicca complex, rash, arthralgia, and ANAs are usually absent.

Treatment

Symptomatic treatment of Sjögren syndrome includes the use of artificial tears, massage of the parotids, oral lozenges, and fluids to limit the damaging effects of decreased secretions. Corticosteroids, nonsteroidal antiinflammatory drugs, and hydroxychloroquine are among the more commonly used agents for treatment, with reports of methotrexate and etanercept used for treatment of arthritis. Stronger immunosuppressive agents, such as cyclosporine and cyclophosphamide, are reserved for severe functional disorders and life-threatening complications.

Complications and Prognosis

The symptoms of Sjögren syndrome develop and progress slowly. Diminished salivary flow typically remains constant for years. Because monoclonal B-lymphocyte disease originates chiefly from lymphocytic foci within salivary glands or from parenchymal internal organs, there is increased risk for mucosa-associated lymphoid tissue lymphoma. Maternal Sjögren syndrome can be an antecedent to the **neonatal lupus** syndrome (see Chapter 183.1).

CHAPTER 188

Hereditary Periodic Fever Syndromes and Other Systemic Autoinflammatory Diseases

James W. Verbsky

The hereditary periodic fever syndromes are a group of monogenic diseases that present with recurrent bouts of fever and associated pleural and/or peritoneal inflammation, arthritis, and various types of skin rash. A number of identifiable disorders present with recurrent episodes of inflammation, although fevers may not be common feature. Therefore the term **systemic autoinflammatory diseases** is used to include all diseases that present with seemingly unprovoked episodes of inflammation, without the high-titer autoantibodies or antigen-specific T cells typically seen in autoimmune diseases. Whereas the autoimmune diseases are disorders of the *adaptive* immune system, driven by B and T lymphocyte effector cells, autoinflammatory diseases largely represent disorders of the phylogenetically more primitive *innate* immune system, mediated by myeloid effector cells and germline-encoded receptors. Autoinflammatory diseases exhibit episodic or persistent inflammation characterized by an acute-phase response with elevation of the erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and serum amyloid A (AA). In some patients, untreated autoinflammatory disorders over time will lead to AA amyloidosis (see Chapter 189).

It is important to note that autoinflammatory disorders are rare, whereas fever in childhood caused by innocuous illness is very common. The approach to a child with fevers should include a detailed history, physical examination, and limited laboratory investigations to rule out other conditions that lead to fevers, including autoimmune disorders and malignancies (Table 188.1). If there is evidence of recurrent infections with fevers, an immune deficiency could be considered and evaluated. If the workup is reassuring, the inflammatory episodes resolve, and the child is otherwise well without unusual physical findings, observance is often warranted because these episodes are likely to resolve as the child's immune system matures.

Table 188.1

Differential Diagnosis of Periodic Fever

Hereditary

See Table 188.2 .

Nonhereditary

A. Infectious
    1. Hidden infectious focus (e.g., aortoenteric fistula, lung sequestration)
    2. Recurrent infection/reinfection (e.g., chronic meningococcemia, immune deficiency)
    3. Specific infection (e.g., Whipple disease, malaria)

B. Noninfectious inflammatory disorder:
    1. Adult-onset Still disease
    2. Systemic-onset juvenile idiopathic arthritis
    3. Periodic fever, aphthous stomatitis, pharyngitis, and adenitis
    4. Schnitzler syndrome
    5. Behçet syndrome
    6. Crohn disease
    7. Sarcoidosis

C. Neoplastic
    1. Lymphoma (e.g., Hodgkin disease, angioimmunoblastic lymphoma)
    2. Solid tumor (e.g., pheochromocytoma, myxoma, colon carcinoma)
    3. Histiocytic disorders

D. Vascular (e.g., recurrent pulmonary embolism)

E. Hypothalamic

F. Psychogenic periodic fever

G. Factitious or fraudulent

Adapted from Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2012, Saunders (Table 97-2).

Classification of Autoinflammatory Disorders

Because of the rapidly expanding number of autoinflammatory disorders and their varied clinical presentation, it can be difficult to group these disorders in a meaningful manner. Some autoinflammatory disorders present with prominent fevers and are known as **hereditary periodic fever syndromes** . These include 2 disorders with an *autosomal recessive* mode of inheritance, familial Mediterranean fever (**FMF** ; MIM249100) and the hyperimmunoglobulinemia D (hyper-IgD) with periodic fever syndrome (**HIDS** ; MIM260920). Hereditary periodic fever syndromes with an *autosomal dominant* mode of inheritance include the tumor necrosis factor (TNF) receptor–associated periodic syndrome (**TRAPS** ; MIM191190) and a spectrum of disorders known as the cryopyrin-associated periodic syndromes (**CAPS**), or cryopyrinopathies. From mildest to most severe, CAPS include the familial cold autoinflammatory syndrome (**FCAS1** ; MIM120100), Muckle-Wells syndrome (**MWS** ; MIM191100), and neonatal-onset multisystem inflammatory disease (**NOMID** ; MIM607115) (also known as chronic infantile neurologic cutaneous and articular syndrome, **CINCA**) (Table 188.2).

Table 188.2

Autoinflammatory Disorders

DISEASE	GENETIC DEFECT/PRESUMED PATHOGENESIS	INHERITANCE	AFFECTED CELLS	FUNCTIONAL DEFECTS	AS FE

Early-onset inflammatory bowel disease	Mutations in *IL-10RB* (see above)	AR	Monocyte/macrophage, activated T cells	Mutation in IL-10 receptor beta leads to increase of TNFγ and other proinflammatory cytokines	En ent per abs chr fol

AD, autosomal dominant; AR, autosomal recessive; Ig, immunoglobulin; IL, interleukin; NF-κB, nuclear factor-κB; PMN, polymorphonuclear neutrophil; SNHL, sensorineural hearing loss; TNF, tumor necrosis factor.

From Verbsky JW, Routes JR: Recurrent fever, infections, immune disorders, and autoinflammatory diseases. In Kliegman RM, Lyse PS, Bordini BJ, et al, editors: Nelson pediatric symptom-based diagnosis. Philadelphia, 2018, Elsevier, Table 41-5.

A variety of mendelian *autoinflammatory disorders* may or may not exhibit prominent fevers and are not considered periodic fever syndromes, but do have continuous or repeated episodes of spontaneous inflammation with unique clinical characteristics. These include the syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (**PAPA** ; MIM604416), deficiency of the interleukin-1 (IL-1) receptor antagonist (**DIRA** ; MIM612852), **Blau syndrome** caused by mutations in *NOD2* (also known as *early-onset sarcoidosis* ; MIM186580), autoinflammation with phospholipase Cγ_2 -associated antibody deficiency and immune dysregulation (**APLAID** ; MIM614878), and deficiency of adenosine deaminase-2 (**DADA2**). Other disorders include congenital sideroblastic anemia with B-cell immunodeficiency, periodic fevers, and developmental delay (**SIFD**) caused by biallelic mutations of the *TRNT1* gene (MIM616084), autoinflammation with infantile enterocolitis caused by mutations in *NLRC4* (**AIFEC** ; MIM616060), familial cold autoinflammatory syndrome type 2 caused by mutations in *NLRP12* (**FCAS2** ; MIM611762), **CARD14** (MIM607211), and deficiency in IL-36 receptor antagonist (**DITRA** ; 614204).

In addition to the previous autoinflammatory disorders, a variety of disorders are characterized by inappropriate *interferon expression* , the **interferonopathies** . Type 1 interferons (e.g., IFN-α, IFN-β) are cytokines expressed by many cells in response to viral infections. Disorders that result in spontaneous interferon production and inflammatory manifestations include STING-associated vasculopathy of infancy (**SAVI** ; MIM615934) and chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (**CANDLE** ; MIM256040).

There are also a number of autoinflammatory disorders with a complex mode of inheritance. These include the syndrome of periodic fever with aphthous stomatitis, pharyngitis, and adenitis (**PFAPA**) and chronic recurrent multifocal osteomyelitis (**CRMO** ; MIM259680). Other genetically complex disorders that are sometimes considered autoinflammatory include **systemic-onset juvenile idiopathic arthritis** (see Chapter 180), **Behçet disease** (see Chapter 186), and **Crohn disease** (see Chapter 362.2).

Distinguishing autoinflammatory disorders from one another can be difficult because their presentations can vary, and many display similarities. Some disorders have characteristic fever patterns (Fig. 188.1), whereas others have characteristic skin findings that can aid in a diagnosis (Table 188.3). Others can have characteristic physical features or organ involvement. Some of these disorders have bone involvement (Table 188.4). Other clinical features can also be helpful, such as ethnicity, age of onset, triggers, laboratory testing, and response to therapies (Table 188.5). Genetic panels are increasingly being used to screen for most if not all of these defects in a single test, rather than individual genetic assessment based on clinical findings.

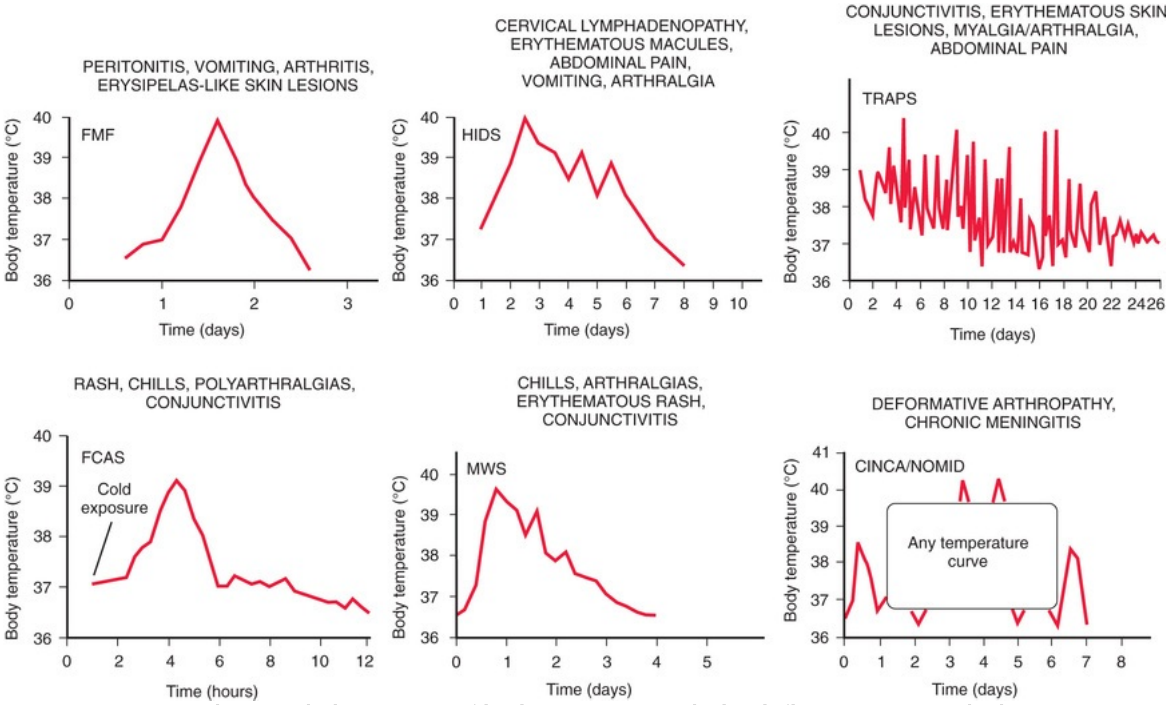

FIG. 188.1 Characteristic patterns of body temperature during inflammatory attacks in the familial autoinflammatory syndromes. Interindividual variability for each syndrome is considerable, and even for the individual patient, the fever pattern may vary greatly from episode to episode. Note the different time scales on the *x* axes. CINCA/NOMID, Chronic infantile neurologic cutaneous and articular syndrome/neonatal-onset multisystemic inflammatory disease; FCAS, familial cold autoinflammatory syndrome; HIDS, hyper-IgD syndrome; MWS, Muckle-Wells syndrome; TRAPS, tumor necrosis factor receptor–associated periodic syndrome. (From Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2012, Saunders, Fig 97-1.)

Table 188.3

Clinical Grouping of Autoinflammatory Diseases by Skin Manifestations

1. Neutrophilic urticaria (the cryopyrinopathies)

    Recurrent fever attacks of short duration (typically <24 hr)
    - CAPS/FCAS: familial cold autoinflammatory syndrome
    - CAPS/MWS: Muckle-Wells syndrome
    - FCAS2/NLRP12

    Continuous low-grade fever
    - CAPS/NOMID: neonatal-onset multisystem inflammatory disease (NOMID)/chronic infantile neurologic cutaneous and articular syndrome (CINCA)

2. Granulomatous skin lesions and minimal or low-grade fever attacks
    - Blau syndrome/early-onset sarcoidosis (pediatric granulomatous arthritis)
3. Pustular skin rashes and fever

    With inflammatory bone disease
    - DIRA: deficiency of interleukin-1 receptor agonist
    - Majeed syndrome

    With pyogenic arthritis
    - PAPA: pyogenic arthritis, pyoderma gangrenosum, and acne syndrome

    Without other organ involvement
    - DITRA: deficiency of interleukin-36 receptor antagonist
    - CAMPS: CARD14-mediated psoriasis
4. Atypical neutrophilic dermatosis with histiocytic-like infiltrate
    - CANDLE: proteasome associated autoinflammatory syndromes
5. Livedo reticularis, vasculopathy with ulcerations
    - SAVI; STING associated vasculopathy, infantile onset
6. Livedo racemosa, vasculitis with ulcerations
    - ADA2; adenosine deaminase-2 deficiency

CAPS, Cryopyrin-associated periodic syndromes.

Table 188.5

Clues That May Assist in Diagnosis of Autoinflammatory Syndromes

AGE OF ONSET	
At birth	NOMID, DIRA, MWS

Infancy and 1st yr of life	HIDS, FCAS, NLRP12
Toddler	PFAPA
Late childhood	PAPA
Most common of autoinflammatory syndromes to have onset in adulthood	TRAPS, DITRA
Variable (mostly in childhood)	All others
ETHNICITY AND GEOGRAPHY	
Armenians, Turks, Italian, Sephardic Jews	FMF
Arabs	FMF, DITRA (Arab Tunisian)
Dutch, French, German, Western Europe	HIDS, MWS, NLRP12
United States	FCAS
Can occur in blacks (West Africa origin)	TRAPS
Eastern Canada, Puerto Rico	DIRA
Worldwide	All others
TRIGGERS	
Vaccines	HIDS
Cold exposure	FCAS, NLRP12
Stress, menses	FMF, TRAPS, MWS, PAPA, DITRA
Minor trauma	PAPA, MWS, TRAPS, HIDS
Exercise	FMF, TRAPS
Pregnancy	DITRA
Infections	All, especially DITRA
ATTACK DURATION	
<24 hr	FCAS, FMF
1-3 days	FMF, MWS, DITRA (fever)
3-7 days	HIDS, PFAPA
>7 days	TRAPS, PAPA
Almost always “in attack”	NOMID, DIRA
INTERVAL BETWEEN ATTACKS	
3-6 wk	PFAPA, HIDS
>6 wk	TRAPS
Mostly unpredictable	All others
Truly periodic	PFAPA, cyclic neutropenia
USEFUL LABORATORY TESTS	
Acute-phase reactants must be normal between attacks	PFAPA
Urine mevalonic acid in attack	HIDS
IgD > 100 mg/dL	HIDS
Proteinuria (amyloidosis)	FMF, TRAPS, MWS, NOMID
RESPONSE TO THERAPY	
Corticosteroid dramatic	PFAPA
Corticosteroid partial	TRAPS, FCAS, MWS, NOMID, PAPA*
Colchicine	FMF, PFAPA (30% effective)
Cimetidine	PFAPA (30% effective)
Etanercept	TRAPS, FMF arthritis
Anti–IL-1 dramatic	DIRA (anakinra), FCAS, MWS, NOMID, PFAPA
Anti–IL-1 mostly	TRAPS, FMF
Anti–IL-1 partial	HIDS, PAPA

* For intraarticular corticosteroids.

DIRA, Deficiency of IL-1 receptor antagonist; DITRA, deficiency of IL-36 receptor antagonist (generalized pustular psoriasis); FCAS, familial cold autoinflammatory syndrome; FMF, familial

Mediterranean fever; HIDS, hyper-IgD syndrome; IL, interleukin; MWS, Muckle-Wells syndrome; NLRP, nucleotide oligomerization domain–like receptor family, pyrin domain; NOMID, neonatal-onset multisystem inflammatory disorder; PAPA, pyogenic sterile arthritis, pyoderma gangrenosum, acne syndrome; PFAPA, periodic fever, aphthous stomatitis, pharyngitis, adenitis; TRAPS, tumor necrosis factor receptor–associated periodic syndrome.

Autoinflammatory Diseases With Periodic or Prominent Fevers

The first descriptions of autoinflammatory disorders focused on genetic diseases that presented with prominent fevers, the periodic fever syndromes. As new autoinflammatory diseases were discovered, it was clear that a variety of inflammatory disorders can occur in the absence of fever.

Familial Mediterranean Fever

FMF is a recessively inherited autoinflammatory disease usually characterized by recurrent, short-lived (1-3 days), self-limited episodes of fever, serositis, mono- or pauciarticular arthritis, or an erysipeloid rash, sometimes complicated by AA amyloidosis. Most patients with FMF present with symptoms in childhood, with 90% presenting before age 20. Clinical features of FMF may include fever, serositis presenting as pleuritic chest pain or severe abdominal pain, arthritis, and rash. The pleural pain is typically unilateral, whereas the abdominal pain (sterile peritonitis) can be generalized or localized to 1 quadrant, similar to other forms of peritonitis. FMF-associated arthritis occurs primarily in the large joints, may be accompanied by large, neutrophil-rich effusions, and is usually nonerosive and nondestructive. The hallmark cutaneous finding is an erysipeloid erythematous rash that overlies the ankle or dorsum of the foot (Fig. 188.2). Other clinical findings include scrotal pain caused by inflammation of the tunica vaginalis testis, febrile myalgia, exercise-induced myalgia (particularly common in children), and an association with various forms of vasculitis, including Henoch-Schönlein purpura, in as many as 5% of pediatric patients. FMF episodes may be triggered by stress, menses, or infections. Between flares, patients are generally symptom free but may have persistent elevation of their inflammatory markers. The attack frequency can vary from weekly to 1-2 flares per year. Table 188.6 lists diagnostic criteria for FMF.

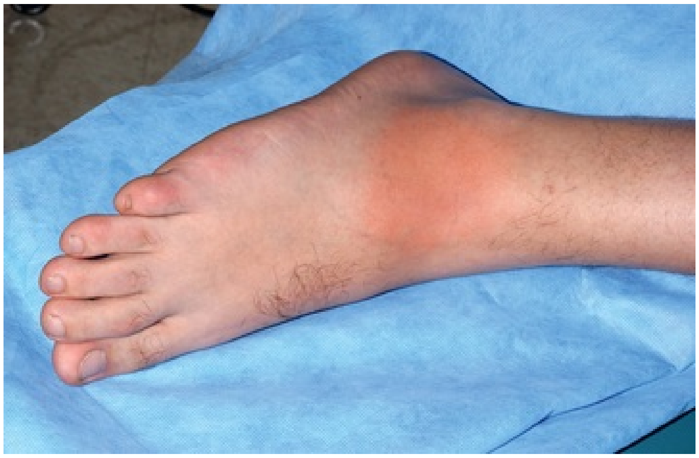

FIG. 188.2 **Characteristic erysipeloid erythema associated with familial Mediterranean fever. This rash appears during a flare and overlies the ankle or dorsum of the foot.**

Table 188.6

Diagnostic Criteria for Familial Mediterranean Fever (FMF)*

Major Criteria

1. Typical attacks [†] with peritonitis (generalized)
2. Typical attacks with pleuritis (unilateral) or pericarditis
3. Typical attacks with monoarthritis (hip, knee, ankle)
4. Typical attacks with fever alone
5. Incomplete abdominal attack

Minor Criteria

1. Incomplete attacks [‡] involving chest pain
2. Incomplete attacks involving monoarthritis
3. Exertional leg pain
4. Favorable response to colchicine

[*] Requirements for diagnosis of FMF are ≥1 major criteria or ≥2 minor criteria.

[†] Typical attacks are defined as recurrent (≥3 of the same type), febrile (≥38°C), and short (lasting between 12 hr and 3 days).

[‡] Incomplete attacks are defined as painful and recurrent attacks not fulfilling the criteria for a typical attack.

From Livneh A, Langevitz P, Zemer D, et al: Criteria for the diagnosis of familial Mediterranean fever, *Arthritis Rheum* 40:1879–1885, 1997.

FMF is caused by autosomal recessive mutations in *MEFV* , a gene encoding a 781 amino acid protein denoted *pyrin* (Greek for “fever”). Pyrin is expressed in granulocytes, monocytes, and dendritic cells (DCs) and in peritoneal, synovial, and dermal fibroblasts. The N-terminal approximately 90 amino acids of pyrin are the prototype for a motif (the PYRIN domain) that mediates protein-protein interactions and is found in >20 different human proteins that regulate inflammation and apoptosis. Many of the FMF-associated mutations in pyrin are found at the C-terminal B30.2 domain of pyrin, encoded by exon 10 of *MEFV.* More than 50 such FMF mutations are listed in an online database (http://fmf.igh.cnrs.fr/ISSAID/infevers/), almost all of which are missense substitutions. Homozygosity for the M694V mutation may be associated with an earlier age of onset, arthritis, and an increased risk of amyloidosis. The substitution of glutamine for glutamic acid at residue 148 (E148Q) is considered either a mild mutation or a functional polymorphism in the pyrin protein. The carrier frequency of FMF mutations among several Mediterranean populations is very high, suggesting the possibility of a heterozygote advantage.

FMF occurs primarily among ethnic groups of Mediterranean ancestry, most frequently Jews, Turks, Armenians, Arabs, and Italians. Because of a higher frequency of the M694V mutation, FMF is more severe and more readily recognized in the Sephardic (North African) than the Ashkenazi (East European) Jewish population. With the advent of genetic testing, mutation-positive FMF has been documented worldwide, although at lower frequency than in the Mediterranean basin and Middle East.

Through PYRIN-domain interactions, pyrin can activate **caspase-1** , the enzyme that converts the 31 kDa pro–IL-1β molecule into the biologically active 17 kDa IL-1β, which is a major mediator of fever and inflammation. FMF mutations lead to a gain-of-function activation of caspase-1 and IL-1β–

dependent inflammation, with a gene-dosage effect. These results may explain why as many as 30% of heterozygous carriers of FMF mutations have biochemical evidence of inflammation.

Prophylactic daily oral colchicine decreases the frequency, duration, and intensity of FMF flares. This regimen also prevents the development of systemic AA amyloidosis. Colchicine is generally well tolerated and safe in children, with the most common side effects being diarrhea and other gastrointestinal (GI) complaints. Some patients develop lactose intolerance while taking colchicine. GI side effects can be minimized by initiating therapy at a low dose (for young children, 0.3 mg/day) and slowly titrating upward. A dose-related transaminitis may also be observed; bone marrow suppression is rarely seen at the dosages prescribed for FMF. Pediatric patients may require doses of colchicine similar to those needed in adults (1-2 mg/day), reflecting that children metabolize the drug more rapidly than adults. It is not always possible to find a tolerated dose of colchicine at which all symptoms are suppressed, but approximately 90% of patients have a marked improvement in disease-related symptoms. A small percentage of FMF patients are either unresponsive to or intolerant of therapeutic doses of colchicine. Based on the role of pyrin in IL-1β activation, a trial demonstrated the safety and effectiveness of *rilonacept,* an IL-1 inhibitor, in FMF; there are case reports of the effectiveness of *anakinra,* a recombinant interleukin-1 receptor (IL-1R) antagonist.

Amyloidosis is the most serious complication of FMF, and in its absence FMF patients may live a normal life span. Amyloidosis may develop when serum AA, an acute-phase reactant found at extremely high levels in the blood during FMF attacks, is cleaved to produce a 76–amino acid fragment that misfolds and deposits ectopically, usually in the kidneys, GI tract, spleen, lungs, testes, thyroid, and adrenals. Rarely, cardiac amyloidosis may develop; macroglossia and amyloid neuropathy are generally not seen with the amyloidosis of FMF. The most common presenting sign of AA amyloidosis is proteinuria. The diagnosis is then usually confirmed by rectal or renal biopsy. In a small number of case reports, mostly from the Middle East, amyloidosis may actually precede overt FMF attacks, presumably because of subclinical inflammation. Risk factors for the development of amyloidosis in FMF include homozygosity for the M694V *MEFV* mutation, polymorphisms of the serum AA gene (encoding AA), noncompliance with colchicine treatment, male gender, and a positive family history of AA amyloid. For unclear reasons, country of origin is also a major risk factor for amyloidosis in FMF, with patients raised in the Middle East having a much higher risk than genotypically identical patients raised in the West. Aggressive lifelong suppression of the acute-phase reactants should be the goal in patients with FMF amyloidosis, and documented cases show this may result in resorption of amyloid deposits. The natural history of untreated amyloidosis in FMF is the inexorable progression to renal failure, often within 3-5 yr.

Hyperimmunoglobulinemia D With Periodic Fever Syndrome

HIDS, also known as **mevalonate kinase deficiency** , was initially described in a cohort of Dutch patients and occurs primarily in patients of Northern European descent. HIDS is recessively inherited and caused by mutations of *MVK* , a gene that encodes mevalonate kinase (MK). The clinical features of HIDS generally appear within the 1st 6 mo of life. Febrile attacks last 3-7 days, with abdominal pain often accompanied by diarrhea, nausea, and vomiting. Other clinical manifestations include cervical lymphadenopathy, diffuse macular rash, aphthous ulcers, headaches, and occasional splenomegaly (Figs. 188.3 to 188.5). Arthritis or arthralgia can be present in an oligoarticular or polyarticular pattern. Inflammatory disease–like illness and Kawasaki disease–like presentation have also been reported. Attacks are often precipitated by intercurrent illness, immunizations, and surgery. Families frequently recount flares around the time of birthdays, holidays, and family vacations. The symptoms of HIDS may persist for years but tend to become less prominent in adulthood. Patients with HIDS usually have a normal life span. Unlike FMF and TRAPS, the incidence of AA amyloidosis is quite low. Complete MK deficiency results in mevalonic aciduria that presents with severe mental retardation, ataxia, myopathy, cataracts, and failure to thrive (see Chapter 103).

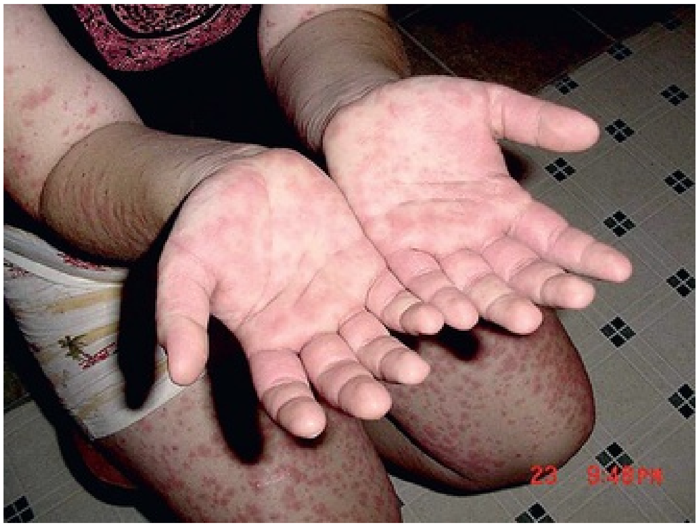

FIG. 188.3 Polymorphic rash on the hands, arms, and legs of a patient with hyper-IgD syndrome (HIDS). (From Takada K, Aksentijevich I, Mahadevan V, et al. Favorable preliminary experience with etanercept in two patients with the hyperimmunoglobulinemia D and periodic fever syndrome, *Arthritis Rheum* 48:2646, 2003.)

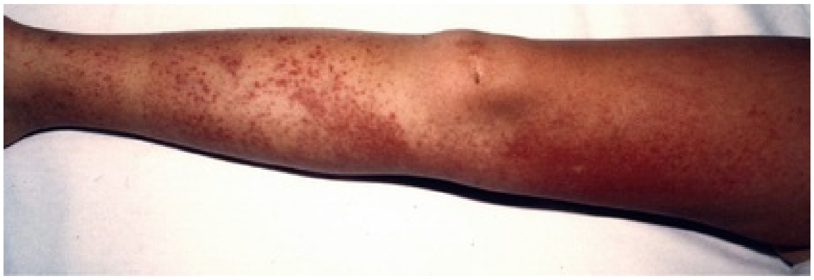

FIG. 188.4 Petechiae on the leg of a hyper-IgD syndrome patient during a febrile attack. (From Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2012, Saunders, Fig 97-7.)

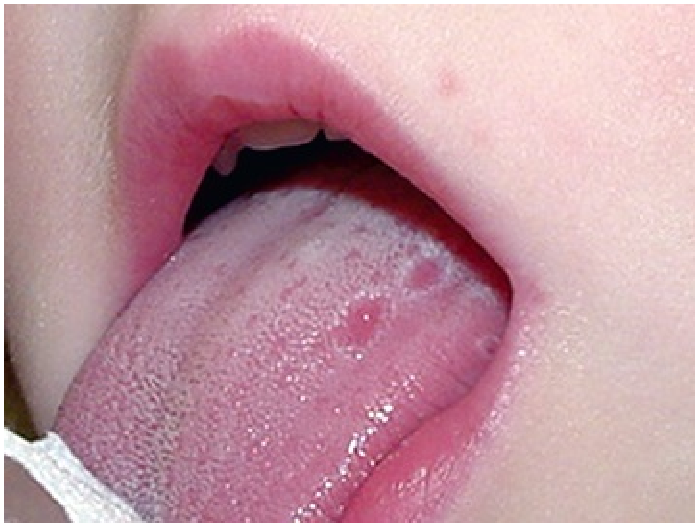

FIG. 188.5 **Aphthous ulceration detected on the tongue of a patient with hyper-IgD syndrome. (Courtesy Dr. K. Antila, North Carelian Central Hospital, Joensuu, Finland; from Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2012, Saunders, Fig 97-8.)**

MK is expressed in multiple tissues and catalyzes the conversion of mevalonic acid to 5-phosphomevalonic acid in the biosynthesis of cholesterol and nonsterol isoprenoids. Patients with HIDS-associated mutations have greatly reduced, but not absent, MK enzymatic activity. HIDS patients usually have low-normal serum cholesterol levels, but the deficiency of isoprenoids may cause increased IL-1β production by aberrant activation of the small guanosine triphosphatase Rac1. Temperature elevation may further exacerbate this process by more complete inhibition of MK activity, leading to a possible positive feedback loop.

The diagnosis of HIDS may be confirmed either by 2 mutations in *MVK* (approximately 10% of patients with seemingly typical disease have only a single identifiable mutation) or by elevated levels of mevalonate in the urine during acute attacks. HIDS-associated mutations are distributed throughout the MK protein, but the 2 most common mutations are the substitution of isoleucine for valine at residue 377 (V377I), a variant that is quite common in the Dutch population, and the substitution of threonine for isoleucine at residue 268 (I268T). The eponymous elevation in serum IgD levels is not universally present, especially in young children; IgA levels can also be elevated. Conversely, serum IgD levels may be increased in other autoinflammatory disorders as well as in some chronic infections. During attacks, leukocytosis and increased serum levels of acute-phase reactants and proinflammatory cytokines are frequently present. Table 188.7 lists diagnostic criteria for HIDS.

Table 188.7

Diagnostic Indicators of Hyper-IgD Syndrome

At Time of Attacks

1. Elevated erythrocyte sedimentation rate and leukocytosis
2. Abrupt onset of fever (≥38.5°C)
3. Recurrent attacks
4. Lymphadenopathy (especially cervical)
5. Abdominal distress (e.g., vomiting, diarrhea, pain)
6. Skin manifestations (e.g., erythematous macules and papules)
7. Arthralgias and arthritis
8. Splenomegaly

Constantly Present

1. Elevated IgD (above upper limit of normal) measured on 2 occasions at least 1 mo apart*
2. Elevated IgA (≥2.6 g/L)

Specific Features

1. Mutations in mevalonate kinase gene
2. Decreased mevalonate kinase enzyme activity

---

* Extremely high serum concentrations of IgD are characteristic but not obligatory.

From Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelly & Firestein's textbook of rheumatology,* ed 10, Philadelphia, 2016, Elsevier (Table 97-4, p 1674).

Standards for the **treatment** of HIDS are evolving. Very few patients respond to colchicine, and milder disease courses may respond to nonsteroidal antiinflammatory drugs (NSAIDs). Corticosteroids are of limited utility. Small trials of both etanercept and either intermittent or daily anakinra in HIDS are promising.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

TRAPS is characterized by recurrent fevers and localized inflammation and is inherited in an autosomal dominant manner. TRAPS has a number of distinguishing clinical and immunologic features. TRAPS was first recognized in patients of Irish descent and denoted *familial Hibernian fever* to draw a contrast with FMF, but the current nomenclature was proposed when mutations in *TNFRSF1A* were discovered not only in the original Irish family, but in families from a number of other ethnic backgrounds. *TNFRSF1A* encodes the 55 kDa receptor (denoted p55, TNFR1, or CD120a) for TNF-α that is widely expressed on a number of cell types. A 2nd 75 kDa receptor is largely restricted to leukocytes.

Patients with TRAPS typically present within the 1st decade of life with flares that occur with variable frequency but of often substantially longer duration than FMF or HIDS flares. The febrile episodes of TRAPS last at least 3 days and can persist for weeks. There may be pleural and peritoneal involvement. At times, patients present with signs of an acute abdomen; on exploration such patients have *sterile peritonitis* , sometimes with adhesions from previous episodes. Patients may also have nausea and frequently report constipation at the onset of flares that progresses to diarrhea by the conclusion. Ocular signs include periorbital edema and conjunctivitis. TRAPS patients may also experience severe myalgia and on imaging, the muscle groups may have focal areas of edema. Many rashes can be seen in TRAPS patients, but the most common is an erythematous macular rash that on biopsy contains superficial and deep perivascular infiltrates of mononuclear cells. Patients often report that the rash migrates distally on a limb during its course with an underlying myalgia and can resemble cellulitis. Other rashes include erythematous annular patches as well as a serpiginous rash (Fig. 188.6). Approximately 10–15% of patients with TRAPS may develop AA amyloidosis; the presence of cysteine mutations and a positive family history are risk factors for this complication. If amyloidosis does not develop, TRAPS patients have a normal life expectancy. Table 188.8 lists diagnostic criteria.

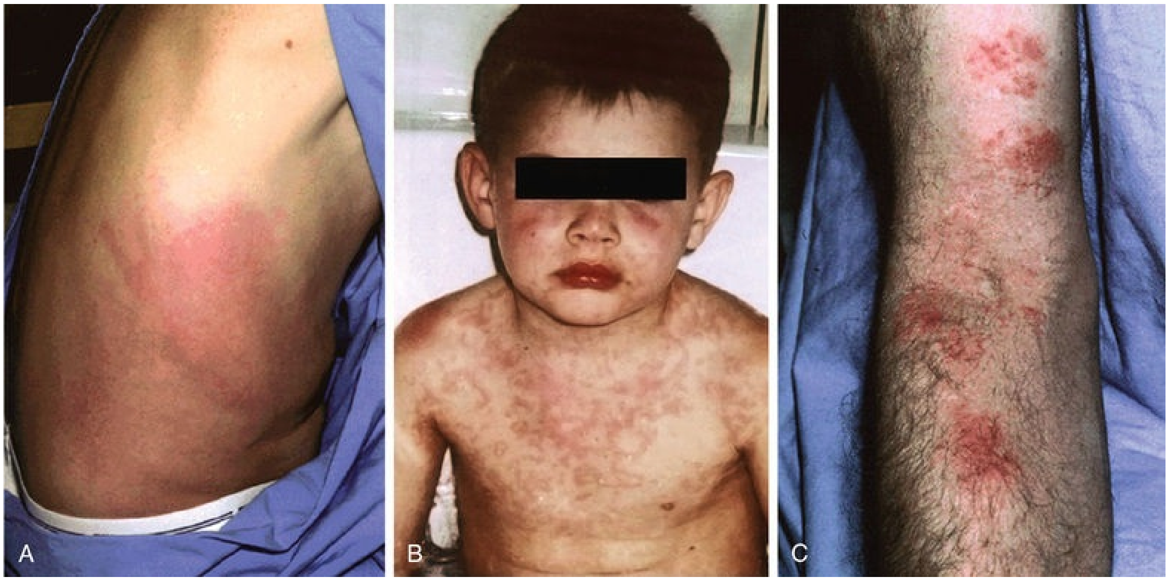

FIG. 188.6 Cutaneous manifestations of tumor necrosis factor receptor–associated periodic syndrome. A, Right flank of a patient with the T50M mutation. B, Serpiginous rash involving the face, neck, torso, and upper extremities of a child with the C30S mutation. C, Erythematous, macular patches with crusting on the flexor surface of the right arm of a patient with the T50M mutation. (From Hull KM, Drewe, Aksentijevich I, et al: The TNF receptor-associated periodic syndrome [TRAPS]: emerging concepts of an autoinflammatory syndrome, *Medicine (Baltimore)* 81:349–368, 2002.)

Table 188.8

Diagnostic Indicators of Tumor Necrosis Factor Receptor–Associated Periodic Syndrome (TRAPS)

1. Recurrent episodes of inflammatory symptoms spanning >6 mo duration (several symptoms generally occur simultaneously)
    a. Fever
    b. Abdominal pain
    c. Myalgia (migratory)
    d. Rash (erythematous macular rash occurs with myalgia)
    e. Conjunctivitis or periorbital edema
    f. Chest pain
    g. Arthralgia or monoarticular synovitis
2. Episodes last >5 days on average (although variable)
3. Responsive to glucocorticosteroids but not colchicine
4. Affects family members in autosomal dominant pattern (although may not

always be present)
5. Any ethnicity may be affected

From Hull KM, Drewe E, Aksentijevich I, et al: The TNF receptor-associated periodic syndrome (TRAPS): emerging concepts of an autoinflammatory disorder, *Medicine (Baltimore)* 81:349–368, 2002.

Almost all the TRAPS-associated mutations are in the extracellular domain of the TNFR1 protein, with about one-third involving the substitution of another amino acid for a highly conserved cysteine residue, thus disrupting disulfide bonds and leading to protein misfolding. A number of other missense mutations not involving cysteine residues have been shown to have a similar effect on TNFR1 protein folding. Misfolded TNFR1 aggregates intracellularly and leads to constitutive signaling through mitogen-activated protein kinases or nuclear factor (NF)-κB, resulting in the release of proinflammatory cytokines such as IL-6, IL-1β and TNF-α. The substitution of glutamine for arginine at residue 92 (R92Q) and the substitution of leucine for proline at residue 46 (P46L) are seen in >1% of the white and black population, respectively. These variants do not lead to the same biochemical or signaling abnormalities seen with more-severe TRAPS mutations, and as with E148Q in FMF, debate surrounds whether they are mild mutations or functional polymorphisms.

Colchicine is generally not effective in TRAPS. For relatively mild disease, NSAIDs may suffice. For more severe disease with infrequent attacks, corticosteroids at the time of an attack may be effective, but it is not unusual for steroid requirements to increase over time. Etanercept is often effective in reducing the severity and frequency of flares, but longitudinal follow-up of TRAPS patients treated with etanercept indicates waning efficacy with time. Of note, treatment of TRAPS with anti-TNF-α monoclonal antibodies has sometimes led to a paradoxical worsening of disease. Clinical responses to anakinra, *canakinumab,* a monoclonal anti–IL-1β antibody, and *tocilizumab,* a monoclonal anti-IL6 antibody, has been favorable in TRAPS patients.

Cryopyrin-Associated Periodic Fever Syndromes

CAPS represent a spectrum of clinical disorders, including **familial cold**

autoinflammatory syndrome (FCAS), **Muckle-Wells syndrome** (MWS), and **neonatal-onset multisystem inflammatory disorder** (NOMID). Although 3 separate clinical diagnoses have been defined, it should be emphasized that the **cryopyrinopathies** are really a continuum of disease severity. This spectrum of illness is caused by mutations in *NLRP3* (formerly known as *CIAS1*), which encodes a protein called **cryopyrin** ; >100 disease-associated *NLRP3* mutations have been enumerated on the *Infevers* online database. Advances in next-generation sequencing have also permitted the identification of symptomatic individuals with somatic *NLRP3* mosaicism.

NLRP3 is a PYRIN domain-containing protein that is strongly expressed in myeloid cells and to a lesser degree in other tissues. It is a part of a macromolecular complex termed the *NLRP3 inflammasome* that activates pro–IL-1β to its mature form in response to a variety of endogenous danger-associated molecular patterns and pathogen-associated molecular patterns. Patients with cryopyrinopathies have *gain-of-function mutations* in *NLRP3* that result in constitutive or easily-triggered activation of the NLRP3 inflammasome.

The cryopyrinopathies are characterized by recurrent fevers and an urticaria-like rash that develops early in infancy (Fig. 188.7). Histopathologic examination reveals a perivascular neutrophilic infiltrate without the mast cells or mast cell degranulation seen with true urticaria. In patients with FCAS, febrile attacks generally begin 1-3 hr after generalized cold exposure. FCAS patients also experience polyarthralgia of the hands, knees, and ankles, and conjunctivitis may also develop during attacks. FCAS episodes are self-limited and generally resolve within 24 hr. AA amyloidosis rarely occurs in FCAS. Table 188.9 lists diagnostic criteria for FCAS.

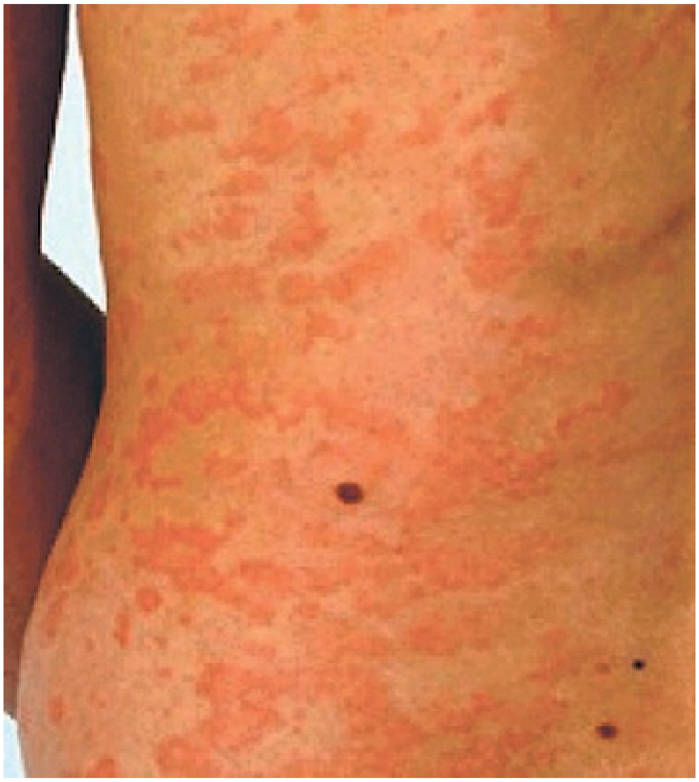

FIG. 188.7 Urticarial-like rash. Inflammatory clinical manifestations and organ damage in the IL-1–mediated diseases; in neonatal-onset multisystem inflammatory disease (NOMID), which is the severe form of cryopyrin-associated periodic syndromes (CAPS); and deficiency of IL-1 receptor antagonist (DIRA). This rash is not truly urticarial and occurs due to neutrophil infiltrates into the skin. (From Jesus AA, Goldbach-Mansky R: IL-1 blockade in autoinflammatory syndromes. *Annu Rev Med* 65:223–244, 2014, Fig. 2.)

Table 188.9

Diagnostic Criteria for Familial Cold Autoinflammatory Syndrome (FCAS)

1. Recurrent intermittent episodes of fever and rash that primarily follow generalized cold exposures
2. Autosomal dominant pattern of disease inheritance
3. Age of onset <6 mo
4. Duration of most attacks <24 hr
5. Presence of conjunctivitis associated with attacks
6. Absence of deafness, periorbital edema, lymphadenopathy, and serositis

From Hoffman HM, Wanderer AA, Broide DH: Familial cold autoinflammatory syndrome: phenotype and genotype of an autosomal dominant periodic fever, *J Allergy Clin Immunol* 108:615–620, 2001.

In contrast to FCAS, the febrile episodes of **MWS** are not cold induced but are characterized by the same urticarial-like rash seen in FCAS (Fig. 188.8). Many MWS patients also develop progressive sensorineural hearing loss, and untreated, approximately 30% of MWS patients develop AA amyloidosis. **NOMID** patients present in the neonatal period with a diffuse, urticarial rash, daily fevers, and dysmorphic features (Fig. 188.9). Significant joint deformities, particularly of the knees, may develop because of bony overgrowth of the epiphyses of the long bones (Fig. 188.10). NOMID patients also develop chronic aseptic meningitis, leading to increased intracranial pressure, optic disc edema, visual impairment, progressive sensorineural hearing loss, and intellectual disability (Fig. 188.11).

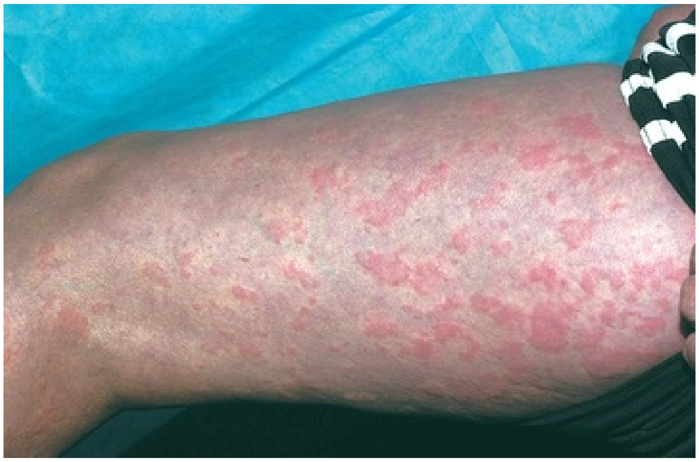

FIG. 188.8 **Urticarial-like skin rash in a patient with Muckle-Wells syndrome. (Courtesy Dr. D. L. Kastner, National Institutes of Health, Bethesda, Maryland; from Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2012, Saunders, Fig 97-14.)**

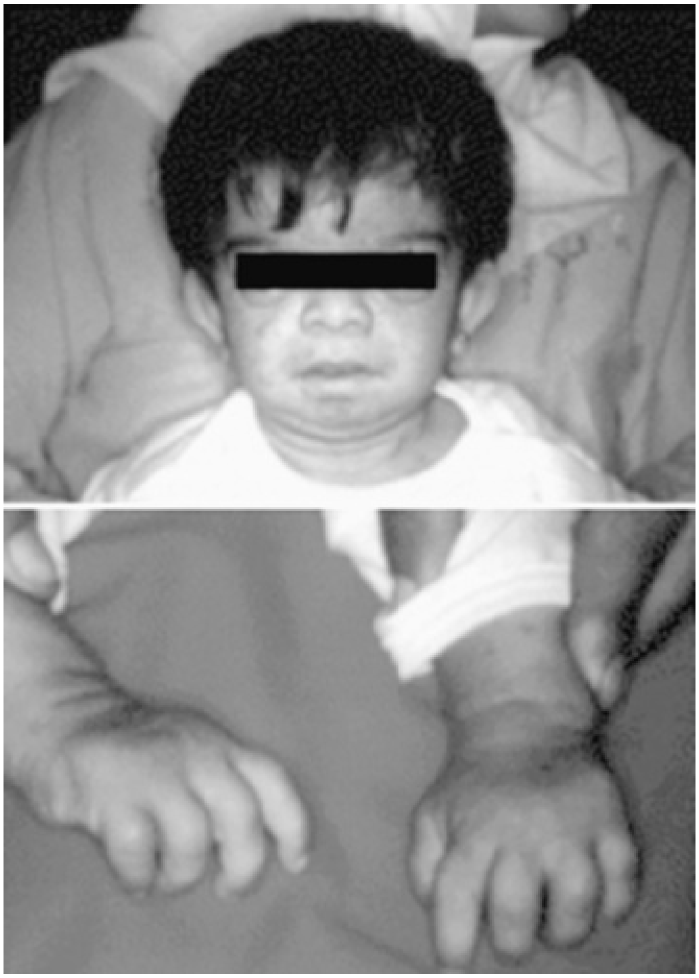

FIG. 188.9 A 3 yr old girl with NOMID/CINCA disease. Note the markedly deformed hands, rash, frontal bossing, and large head. (From Padeh S: Periodic fever syndromes, *Pediatr Clin North Am* 52:577–560, 2005.)

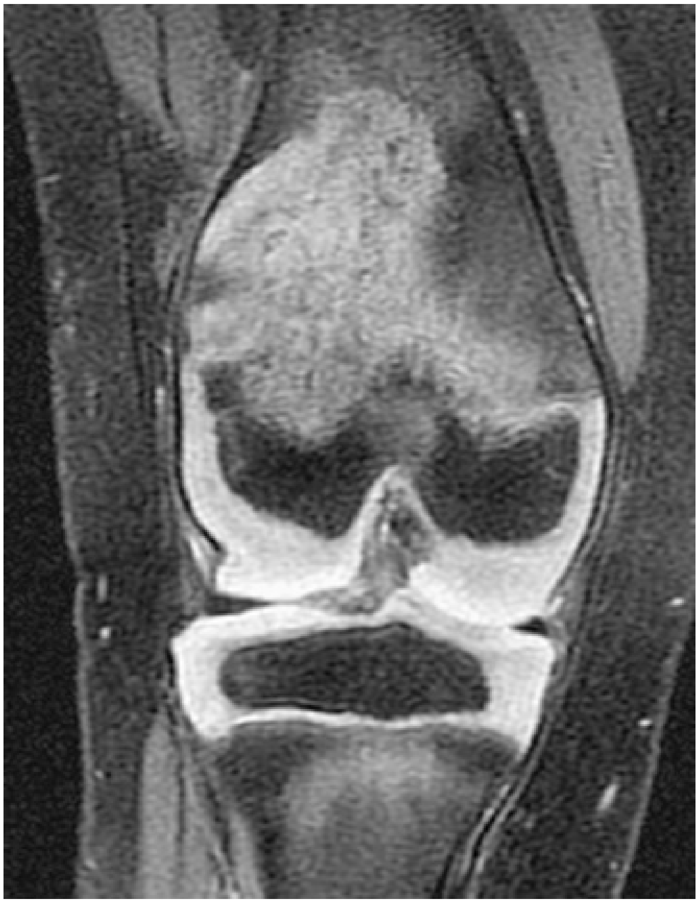

FIG. 188.10 **Metaphyseal bone overgrowth. Inflammatory clinical manifestations and organ damage in the IL-1–mediated diseases; in NOMID, the severe form of CAPS; and DIRA. (From Jesus AA, Goldbach-Mansky R: IL-1 blockade in autoinflammatory syndromes. *Annu Rev Med* 65:223–244, 2014, Fig 2.)**

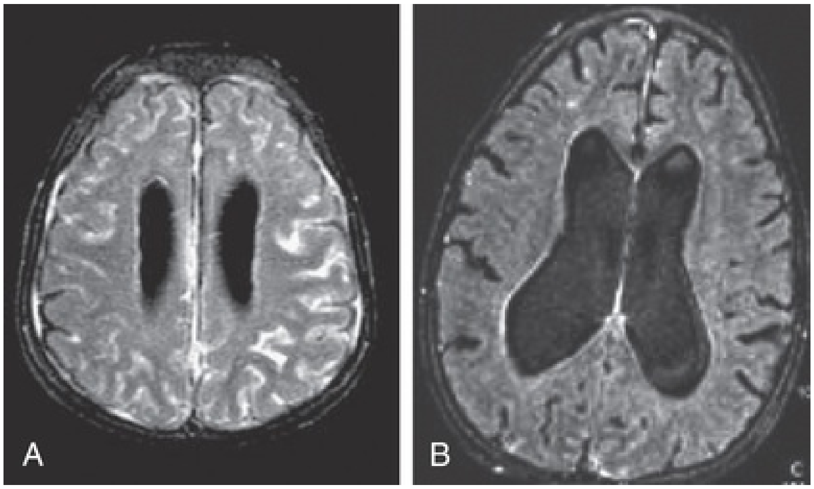

FIG. 188.11 **A,** Leptomeningeal enhancement; **B,** hydrocephalus and

cerebral atrophy. Inflammatory clinical manifestations and organ damage in the IL-1–mediated diseases, NOMID (severe form of CAPS), and DIRA. (From Jesus AA, Goldbach-Mansky R: IL-1 blockade in autoinflammatory syndromes, *Annu Rev Med* 65:223–244, 2014, Fig 2.)

Targeted therapy with anakinra (recombinant IL-1R antagonist) *has been life changing for NOMID patients* , not only controlling fever and rash, but also preventing end-organ damage. Anakinra, rilonocept, and canakinumab are all effective in both FCAS and MWS; they are approved by the U.S. Food and Drug Administration (FDA) for both conditions. Aggressive IL-1 blockade has resulted in attenuation of amyloidosis in the cryopyrinopathies.

Other Mendelian Autoinflammatory Diseases

Syndrome of Pyogenic Arthritis With Pyoderma Gangrenosum and Acne

PAPA syndrome is a rare autosomal dominant disorder caused by mutations in *PSTPIP1*, a gene that encodes the cytoskeletal proline serine threonine phosphatase–interacting protein-1 (PSTPIP). The PSTPIP1 protein interacts with a number of immunologically important molecules, including CD2, the Wiskott-Aldrich syndrome protein (WASP), and pyrin. PAPA-associated *PSTPIP1* mutations greatly increase its affinity to pyrin and cause increased IL-1β production.

Clinical manifestations of PAPA syndrome begin in early childhood with recurrent episodes of sterile, pyogenic arthritis that leads to erosions and joint destruction, and appears to develop spontaneously or after minor trauma. Fever is not a dominant feature. Cutaneous manifestations tend to develop in adolescence, at which time patients are prone to developing severe cystic acne. Additionally, PAPA patients commonly develop ulcerating pyoderma gangrenosum lesions (Fig. 188.12), and some develop pathergy reactions.

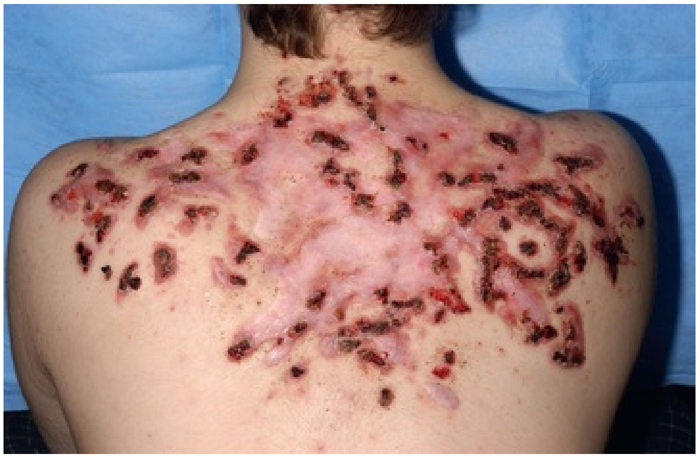

FIG. 188.12 **Pyoderma gangrenosum lesions in a patient with PAPA syndrome and the A230T mutation in *PSTPIP1.* Note the diffuse scarring indicative of prior lesions on his upper back.**

The treatment of PAPA syndrome may involve the use of corticosteroids, IL-1 antagonists, and TNF-α inhibitors, sometimes in combination. The joint manifestations of PAPA appear to respond to IL-1 blockade, whereas the cutaneous manifestations seem to respond more favorably to TNF-α blockade. Local measures, such as joint aspiration and drainage and intensive wound care, are also important in the care of PAPA patients, as is pain management for cutaneous disease. Caution should be taken when prescribing sulfonamides because some PAPA patients develop pancytopenia.

Deficiency of Interleukin-1 Receptor Antagonist

DIRA is an autosomal recessive autoinflammatory disease that is distinct from the cryopyrinopathies. DIRA typically presents in the neonatal period with systemic inflammation and a neutrophilic pustulosis, sterile multifocal osteomyelitis, widening of the anterior ends of the ribs, periostitis, and osteopenia (Figs. 188.13 and 188.14). Although fever is not a prominent clinical feature, patients do have greatly elevated acute-phase reactants. Multiorgan failure and pulmonary interstitial fibrosis can occur and can be fatal.

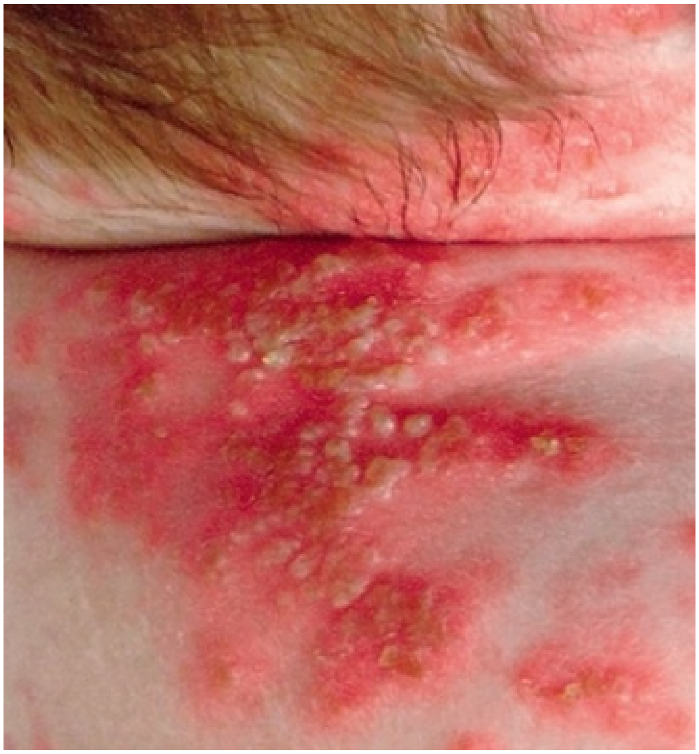

FIG. 188.13 **Pustular rash. Inflammatory clinical manifestations and organ damage in the IL-1–mediated diseases, NOMID (severe form of CAPS), and DIRA. This can also be seen in deficiency of IL-36 receptor antagonist (DITRA). (From Jesus AA, Goldbach-Mansky R: IL-1 blockade in autoinflammatory syndromes, *Annu Rev Med* 65:223–244, 2014, Fig 2.)**

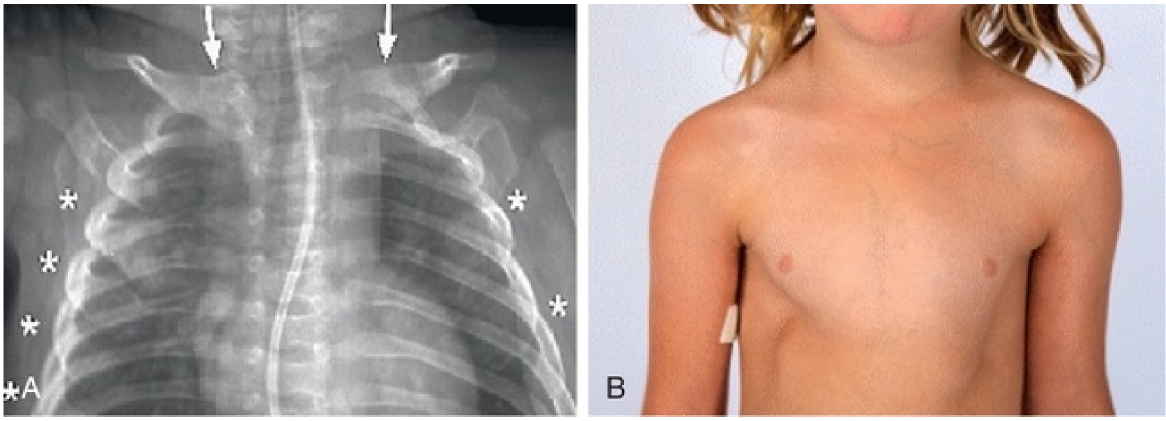

FIG. 188.14 **A,** Widening of multiple ribs (*) and clavicles *(arrows)* in DIRA osteomyelitis; **B,** chest deformity. Inflammatory clinical manifestations and organ damage in the IL-1-mediated diseases, NOMID, and DIRA. (From Jesus AA, Goldbach-Mansky R: IL-1 blockade in autoinflammatory syndromes, *Annu Rev Med* 65:223–244, 2014, Fig 2.)

DIRA is caused by loss-of-function mutations in *IL1RN* , encoding the IL-1R antagonist. Because of the lack of antagonistic activity, the cells are hyperresponsive to IL-1β stimulation. Numerous treatments for DIRA have been tried, including NSAIDs, glucocorticoids, intravenous immune globulin (IVIG), methotrexate, cyclosporine, and etanercept. However, *anakinra is the treatment of choice,* essentially replacing the lost protein and resulting in a rapid clinical response. Anakinra is dosed daily, with the dose titrated to achieve a normal CRP. There are now longer-acting anti-IL-1 agents, canakinumab and rilonacept, which are effective and require less frequent dosing than anakinra.

Blau Syndrome

Blau syndrome is a rare autosomal dominant disorder that manifests as early-onset (<5 yr of age) granulomatous arthritis, uveitis, and rash. The arthritis may affect the ankles and wrists and may lead to flexion contractures of the fingers and toes (camptodactyly). **Early-onset sarcoidosis** presents with a similar clinical picture, sometimes with visceral involvement, and both conditions are caused by mutations in the caspase recruitment domain protein 15 (CARD15), also known as nucleotide-binding oligomerization domain-2 protein (NOD2). NOD2 is an intracellular sensor of bacterial products in DCs, myelomonocytic cells, and Paneth cells. Mutations in the NACHT oligomerization domain of this protein cause Blau syndrome/early-onset sarcoidosis, whereas variants primarily in the leucine-rich repeat domain are associated with susceptibility to **Crohn disease** . Corticosteroids have been the mainstay of therapy for Blau syndrome. There are a number of case reports of the beneficial effects of TNF-α inhibitors in Blau syndrome.

Autoinflammation With Phospholipase Cγ$_2$ –Associated Antibody Deficiency and Immune Dysregulation

APLAID is a dominantly inherited disorder characterized by recurrent blistering skin lesions, bronchiolitis, arthralgia, ocular inflammation, enterocolitis, absence of autoantibodies, and mild immunodeficiency. Rash is the first manifestation of APLAID, which is described as a full-body epidermolysis bullosa–like eruption. Over time, this rash changes to recurrent plaques and vesiculopustular lesions that are triggered by heat and sunlight. Colitis also presents in childhood before age 5 yr. Ocular manifestations begin before age 1 yr and include corneal ulcerations and erosions as well as cataracts. Immune manifestations include markedly decreased class-switched memory B cells, resulting in low IgM and IgA.

Patients with APLAID show a gain-of-function missense mutation in the autoinhibitory region of phospholipase Cγ_2 (PLCγ_2), leading to increased activity of downstream mediators and stimulation of lymphocytes. Despite the enhanced signaling, the resulting populations of immune cells have poor function. Interestingly, a different mutation in the PLCγ_2 complex leads to a syndrome known as **PLCγ_2 -associated antibody deficiency and immune dysregulation (PLAID)** , characterized by cold-induced urticaria, hypogammaglobulinemia with resulting susceptibility to infection, and autoimmunity.

Because of the low number of affected patients described, there are no agreed treatment regimens for APLAID. Patients have been treated with NSAIDs, and corticosteroids can be effective, but side effects limit their long term use. TNF-α inhibitors and IL-1 inhibitors have been used with some success.

Deficiency of Adenosine Deaminase 2

DADA2 is an autoinflammatory disorder caused by loss-of-function mutations in *CECR1* , encoding adenosine deaminase 2. DADA2 presents with recurrent fevers and a spectrum of vascular manifestations that includes livedo racemosa, early-onset ischemic lacunar strokes, and systemic vasculitis of medium side vessels similar to **polyarteritis nodosa** . The lacunar strokes, typically affecting the deep brain nuclei and the brainstem, transpire before age 5 yr and typically occur during inflammatory episodes. The livedoid rash is also a prominent feature during inflammatory episodes, and biopsies demonstrate a predominance of neutrophils and macrophages as well as vasculitis in medium-sized vessels. Acute-phase reactants are typically elevated. Other features include ophthalmologic involvement, various degrees of lymphopenia, hypogammaglobulinemia (usually IgM), hepatosplenomegaly, portal hypertension, and neutropenia. Patients may meet criteria for polyarteritis nodosa and can exhibit digit necrosis and Raynaud phenomenon.

ADA2 is produced primarily by monocytes and macrophages, is found in plasma, and appears to act as a growth and differentiation factor for a subset of inflammatory macrophages. Numerous antiinflammatories have been tried in patients with DAD2, including glucocorticoids and cyclophosphamide. TNF-α inhibitors (etanercept or adalimumab) are the mainstay of treatment, and anecdotal reports have shown a benefit of anakinra. Macrophages and monocytes are the main sources of ADA2, raising the possibility of bone marrow transplant to achieve a permanent cure.

Sideroblastic Anemia With Immunodeficiency, Fevers, and Development Delay

SIFD is a syndrome characterized by systemic inflammation, fevers, enteritis, and sideroblastic anemia and caused by biallelic mutations in *TRNT1* . SIFD presents in infancy with fever, elevated inflammatory markers, gastroenteritis, and anemia. Bone marrow biopsies demonstrate ringed sideroblasts. Other features include hypogammaglobulinemia, B-cell lymphopenia, developmental delay, and variable neurodevelopmental degeneration, seizures, and sensorineural hearing loss. Brain imaging was notable for cerebellar atrophy, delayed white matter myelination, and decreased perfusion. Other, isolated clinical features include nephrocalcinosis, aminoaciduria, ichthyotic skin, cardiomyopathy, and retinitis pigmentosa. TRNT1 is an RNA polymerase that is necessary for maturation of cytosolic and mitochondrial transfer RNAs, by the addition of 2 cytosines and 1 adenosine to the tRNA ends.

Symptomatic treatment with regular blood transfusions and immunoglobulin replacement therapy is the mainstay of SIFD therapy. Iron overload from the transfusion often requires chelation therapy. Anakinra relieved the febrile episodes in one patient but did not alter the other clinical manifestations. Patients with SIFD have a high mortality rate. One patient underwent hematopoietic bone marrow transplantation at 9 mo of age that resulted in correction of the hematologic and immunologic abnormalities.

Deficiency of Interleukin-36 Receptor Antagonist (DITRA)

DITRA is characterized by episodes of diffuse erythematous pustular rash (generalized pustular psoriasis), fevers, general malaise, and systemic inflammation. Attacks can be triggered by events such as infections, pregnancy, or menstruation or can occur randomly. The underlying genetic etiology has been determined to be autosomal recessive mutations in the *IL36RN* gene, which encodes an IL-36R antagonist. IL-36 is related to and acts similarly to IL1R antagonist, preventing production of inflammatory cytokines such as IL-8. Interestingly, the rash of DITRA is similar to the rash of DIRA (IL-1R deficiency; see earlier), but DITRA is largely skin limited. DITRA has been treated with various modalities, including vitamin A analogs, cyclosporine, methotrexate, and TNF-α inhibitors. The use of anakinra has been described in case reports and results in alleviation of the symptoms.

Familial Cold Autoinflammatory Syndrome Type 2

Mutations in *NLRP12* lead to a periodic fever syndrome characterized by fevers >40°C, arthralgias, and myalgias lasting from 2-10 days. This disorder is named FCAS2 because these episodes can be precipitated by cold. Clinical findings may include an urticarial-like rash, abdominal pain and vomiting, aphthous ulcers, and lymphadenopathy. As with Muckle-Wells syndrome, sensorineural hearing loss and optic neuritis have been described. NALP12 is a member of the CATERPILLAR family of proteins, which are important in innate immunity. Similar to Toll-like receptors (TLRs) that act to recognize pathogen-associated molecular patterns (PAMPs), NLRP12 also senses PAMPs and can lead to the activation of the inflammasome and generation of IL-1β. Treatment of *NALP12* mutations was difficult until the advent of anti–IL-1 agents (e.g., anakinra), which are the preferred treatment for FCAS2 and result in remarkable resolution of symptoms. Colchicine can be partially effective, and systemic glucocorticoids can reduce the duration of the attacks.

Autoinflammation With Enterocolitis

A disorder caused by mutations in *NLRC4* was described with neonatal-onset enterocolitis, fever, and autoinflammatory episodes. Inflammatory markers are typically elevated, including CRP and ferritin. **Macrophage activation syndrome** , characterized by pancytopenia, hypertriglyceridemia, and coagulopathies, is common during acute flares, which can be precipitated by emotional and physical stress. Recurrent myalgias with febrile episodes often occur as well. This disorder is caused by gain-of-function missense mutations in NOD-like receptor C4 (NLRC4), which normally aids in the activation of the inflammasome. The resulting protein leads to constitutive production of IL-1. The mainstay of treatment is anti-IL-1 agents such as anakinra, canakinumab, and rilonacept. Before their diagnosis, patients with *NLRC4* mutations had been treated with colchicine and oral glucocorticoids, with varying success.

Majeed Syndrome

Majeed syndrome is an autosomal recessive disorder caused by mutations in the *LPIN2* gene (see Table 188.4). The clinical manifestation of Majeed syndrome begin in childhood with recurrent fevers, sterile osteomyelitis, congenital dyserythropoietic anemia (CDA), neutrophilic dermatosis, failure to thrive, and hepatomegaly. Treatment of Majeed syndrome has included NSAIDs, corticosteroids, and IL-1R antagonist. How mutations in *LPIN2* lead to an autoinflammatory disorder is not known.

Interferonopathies

Type 1 interferons (IFN-α and IFN-β) are the first line of defense against viral infections and are produced by a variety of cell types. During viral infections, a variety of products are made by the virus, including ssRNA, dsRNA, and CpG-containing DNA, and are recognized by intracellular sensors. These sensors then induce type 1 IFN production that activates IFN receptors and activates IFN-responsive genes to help control the spread of the virus until the adaptive immune system can be activated to clear the virus. Inappropriate activation of these pathways leads to IFN production and interferonopathies.

Chronic Atypical Neutrophilic Dermatosis With Lipodystrophy and Elevated Temperature

CANDLE syndrome, also known as **proteasome-associated autoinflammatory syndrome (PRAAS)** or **joint contractures, muscular atrophy, panniculitis-induced lipodystrophy (JMP) syndrome** , is an autosomal recessive disease. Patients present early in life with recurrent fevers and systemic inflammation; skin involvement, including annular erythema, erythema nodosum–like panniculitis, or neutrophilic dermatosis; small joint contractures; lipodystrophy; muscle atrophy or myositis; violaceous eyelid swelling; and anemia. Conjunctivitis, aseptic meningitis, and organomegaly are common. Acute-phase reactants and platelet counts are elevated. Autoimmunity can occur, including Coombs-positive hemolytic anemia and hypothyroidism. Intelligence and development are typically spared, although mild developmental delays have been reported. CANDLE is caused by loss-of-function mutations in *PSMB8*, the gene that encodes the β5i subunit of the proteasome. Proteosomes are important in the degradation of ubiquinated proteins to ensure proper protein homeostasis, and defects in proteasomes result in cellular stress and inflammatory cytokine release, including type 1 interferons.

There is no established treatment for CANDLE, although multiple treatment modalities have been attempted, including colchicine, dapsone, cyclosporine, infliximab, and etanercept, all with minimal success. Glucocorticoids and methotrexate have provided slight improvement in symptoms. Anakinra has not proved successful, whereas IL-6–blocking agents have shown some benefit. Since interferon receptors use the JAK/STAT pathway to signal, JAK inhibitors (tofacitinib, ruxolitinib, and baricitinib) show promise.

STING-Associated Vasculopathy With Onset in Infancy

SAVI is a rare disorder that presents in infancy. It is caused by mutations in the *TMEM173* gene, which encodes for the stimulator of interferon genes (STING). Systemic inflammation is an early manifestation, with fever and elevated inflammatory markers. Skin involvement includes a neutrophilic rash as well as violaceous lesions of fingers, toes, nose, cheeks, and ears. These lesions worsen over time and can become necrotic with vascular occlusion. Histology of the lesions reveals dermal inflammation with leukocytoclastic vasculitis and microthrombotic angiopathy. Since STING is also expressed in pulmonary epithelium, SAVI patients also developed pulmonary complications, including paratracheal adenopathy, interstitial lung disease, and fibrosis.

STING is an adapter protein of the intracellular DNA sensing machinery and mediates the production of interferon-β (IFN-β). The IFN-β then signals through the IFN receptor by activating the JAK/STAT signaling pathway and downstream IFN-responsive genes, including IL-6 and TNF-α. Mutations in STING that cause SAVI are de novo gain-of-function mutations that activate spontaneous IFN-β production.

Treatment options for patients with SAVI are limited at this time, although recent data with JAK inhibitors (tofacitinib, ruxolitinib, and baricitinib) have shown promise in blocking IFN-β receptor signaling and the activation of IFN-response genes.

Genetically Complex Autoinflammatory Diseases

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis

PFAPA is the most common recurrent fever syndrome in children. It usually presents between ages 2 and 5 yr with recurring episodes of fever, malaise, exudative-appearing tonsillitis with negative throat cultures, cervical lymphadenopathy, oral aphthae, and less often headache, abdominal pain, and arthralgia. The episodes last 4-6 days, regardless of antipyretic or antibiotic treatment, and often occur with clock-like regularity on 3-6 wk cycles. Findings during the episodes may include mild hepatosplenomegaly, mild leukocytosis, and elevated acute-phase reactants. Both the frequency and the intensity of the episodes diminish with increasing age. The etiology and pathogenesis of PFAPA remain unknown.

Most patients show dramatic response to a single oral dose of prednisone (0.6-2.0 mg/kg), although this approach does not prevent recurrence and may actually shorten the interval between flares. Cimetidine at 20-40 mg/kg/day is effective at preventing recurrences in approximately one third of cases. Small series have shown that anakinra may be effective during a flare, but because corticosteroids are effective, this may not be a cost-effective approach. Colchicine may extend the time between flares. Complete resolution has been reported after tonsillectomy, although medical management should be the first approach.

Chronic Recurrent Multifocal Osteomyelitis

CRMO is a form of inflammatory bone disease most frequently seen in children (see Table 188.4). Histologically and radiologically, CRMO is virtually indistinguishable from infectious osteomyelitis (Fig. 188.15). Patients typically present with bone pain and may also have fever, soft tissue swelling, and elevated acute-phase reactants. Cultures are sterile. Typically involved bones include the distal femur, proximal tibia or fibula, spine, and pelvis. Both metaphyseal and epiphyseal lesions may occur; premature physeal closure may develop. Less frequently involved bones include the clavicle and mandible. The differential diagnosis includes infectious osteomyelitis, histiocytosis, and malignancy (neuroblastoma, lymphoma, leukemia, Ewing sarcoma). **SAPHO** (synovitis, acne, pustulosis, hyperostosis, and osteitis) may be an adult equivalent to CRMO. The etiology of sporadic CRMO is unknown. CRMO is seen in Majeed syndrome (see earlier), in association with inflammatory bowel disease, and inflammatory skin disease such as palmoplantar pustulosis. Initial therapy includes NSAIDs. Second-line treatments include corticosteroids, TNF inhibitors, and bisphosphonates.

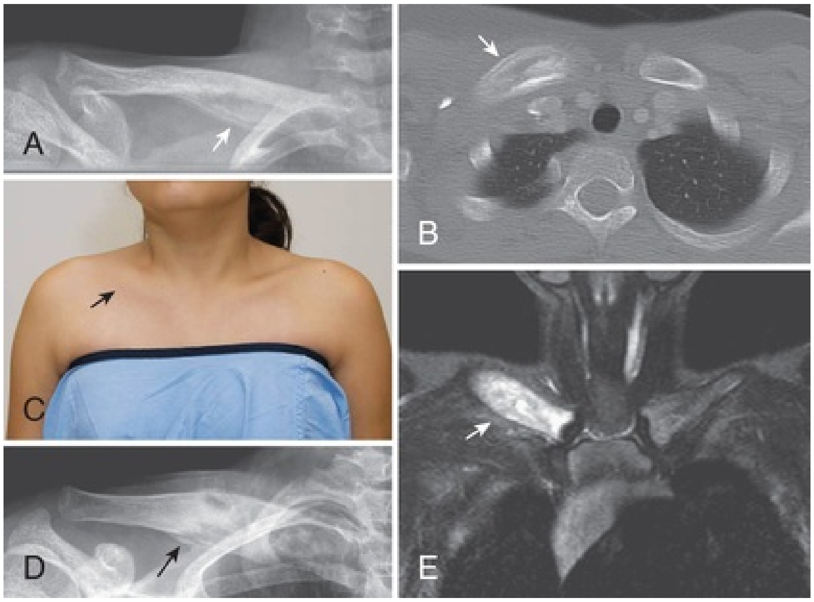

FIG. 188.15 Clavicular involvement in chronic recurrent multifocal osteomyelitis. Adolescent female with unilateral clavicular involvement. A, Plain radiograph of the right clavicle at presentation reveals widening of the medial two thirds, with associated periosteal reaction. B, Corresponding CT scan of the right clavicle demonstrates expansion of the medial right clavicle with areas of increased sclerosis accompanied by a surrounding periosteal reaction *(arrow)* . C, Flare of disease 18 months later showing further clavicular enlargement (clinical photo). D, Plain radiograph of the right clavicle at that time demonstrates marked interval sclerosis and thickening. E, MRI at the same time shows increased signal intensity on fat-suppressed contrast-enhanced T1-weighted images of the right medial clavicle consistent with continued inflammation. CHAPTER 189

Amyloidosis

Karyl S. Barron, Amanda K. Ombrello

Amyloidosis comprises a group of diseases characterized by extracellular deposition of insoluble, fibrous amyloid proteins in various body tissues.

Etiology

Amyloidosis is a disease caused by protein misfolding. These misfolded proteins infiltrate, aggregate, and form insoluble fibrils that can affect the normal function of a number of vital organs.

In the amyloidosis nomenclature, a distinction is made between amyloidosis that develops from mutations in the *amyloid fibril protein itself* and amyloidosis associated with genetic mutation in nonamyloid proteins. The former are referred to as **hereditary amyloidoses** ; examples include mutations in the genes for transthyretin and apolipoprotein A, both of which are uncommon in young children. This is in contrast to **amyloid A (AA) amyloidosis** , which develops in patients with chronic inflammatory states. It is estimated that, worldwide, approximately 45% of all amyloid cases are AA amyloidosis. In the past, chronic infectious diseases such as tuberculosis, malaria, leprosy, and chronic osteomyelitis accounted for most cases of AA amyloidosis. With effective treatment for these infections, other causes of AA have become more common. A number of chronic inflammatory rheumatic diseases, such as **rheumatoid arthritis (RA)** , **juvenile idiopathic arthritis (JIA)** , and **ankylosing spondylitis** , as well as hereditary autoinflammatory diseases, have an increased risk for the development of AA amyloidosis. AA amyloidosis has also been associated with granulomatous diseases such as sarcoidosis, cystic fibrosis, Crohn disease, malignancies such as mesothelioma and Hodgkin diseases, intravenous drug abuse, and other infections, such as bronchiectasis and HIV.

Approximately 6% of AA amyloidosis cases have no identified disease association. **AL amyloidosis** (formerly known as *idiopathic amyloidosis* or *myeloma-associated amyloidosis*) is extremely rare in children, occurring in middle-aged or older individuals.

Epidemiology

Only AA amyloidosis affects children in appreciable numbers. The factors that determine the risk for amyloidosis as a complication of inflammation are not clear, because many individuals with long-standing inflammatory disease do not demonstrate tissue amyloid deposition, whereas some children with relatively recent onset of disease may develop amyloid. In developed countries, before the initiation of therapy with disease-modifying antirheumatic drugs (DMARDs) and biologic agents, RA was the most common inflammatory disease associated with AA amyloidosis. Patients who had a long history of poorly controlled severe disease with extraarticular manifestations were the most at risk for developing amyloidosis, and the median time from first symptoms of their rheumatic condition to the diagnosis of amyloidosis was 212 mo. The full effect of DMARD and biologic therapy in RA-associated amyloidosis has yet to be fully appreciated, but studies are showing a sustained decline in the number of new cases.

JIA is another rheumatic disease associated with development of AA amyloidosis, with the highest prevalence in patients with systemic JIA, followed by those with polyarticular disease (see Chapter 180). In the pre-DMARDs and prebiologics era, the prevalence of AA amyloidosis in JIA patients ranged from 1–10%. Higher prevalence was seen in Northern European patients, especially Polish patients, who had a prevalence of 10.6%; lower prevalence was observed in North America. The reasons for this discrepancy are not completely understood, although it is speculated that selection bias, genetic background, and tendency toward earlier, more aggressive therapy in North Americans may have played a role. AA amyloidosis has been observed in JIA patients as early as 1 yr after diagnosis. Similar to RA, the occurrence of new amyloid cases has significantly decreased in the past 20 yr because of the increased efficacy of treatment with DMARDs and biologics.

The **hereditary autoinflammatory diseases** define a group of illnesses characterized by attacks of seemingly unprovoked recurrent inflammation without significant levels of either autoantibodies or antigen-specific T cells, which are typically found in patients with autoimmune diseases (see Chapter 188). Although seemingly unprovoked, these attacks are often initiated by stress, immunization, or trauma, suggesting that gene-environment interactions play an important role in pathogenesis. Although there is some variability among the autoinflammatory diseases, common findings include fevers, cutaneous rashes, arthritis, serositis, and ocular involvement. The inflammatory attacks are accompanied by intense acute-phase responses (erythrocyte sedimentation rate and C-reactive protein) and high levels of serum amyloid A (SAA). Amyloidosis AA is associated with some but not all the hereditary autoinflammatory diseases.

Familial Mediterranean fever (FMF) is the most common of the mendelian autoinflammatory diseases and is seen most frequently in the Armenian, Arab, Turkish, and Sephardi Jewish populations. FMF is an autosomal recessive disease that results from mutations in the *MEFV* gene, which encodes the pyrin/marenostrin protein. *MEFV* mutations affecting the M680 and M694 amino acid residues are associated with early onset of FMF, severe disease, and an increased risk of AA amyloidosis. Patients residing in Armenia, Turkey, and Arabian countries have an increased risk of developing AA amyloidosis compared to patients with the same mutations of *MEFV* living in North America. While one may assume that FMF patients who have frequent, severe attacks would be at the most risk for the development of AA amyloidosis, this is not always the case. Some patients have had a history of frequent attacks and never develop amyloidosis, and others develop amyloidosis at an early age. There is also a subset of FMF patients referred to as **phenotype II** . These patients present with AA amyloidosis before their first FMF attack. In this group the distribution of the common *MEFV* mutation is similar to that found in FMF patients with typical symptoms.

Tumor necrosis factor receptor–associated periodic syndrome (TRAPS) is associated with mutations in the *TNFRSF1A* gene, which encodes the 55 kDa tumor necrosis factor (TNF) receptor protein (TNFR1). It is estimated that 14-25% of patients with TRAPS develop AA amyloidosis. Patients with mutations in *TNFRSF1A* that affect cysteine residues have the highest risk of developing AA amyloidosis. It is thought that these cysteine residues participate in assembly of disulfide bonds important for TNFR1 folding, and that disruption of these bonds affects protein folding.

Mutations in the *NLRP3* gene (also known as *CIAS1* , cold-induced autoinflammatory syndrome 1) cause 3 clinically distinct diseases: **familial cold autoinflammatory syndrome (FCAS)** , **Muckle-Wells syndrome (MWS)** , and

neonatal-onset multisystem inflammatory disease (NOMID) , also known as **chronic infantile neurologic cutaneous and articular (CINCA) syndrome** . Mutations in *NLRP3* are inherited in an autosomal dominant fashion or as de novo mutations in patients with the most severe disease. A smaller portion of patients have been found to carry somatic mutations in *NLRP3.*

FCAS is generally the least severe of the cryopyrinopathies and is rarely associated with AA amyloidosis. MWS presents with fevers, myalgias, arthralgias, urticarial-like rash, and progressive sensorineural hearing loss. AA amyloidosis is quite common in MWS, affecting up to one third of the patients. NOMID/CINCA is the most severe cryopyrinopathy. Historically, 20% of patients died before reaching adulthood, but with current therapies, many are living longer lives. Some NOMID patients develop AA amyloidosis as they get older, although not as often as MWS patients, possibly because of a shortened life span in these patients.

Hyper-IgD syndrome (HIDS) is another autoinflammatory disease that presents in early childhood with chills, high fevers, abdominal pain, lymphadenopathy, and occasional rash. HIDS is an autosomal recessive disease that involves loss-of-function mutations in the *MVK* gene that encodes the mevalonate kinase enzyme. Severe *MVK* mutations that completely abolish enzyme activity are identified in patients with **mevalonic aciduria** , who present with recurrent fevers, dysmorphic features, and developmental delays. HIDS-associated mutations are milder loss-of-function mutations. Inflammatory markers, including SAA, are high during attacks and may remain elevated in the intercurrent period. AA amyloidosis is rare in HIDS but has been reported.

Although seen less frequently than in the hereditary periodic fever syndromes, the risk of AA amyloidosis has been well established in patients with Crohn disease. AA amyloidosis occurs in an estimated 1% of U.S. patients and up to 3% in Northern European patients. Conversely, AA amyloidosis presenting in patients with ulcerative colitis is extremely rare, with estimated prevalence of 0.07%. The patients have a long-standing history of aggressive, poorly controlled disease, although there are reports of amyloidosis in patients with well-controlled inflammatory markers.

Transthyretin-related hereditary amyloidosis is an autosomal dominant disorder with variable penetrance and onset in the 2nd to 3rd decade of life. More than 120 single or double mutations in the *TTR* gene are responsible for disease. Manifestations include neuropathy (familial amyloidotic polyneuropathy: motor, sensory, autonomic), familial amyloid cardiomyopathy, nephropathy, and ocular disease.

Pathogenesis

The deposition of AA amyloid fibrils is a result of a prolonged inflammatory state that leads to misfolding of the AA amyloid protein and deposition into tissues. The precursor protein of the fibrils in AA amyloidosis is an apolipoprotein called *serum amyloid A* (SAA). SAA is expressed by 3 different genes that are localized on chromosome p15.1. SAA1 and SAA2 are 2 isoforms that are acute-phase reactants synthesized by the liver that can form amyloid. SAA is produced in response to proinflammatory cytokines such as interleukin (IL)-1, IL-6, and TNF-α and can increase >1,000-fold during inflammation. It has been speculated that SAA has a role as a chemoattractant and in lipid metabolism. Supporting this theory is the finding that amyloid deposition occurs initially in organs that are major sites of lipid and cholesterol metabolism, such as the kidney, liver, and spleen. Approximately 80% of secreted SAA1 and SAA2 are bound to lipoprotein.

Under normal circumstances, SAA secreted by the liver is completely degraded by macrophages. The secreted SAA protein is 104 amino acids in length and is primarily secreted in an α-helix structure. For reasons not completely understood, patients with AA amyloidosis have a flaw resulting in incomplete degradation and accumulation of intermediate SAA products. In these patients, SAA is transferred to the lysosome, where the c-terminal portion of the SAA protein is cleaved, allowing the remaining protein to fold into a β-pleated sheet configuration. Deposited amyloid contains only 66-76 amino acids, compared to the 104 in secreted SAA. These cleaved fragments polymerize and form fibrils that are deposited in the extracellular space and bind proteoglycans and other proteins such as serum amyloid P. These fibrils then become resistant to proteolysis and deposit in organ tissues.

Development of AA amyloid may be associated with a number of risk factors. The gene encoding SAA1 has polymorphisms that, when present, carry a 3-7–fold increased risk for the development of AA amyloidosis. Caucasian patients with RA, JIA, or autoinflammatory diseases who have the SAAα/α (alpha/alpha) genotype have an increased risk of amyloidosis. In that group of patients, the SSA1γ (gamma) allele is associated with a decreased risk of amyloidosis. Interestingly, the risk in Japanese patients is reversed, with SAAα/α genotype is associated with a decreased susceptibility to amyloidosis development but the

SAA1γ genotype carries an increased risk.

Clinical Manifestations

Although organ involvement may vary, AA amyloidosis most frequently affects the kidneys; 90% of patients have some degree of renal involvement. Unexplained proteinuria may be the presenting feature in some patients. Nephrotic syndrome and renal failure may develop if the underlying inflammatory condition is not controlled or if diagnosis is delayed. Median survival after diagnosis has been reported to be 133 mo; patients with higher SAA levels had significantly higher risk of death than those with lower SAA levels. Gastrointestinal involvement is seen in approximately 20% of patients and usually manifests as chronic diarrhea, GI bleeding, abdominal pain, and malabsorption. When biopsied, the testes are frequently involved (87%). Relatively uncommon findings associated with AA amyloidosis include anemia, amyloid goiter, hepatomegaly, splenomegaly, adrenal involvement, and pulmonary involvement. Tissues, such as the heart, tongue, and skin, are rarely involved.

Diagnosis

The diagnosis of amyloidosis is established by biopsy demonstrating amyloid fibril proteins in affected tissues. The tissues tested include kidney, rectum, abdominal fat pad, and gingiva. Amyloid deposits are composed of seemingly homogeneous eosinophilic material that stains with Congo red dye and demonstrates the pathognomonic “apple-green birefringence” in polarized light. Tissue and genetic testing is useful for transthyretin amyloidosis.

Laboratory Findings

Patients with AA amyloidosis usually show elevated acute-phase reactants and high levels of immunoglobulins. In the United States, specific laboratory testing is not commercially available for AA amyloid, but in other countries, SAA levels can be monitored and used to guide response to treatment.

Treatment

There is no established therapy for AA amyloidosis, and thus the primary approach is aggressive management of the underlying inflammatory or infectious disease, which decreases levels of SAA protein. As newer therapies are developed to treat the underlying condition, emerging evidence shows that the incidence of AA amyloidosis is decreasing. *Colchicine* is effective not only in controlling the attacks of FMF but also in preventing the development of amyloidosis associated with FMF. Children with FMF who are homozygous for the M694V mutation in *MEFV* are at greater risk for development of amyloidosis and should be monitored closely.

Unlike AA amyloidosis associated with FMF, AA amyloidosis associated with other autoinflammatory diseases (including TRAPS, cryopyrin-associated periodic syndrome, and rarely HIDS) and chronic rheumatic diseases (JIA, RA, and ankylosing spondylitis) does not respond to colchicine. Although AA amyloidosis associated with JIA may respond to *chlorambucil* , this drug is associated with chromosome breakage and a risk of subsequent malignancy.

Increasing use of biologic medicines (**biologics**) against proinflammatory cytokines to treat RA, JIA, spondyloarthropathies, and the hereditary autoinflammatory diseases seems to impact risk factors for the development of AA amyloidosis. The class of medications referred to as the *anti–TNF-α drugs* have been paramount in the management of RA and other autoimmune disease. In both autoimmune and autoinflammatory conditions with accompanying AA amyloidosis, there are reports documenting the effectiveness of anti-TNF agents in blunting the progression of amyloidosis. Adverse effects of anti-TNF medications include reactivation of tuberculosis and hepatitis B, and thus careful screening should be performed before instituting therapy. Additionally, the development of various antibodies, autoantibodies, and autoimmune disease has been noted in patients taking anti-TNF agents. Extreme caution should be used in prescribing anti-TNF agents to patients with a history of heart failure or demyelinating disease, because use can cause exacerbations in their underlying cardiac and neurologic diseases.

The IL-1 pathway is the target of multiple biologic medications used in autoimmune and autoinflammatory diseases. The 3 available IL-1 antagonists are *anakinra* (IL-1 receptor antagonist), *rilonacept* (soluble IL-1 receptor decoy), and *canakinumab* (long-acting fully humanized IgG_1 anti–IL-1β monoclonal antibody). The various IL-1 inhibitors have been successful at slowing the progression of AA amyloidosis, and in some cases treatment results in regression of amyloid-associated proteinuria.

Tocilizumab , an anti–IL-6 receptor antibody, has been shown to attenuate experimental AA amyloid and to reverse AA amyloidosis complicating FMF, JIA, and RA. A recent trial using *eprodisate disodium* in AA amyloid patients failed to meet its primary end-point of reducing progression to end-stage renal disease.

Transthyretin amyloidosis has been treated with liver transplantation and transthyretin-stabilizing agents.

Prognosis

End-stage renal failure is the underlying cause of death in 40–60% of patients with amyloidosis, with a median survival time from diagnosis of 2-10 yr. According to a large-scale study of 374 patients with AA amyloidosis, the factors associated with a poor prognosis include older age, a lower albumin serum level, end-stage renal disease at baseline, and prolonged serum elevation of SAA. An elevated SAA value was the most powerful risk factor for end-stage renal disease and death from AA amyloidosis.

Prevention

The primary means of preventing AA amyloidosis is treatment of the underlying inflammatory or infectious disease, resulting in decreases in the level of SAA protein and the risk of amyloid deposition. Although the period of latency between the onset of inflammation (of the underlying disease) and the initial clinical signs of AA amyloidosis may vary and is often prolonged, progression of the amyloid depositions can be rapid.

CHAPTER 190

Sarcoidosis

Eveline Y. Wu

Sarcoidosis is a rare multisystem granulomatous disease of unknown etiology. The name is derived from a Greek word meaning "flesh-like condition," in reference to the characteristic skin lesions. There appear to be 2 distinct, age-dependent patterns of disease among children with sarcoidosis. The clinical features in older children are similar to those in adults (pediatric-onset adult sarcoidosis), with frequent systemic features (fever, weight loss, malaise), pulmonary involvement, and lymphadenopathy. In contrast, early-onset sarcoidosis manifesting in children <4 yr of age is characterized by the triad of rash, uveitis, and polyarthritis.

Etiology

The etiology of sarcoidosis remains obscure but likely results from exposure of a genetically susceptible individual to 1 or more unidentified antigens. This exposure initiates an exaggerated immunologic response that ultimately leads to the formation of granulomas. The human major histocompatibility complex is located on chromosome 6, and specific human leukocyte antigen (HLA) class I and class II alleles are associated with disease phenotype. Genetic polymorphisms involving various cytokines and chemokines may also have a role in development of sarcoidosis. Familial clustering supports the contribution of genetic factors to sarcoidosis susceptibility. Environmental and occupational exposures are also associated with disease risk. There are positive associations between sarcoidosis and agricultural employment, occupational exposure to insecticides, and moldy environments typically associated with microbial bioaerosols.

Blau syndrome is an autosomal dominant, familial form of sarcoidosis and is typified by the early onset of granulomatous inflammation involving the skin, eyes, and joints. Missense mutations in the *CARD15/NOD2* gene on chromosome 16 have been found in affected family members and appear to be associated with development of sarcoidosis. The 2 most common amino acid substitutions are R334W (arginine to glutamine) and R334Q (arginine to tryptophan). Similar genetic mutations also have been found in individuals with a sporadic **early-onset sarcoidosis (EOS)** (rash, uveitis, arthritis), suggesting that this nonfamilial form and Blau syndrome are genetically and phenotypically identical (see Chapter 188).

Epidemiology

A nationwide patient registry of childhood sarcoidosis in Denmark estimated the annual incidence to be 0.22-0.27 per 100,000 children. The incidence increases with age, and peak onset occurs at 20-39 yr. The most common age of reported childhood cases is 13-15 yr. Annual incidence is about 11 per 100,000 in adult white Americans and is 3 times higher in blacks. There is no clear sex predominance in childhood sarcoidosis. The majority of U.S. childhood sarcoidosis cases are reported in the southeastern and south-central states.

An international registry and Spanish cohort of Blau syndrome and EOS reported the mean age of disease onset as 30 mo and 36 mo, respectively. All but 3 of these young patients presented before 5 yr of age. There does not appear to be a sex predilection in either condition.

Pathology and Pathogenesis

Noncaseating, epithelioid granulomatous lesions are a cardinal feature of sarcoidosis. Activated macrophages, epithelioid cells, and multinucleated giant cells as well as $CD4^+$ T lymphocytes accumulate and become tightly packed in the center of the granuloma. The causative agent that initiates this inflammatory process is not known. The periphery of the granuloma contains a loose collection of monocytes, $CD4^+$ and $CD8^+$ T lymphocytes, and fibroblasts. The interaction between the macrophages and $CD4^+$ T lymphocytes is important in the formation and maintenance of the granuloma. The activated macrophages secrete high levels of tumor necrosis factor (TNF)-α and other proinflammatory mediators. The $CD4^+$ T lymphocytes differentiate into type 1 helper T cells and release interleukin (IL)-2 and interferon (IFN)-γ, promoting proliferation of lymphocytes. Granulomas may heal or resolve with complete preservation of the parenchyma. In approximately 20% of the lesions, the fibroblasts in the periphery proliferate and produce fibrotic scar tissue, leading to significant and irreversible organ dysfunction.

The sarcoid macrophage is able to produce and secrete 1,25-$(OH)_2$ -vitamin D or *calcitriol*, an active form of vitamin D typically produced in the kidneys. The hormone's natural functions are to increase intestinal absorption of calcium and bone resorption and decrease renal excretion of calcium and phosphate. An excess of calcitriol may result in hypercalcemia and hypercalciuria in patients with sarcoidosis.

Clinical Manifestations

Sarcoidosis is a multisystem disease, and granulomatous lesions may occur in any organ of the body. The clinical manifestations depend on the extent and degree of granulomatous inflammation and are extremely variable. Children may present with nonspecific symptoms, such as fever, weight loss, and general malaise. In adults and older children, pulmonary involvement is most frequent, with infiltration of the thoracic lymph nodes and lung parenchyma. Isolated bilateral hilar adenopathy on chest radiograph is the most common finding (Fig. 190.1), but parenchymal infiltrates and miliary nodules may also be seen (Figs. 190.2 and 190.3). Patients with lung involvement are usually found to have restrictive changes on pulmonary function testing. Symptoms of pulmonary disease are seldom severe and generally consist of a dry, persistent cough.

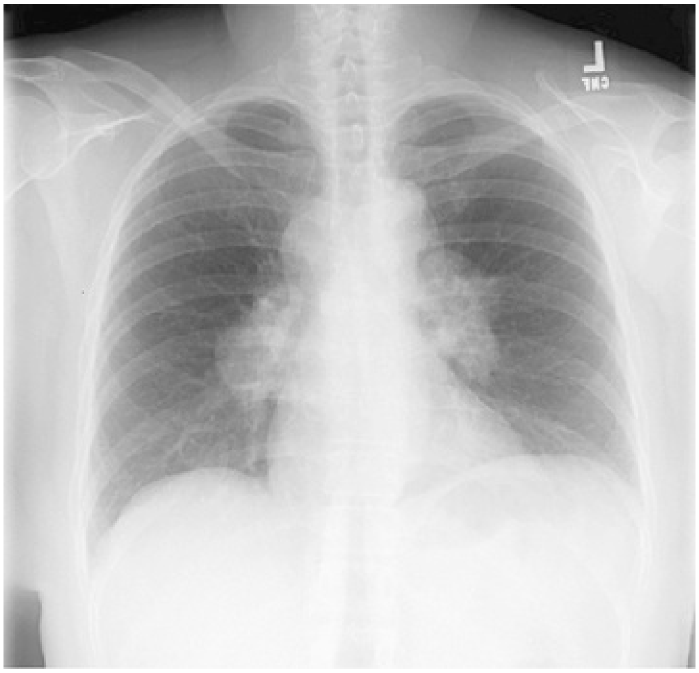

FIG. 190.1 Sarcoidosis. Chest radiograph demonstrating a stage I disease with enlarged mediastinal and hilar lymph nodes. (From Iannuzzi M: Sarcoidosis. In Goldman L, Schafer AI, editors, *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, Saunders, Fig 95-1, p 582.)

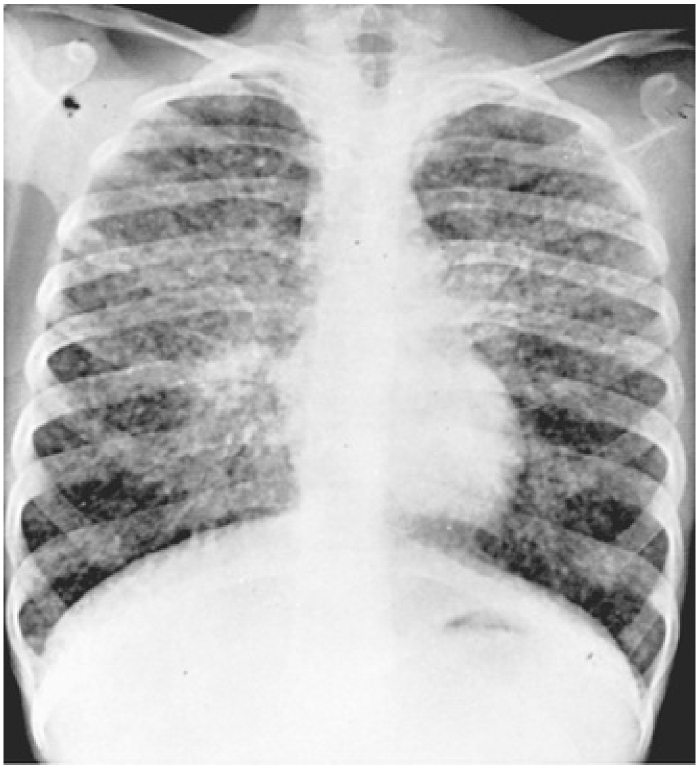

FIG. 190.2 Sarcoidosis. Chest radiograph of 10 yr old girl showing widely disseminated peribronchial infiltrates, multiple small nodular densities, hyperaeration of the lungs, and hilar lymphadenopathy.

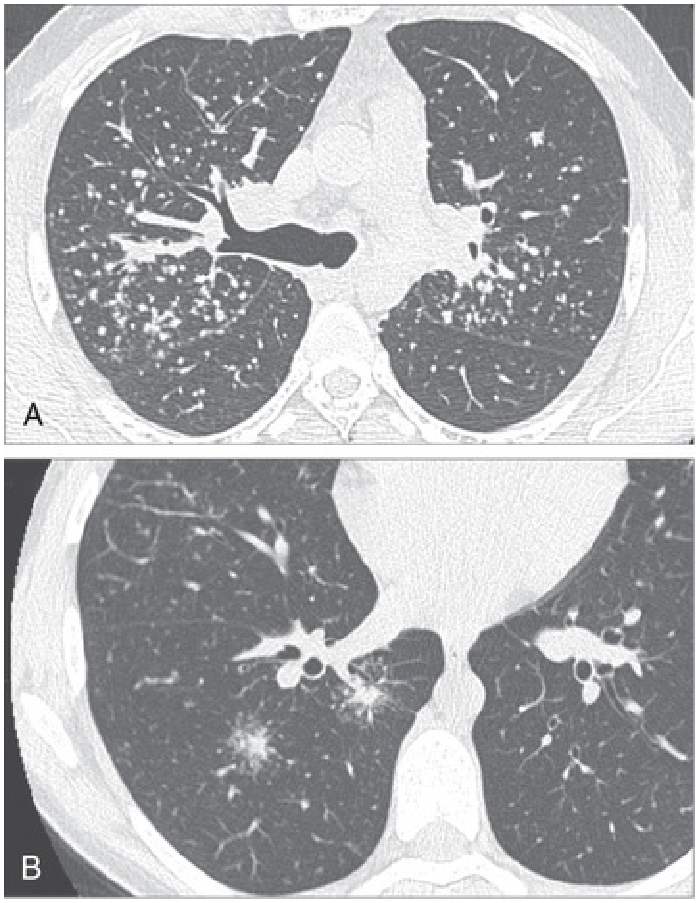

FIG. 190.3 Typical features of lung sarcoidosis on CT. A, Usual perilymphatic distribution of micronodules with fissural spreading. B, Typical nodules with irregular margins and satellite micronodules known as the *galaxy sign* . (From Valerye D, Prasse A, Nunes H, et al: Sarcoidosis, *Lancet* 383:1155–1167, 2014, Fig 2, p 1158).

Extrathoracic lymphadenopathy and infiltration of the liver, spleen, and bone marrow also occur often (Table 190.1). Infiltration of the liver and spleen typically leads to isolated hepatomegaly and splenomegaly, respectively, but actual organ dysfunction is rare. Cutaneous disease, such as plaques, nodules, erythema nodosum in acute disease, or lupus pernio in chronic sarcoidosis, appears in one quarter of cases and is usually present at onset. Red-brown to purple maculopapular lesions <1 cm on the face, neck, upper back, and extremities are the most common skin finding (Fig. 190.4). Ocular involvement is frequent and has variable manifestations, including anterior or posterior uveitis, conjunctival granulomas, eyelid inflammation, and orbital or lacrimal gland infiltration. The arthritis in sarcoidosis can be confused with **juvenile idiopathic arthritis** (JIA). Central nervous system (CNS) involvement is rare in early childhood but may manifest as seizures, cranial nerve involvement, intracranial mass lesions, and hypothalamic dysfunction (Fig. 190.5). Kidney disease occurs infrequently in children but typically manifests as renal insufficiency, proteinuria, transient pyuria, or microscopic hematuria caused by early monocellular infiltration or granuloma formation in kidney tissue. Only a small fraction of children have hypercalcemia or hypercalciuria, which is therefore an infrequent cause of kidney disease. Sarcoid granulomas can also infiltrate the heart and lead to cardiac arrhythmias and, rarely, sudden death. Other rare sites of disease involvement include blood vessels of any size, the gastrointestinal tract, parotid gland, muscles, bones, and testes.

Table 190.1

Sarcoidosis: Extrapulmonary Localizations

	SYMPTOMS
Skin	Papules, nodules, plaques, scar sarcoidosis, lupus pernio, subcutaneous sarcoidosis
Peripheral lymphadenopathy	Mostly cervical or supraclavicular; inguinal, axillary, epitrochlear, or submandibular lymph node sites also possible; painless and mobile
Eye	Anterior, intermediate, or posterior uveitis; retinal vascular change; conjunctival nodules; lacrimal gland enlargement
Liver	Often symptom free; abnormal liver function tests in 20–30% of patients; hepatomegaly; rarely hepatic insufficiency, chronic intrahepatic cholestasis, or portal hypertension
Spleen	Splenomegaly; rarely, pain or pancytopenia; very rarely, splenic rupture
Heart	Atrioventricular or bundle branch block; ventricular tachycardia or fibrillation; congestive heart failure; pericarditis; impairment of sympathetic nerve activity; sudden death
Nervous system	Facial nerve palsy, optic neuritis, leptomeningitis, diabetes insipidus, hypopituitarism, seizures, cognitive dysfunction, deficits, hydrocephalus, psychiatric manifestations, spinal cord disease, polyneuropathy, small-fiber neuropathy
Kidney	Rare symptoms; increased creatininemia sometimes associated with hypercalcemia; nephrocalcinosis; kidney stones
Parotitis	Symmetric parotid swelling; Heerfordt syndrome when associated with uveitis, fever, and facial palsy
Nose	Nasal stuffiness, nasal bleeding, crusting, anosmia
Larynx	Hoarseness, breathlessness, stridor, dysphagia
Bones	Often asymptomatic; hands and feet classically most involved, also large bones and axial skeleton
Skeletal muscles	Proximal muscle weakness, amyotrophy, myalgia, intramuscular nodules
Genitourinary tract	All organs can be involved, including breast, uterus, epididymis, and testicle
Gastrointestinal tract	Most often symptom free, but the esophagus, stomach, small intestine, and colon can be involved

Adapted from Valerye D, Prasse A, Nunes H, et al: Sarcoidosis, *Lancet* 383:1155–1167, 2014 (Table 1, p 1159).

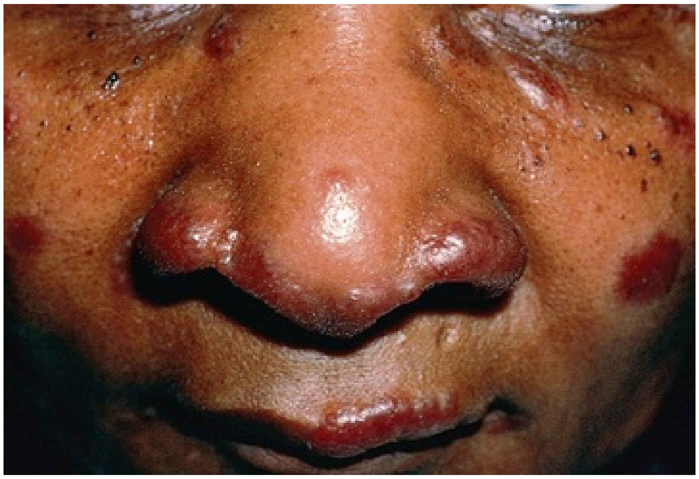

FIG. 190.4 Sarcoidosis nodules on the face. (From Shah BR, Laude TA: *Atlas of pediatric clinical diagnosis,* Philadelphia, 2000, Saunders.)

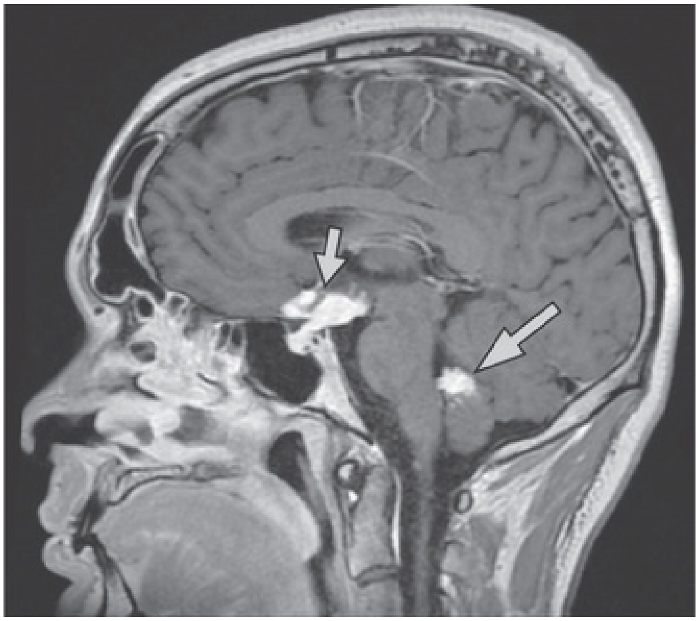

FIG. 190.5 Neurologic involvement in sarcoidosis. Typical involvement of hypothalamus, pituitary gland, and optic chiasm seen on a sagittal gadolinium-enhanced T1-weighted sequence MRI *(small arrow).* Abnormal nodular enhancement of the 4th ventricle is seen *(large arrow).* (Modified from Valerye D, Prasse A, Nunes H, et al: Sarcoidosis, *Lancet* 383:1155–1167, 2014, Fig 3d, p 1160.)

In contrast to the variable clinical presentation of sarcoidosis in older children, **Blau syndrome and EOS** (NOD2-associated sarcoidosis) classically manifests as the triad of uveitis, arthritis, and rash. These classic manifestations do not always occur simultaneously. Skin disease usually develops before 1 yr, arthritis at 2-4 yr, and uveitis before 4 yr. Pulmonary disease and lymphadenopathy are less common. The arthritis is polyarticular and symmetric, with large, boggy effusions. Large and small joints are involved. Tenosynovitis is an associated finding. Joints are stiff and moderately tender. The rash may wax and wane and is diffuse (mostly truncal), erythematous or tan, macular-papular, and often desquamates, at times being confused with eczema or ichthyosis vulgaris. Tender subcutaneous nodules resembling erythema nodosum may be seen on the legs. Noncaseating granulomas are demonstrated on biopsy of the skin or joint synovium. Insidious granulomatous iridocyclitis and posterior uveitis are often bilateral and may progress to **panuveitis** , which has a high risk for vision loss. Iris nodules, photophobia, erythema, cataracts, or glaucoma may be present or develop over time.

Most patients with Blau syndrome and EOS display this more restricted phenotype and develop all or some combination of the rash, arthritis, and uveitis. Many, however, also have an extended phenotype. Additional disease manifestations include fever, hepatosplenomegaly, lymphadenopathy, and lung, kidney, and CNS involvement.

Infantile-onset panniculitis with uveitis and systemic granulomatosis is an uncommon manifestation of sarcoidosis. Sarcoidosis has also been reported in adults treated with type 1 interferons for hepatitis or multiple sclerosis.

Laboratory Findings

There is no single standard laboratory test diagnostic of sarcoidosis. Anemia, leukopenia, and eosinophilia may be seen. Other nonspecific findings include hypergammaglobulinemia and elevations in acute-phase reactants, including erythrocyte sedimentation rate and C-reactive protein value. Hypercalcemia and/or hypercalciuria occur in only a small proportion of children with sarcoidosis. Angiotensin-converting enzyme (ACE) is produced by the epithelioid cells of the granuloma, and its serum value may be elevated, but this finding lacks diagnostic sensitivity and specificity. ACE levels are estimated to be elevated in >50% of children with sarcoidosis. In addition, ACE values may be difficult to interpret because reference values for serum ACE are age dependent. Fluorodeoxyglucose F 18 positron emission tomography can help identify nonpulmonary sites for a diagnostic biopsy.

Diagnosis

Definitive diagnosis ultimately requires demonstration of the characteristic noncaseating granulomatous lesions in a biopsy specimen (usually taken from the most readily available affected organ) and exclusion of other known causes of granulomatous inflammation. Skin and transbronchial lung biopsies have higher yield, greater specificity, and fewer associated adverse events than biopsy of mediastinal lymph nodes or liver. Additional diagnostic testing should include chest radiography, pulmonary function testing with measurement of diffusion capacity, hepatic enzyme measurements, and renal function assessment. Ophthalmologic slit-lamp examination is essential because ocular inflammation is frequently present and may be asymptomatic in sarcoidosis, and vision loss is a sequela of untreated disease.

Bronchoalveolar lavage may be used to assess for disease activity, and the fluid typically reveals an excess of lymphocytes with an increased $CD4^+$ /$CD8^+$ ratio of 2-13 : 1. In addition to flexible bronchoscopy with transbronchial biopsy, endosonographic-guided intrathoracic node aspiration has been valuable in obtaining tissue to assess for noncaseating granulomas.

Differential Diagnosis

Because of its protean manifestations, the differential diagnosis of sarcoidosis is extremely broad and depends largely on the initial clinical manifestations. **Granulomatous infections** , including tuberculosis, cryptococcosis, pulmonary mycoses (histoplasmosis, blastomycosis, coccidioidomycosis), brucellosis, tularemia, and toxoplasmosis, must be excluded. Other causes of granulomatous inflammation are granulomatosis with polyangiitis (formerly Wegener granulomatosis), hypersensitivity pneumonia, chronic berylliosis, and other occupational exposures to metals. Localized granulomatous lesions of the head and neck may be due to **orofacial granulomatosis.** Immunodeficiencies that may manifest with granulomatous lesions include common variable immunodeficiency, selective IgA deficiency, chronic granulomatous disease, ataxia telangiectasia, and severe combined immunodeficiency. Granulomas of the lung, skin, or lymph nodes have been reported in patients treated with anti-TNF agents. Lymphoma should be ruled out in cases of hilar or other lymphadenopathy. Sarcoid arthritis may mimic JIA. Evaluation for endocrine disorders is needed in the setting of hypercalcemia or hypercalciuria.

Treatment

Treatment should be based on disease severity as well as the number and type of organs involved. *Corticosteroids are the mainstay of treatment for most acute and chronic disease manifestations.* The optimal dose and duration of corticosteroid therapy in children have not been established. Induction treatment typically begins with oral prednisone or prednisolone (1-2 mg/kg/day up to 40 mg daily) for 8-12 wk until manifestations improve. Corticosteroid dosage is then gradually decreased over 6-12 mo to the minimal effective maintenance dose (e.g., 5-10 mg/day) that controls symptoms, or discontinued if symptoms resolve. *Methotrexate* or *leflunomide* may be effective as a corticosteroid-sparing agent. On the basis of the role of TNF-α in the formation of granulomas, there is rationale for use of TNF-α antagonists. Results of small clinical trials showed modest effects with *infliximab* and *adalimumab* treatment of selected disease manifestations (CNS, lupus pernio, pulmonary, ocular), whereas etanercept does not appear to be particularly effective. Other therapeutics used for sarcoidosis manifestations include topical corticosteroids (eye), inhaled corticosteroids (lung), azathioprine (CNS), cyclophosphamide (cardiac, CNS), hydroxychloroquine (skin), mycophenolate mofetil (CNS, skin), thalidomide or its analogs (skin), and nonsteroidal antiinflammatory drugs (joints).

With regard to treatment of Blau syndrome and EOS, there are few case reports and series on the successful use of corticosteroids, methotrexate, thalidomide, and TNF-α antagonists adalimumab and infliximab. Findings of elevated IL-1 levels and response to human IL-1 receptor antagonist (anakinra) have been inconsistent.

Prognosis

The prognosis of childhood sarcoidosis is not well defined. The disease may be self-limited with complete recovery or may persist with a progressive or relapsing course. Outcome is worse in the setting of multiorgan or CNS involvement. Most children requiring treatment experience considerable improvement with corticosteroids, although a significant number have morbid sequelae, mainly involving the lungs and eyes. Children with EOS have a poorer prognosis and generally experience a more chronic, progressive disease course. The greatest morbidity is associated with ocular involvement, including cataract formation, development of synechiae, and loss of visual acuity or blindness.

Long-term systemic treatment may be required for the eye disease. Progressive polyarthritis may result in joint destruction. The overall mortality rate in childhood sarcoidosis is low.

Serial pulmonary function tests and chest radiographs are useful in following the course of lung involvement. Monitoring for other organ involvement should also include electrocardiogram with consideration of an echocardiogram, urinalysis, renal function tests, and measurements of hepatic enzymes and serum calcium. Other potential indicators of disease activity include inflammatory markers and serum ACE, although changes in ACE level do not always correlate with other indicators of disease status. Given the frequency of asymptomatic eye disease and the ocular morbidity associated with pediatric sarcoidosis, all patients should have an ophthalmologic examination at presentation with monitoring at regular intervals, perhaps every 3-6 mo, as recommended in children with JIA.

CHAPTER 191

Kawasaki Disease

Mary Beth F. Son, Jane W. Newburger

Kawasaki disease (KD), formerly known as *mucocutaneous lymph node syndrome* and *infantile polyarteritis nodosa* , is an acute febrile illness of childhood seen worldwide, with the highest incidence occurring in Asian children. KD is a systemic inflammatory disorder manifesting as a vasculitis with a predilection for the coronary arteries. Approximately 20–25% of untreated children develop **coronary artery abnormalities (CAA)** including aneurysms, whereas <5% of children treated with intravenous immune globulin (IVIG) develop CAA. Nonetheless, KD is the leading cause of acquired heart disease in children in most developed countries, including the United States and Japan.

Etiology

The cause of KD remains unknown. Certain epidemiologic and clinical features support an infectious origin, including the young age-group affected, epidemics with wavelike geographic spread of illness, the self-limited nature of the acute febrile illness, and the clinical features of fever, rash, enanthem, conjunctival injection, and cervical lymphadenopathy. Further evidence of an infectious trigger includes the infrequent occurrence of the illness in infants <3 mo old, possibly the result of maternal antibodies, and the rarity of cases in adults, possibly the result of prior exposures with subsequent immunity. However, there are features that are not consistent with an infectious origin. For example, it is unusual to have multiple cases present at the same time within a family or daycare center. Furthermore, no single infectious etiologic agent has been successfully identified, despite a comprehensive search.

A genetic role in the pathogenesis of KD seems likely, as evidenced by the higher risk of KD in Asian children regardless of country of residence and in siblings and children of individuals with a history of KD. Furthermore, linkage studies and genome-wide association studies (GWAS) have identified significant potential associations between polymorphisms in the *ITPKC* gene, a T-cell regulator, with increased susceptibility to KD and more severe disease. Other candidate genes for KD identified by GWAS include *CASP3, BLK,* and *FCGR2A.* Lastly, associations of single nucleotide polymorphisms (SNPs) in the human leukocyte antigen class II region (HLA-DQB2 and HLA-DOB) with KD have been reported. The concordance rate among identical twins, however, is approximately 13%.

Epidemiology

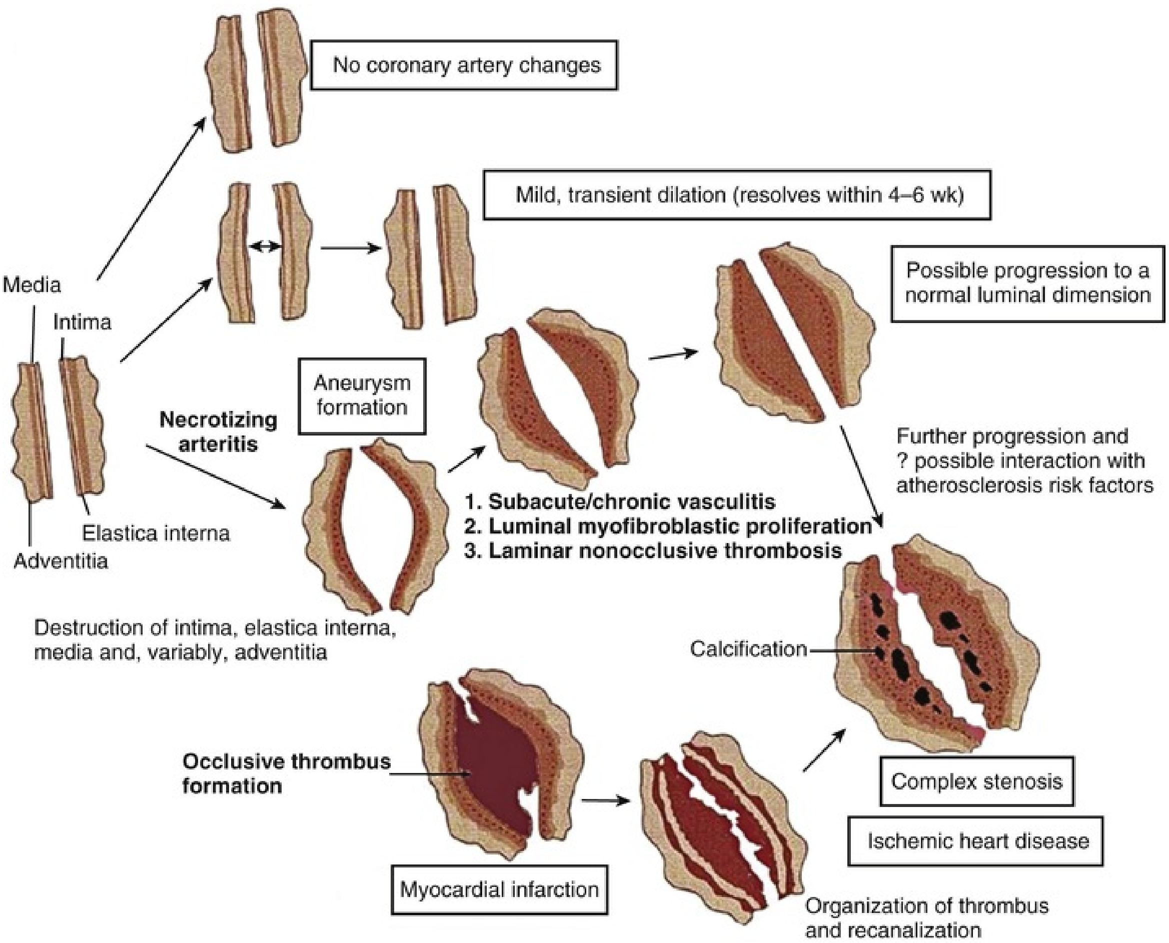
For the majority of patients, KD is a disease of early childhood, and nearly all epidemiologic studies show a higher susceptibility to KD in boys. Data from the Kids Inpatient Database to study trends in KD hospitalizations in 2003, 2006, 2009, and 2012 reported that U.S. hospitalizations for KD seemed to decline significantly over the study period, with 6.68 per 100,000 children hospitalized for KD in 2006 vs 6.11 per 100,000 in 2012. Children age <5 yr had the highest annual hospitalization rates, and children of Asian and Pacific Islander ancestry had the highest rates among all racial groups. In other countries, such as the United Kingdom, South Korea, and Japan, the rate of KD seems to be increasing.

In Japan, nationwide surveys have been administered every 2 yr to monitor trends in KD incidence. In 2012 the highest recorded rate thus far of 264.8 per 100,000 children ages 0-4 yr was described, with the highest rate in young children ages 9-11 mo. Fortunately, the proportion of Japanese patients with coronary aneurysm and myocardial infarction has decreased over time, at 2.8% in the most recent survey.

Several risk stratification models have been constructed to determine which patients with KD are at highest risk for CAA. Predictors of poor outcome across several studies include young age, male gender, persistent fever, poor response to IVIG, and laboratory abnormalities, including neutrophilia, thrombocytopenia, transaminitis, hyponatremia, hypoalbuminemia, elevated levels of N-terminal–brain natriuretic protein and elevated C-reactive protein (CRP) levels. Asian and Pacific Islander race and Hispanic ethnicity are also risk factors for CAA. Three specific risk scores have been constructed by Japanese researchers; of these, the **Kobayashi score** is the most widely used and has high sensitivity and specificity. Unfortunately, application of these risk scores in non-Japanese populations does not appear to accurately identify all children at risk for IVIG resistance and CAA. Body surface area (BSA)–adjusted coronary artery dimensions on baseline echocardiography in the 1st 10 days of illness appear to be good predictors of involvement during follow-up. Accordingly, baseline *z* scores may provide a useful imaging biomarker.

Pathology

KD is a vasculitis that predominantly affects the medium-size arteries. The coronary arteries are most often involved, although other arteries (e.g., axillary, subclavian, femoral, popliteal, brachial) can also develop dilation. A 3-phase process to the arteriopathy of KD has been described. The 1st phase is a neutrophilic necrotizing arteritis occurring in the 1st 2 wk of illness that begins in the endothelium and moves through the coronary wall. Saccular aneurysms may form from this arteritis. The 2nd phase is a subacute/chronic vasculitis driven by lymphocytes, plasma cells, and eosinophils, which may last weeks to years and results in fusiform aneurysms. The vessels affected by the subacute/chronic vasculitis then develop smooth muscle cell myofibroblasts, which cause progressive stenosis in the 3rd phase. Thrombi may form in the lumen and obstruct blood flow (Fig. 191.1).



No coronary artery changes
Mild, transient dilation (resolves within 4–6 wk)
Media
Intima
Possible progression to a normal luminal dimension
Aneurysm formation
Necrotizing arteritis
Further progression and ? possible interaction with atherosclerosis risk factors
1. Subacute/chronic vasculitis
2. Luminal myofibroblastic proliferation
3. Laminar nonocclusive thrombosis
Elastica interna
Adventitia
Destruction of intima, elastica interna, media and, variably, adventitia
Calcification
Occlusive thrombus formation
Complex stenosis
Ischemic heart disease
Myocardial infarction
Organization of thrombus and recanalization

FIG. 191.1 Natural history of coronary artery abnormalities. (Modified from Kato H: Cardiovascular complications in Kawasaki disease: coronary artery lumen and long-term consequences, *Prog Pediatr Cardiol* 19:137–145, 2004.)

Clinical Manifestations

Fever is characteristically high spiking (≥38.3°C [101°F]), remitting, and unresponsive to antipyretics. The duration of fever without treatment is generally 1-2 wk but may be as short as 5 days or may persist for 3-4 wk. In addition to fever, the **5 principal clinical criteria** of KD are (1) bilateral *nonexudative* conjunctival injection with limbal sparing; (2) erythema of the oral and pharyngeal mucosa with strawberry tongue and red, cracked lips; (3) edema (induration) and erythema of the hands and feet; (4) rash of various forms (maculopapular, erythema multiforme, scarlatiniform or less often psoriatic-like, urticarial or micropustular); and (5) nonsuppurative cervical lymphadenopathy, usually unilateral, with node size >1.5 cm (Table 191.1 and Figs. 191.2 to 191.5

). Perineal desquamation is common in the acute phase. Periungual desquamation of the fingers and toes begins 2-3 wk after the onset of illness and may progress to involve the entire hand and foot (Fig. 191.6).

Table 191.1

Clinical and Laboratory Features of Kawasaki Disease

Epidemiologic Case Definition (Classic Clinical Criteria)*

Fever persisting at least 5 days †
Presence of at least 4 principal features:
  Changes in extremities
    - Acute: erythema of palms, soles; edema of hands, feet
    - Subacute: periungual peeling of fingers, toes in wk 2 and 3
  Polymorphous exanthem
  Bilateral bulbar conjunctival injection without exudate
  Erythema and cracking of lips, strawberry tongue, and/or erythema of oral and pharyngeal mucosa
  Cervical lymphadenopathy (>1.5 cm diameter), usually unilateral
Exclusion of other diseases with similar findings ‡

These features do not have to occur concurrently.

Other Clinical and Laboratory Findings

Cardiovascular System

Myocarditis, pericarditis, valvular regurgitation, shock
Coronary artery abnormalities
Aneurysms of medium-sized noncoronary arteries
Peripheral gangrene
Aortic root enlargement

Respiratory System

Peribronchial and interstitial infiltrates on chest radiograph
Pulmonary nodules

Musculoskeletal System

Arthritis, arthralgias (pleocytosis of synovial fluid)

Gastrointestinal Tract

Diarrhea, vomiting, abdominal pain
Hepatitis, jaundice
Hydrops of gallbladder
Pancreatitis

Central Nervous System

Extreme irritability
Aseptic meningitis (pleocytosis of cerebrospinal fluid)
Facial nerve palsy
Sensorineural hearing loss

Genitourinary System

Urethritis/meatitis, hydrocele

Other Findings

Desquamating rash in groin
Retropharyngeal phlegmon
Anterior uveitis by slit-lamp examination
Erythema, induration at bacille Calmette-Guérin inoculation site

Laboratory Findings in Acute Kawasaki Disease

Leukocytosis with neutrophilia and immature forms

- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein
- Anemia
- Abnormal plasma lipids
- Hypoalbuminemia
- Hyponatremia
- Thrombocytosis after wk 1 [§]
- Sterile pyuria
- Elevated serum transaminases
- Elevated serum γ-glutamyl transpeptidase
- Pleocytosis of cerebrospinal fluid
- Leukocytosis in synovial fluid

---

[*] Patients with fever at least 5 days and <4 principal criteria can be diagnosed with Kawasaki disease when coronary artery abnormalities are detected by 2-dimensional echocardiography or angiography.

[†] In the presence of ≥4 principal criteria, particularly when redness and swelling of the hands and feet are present, Kawasaki disease diagnosis can be made on day 4 of illness. Experienced clinicians who have treated many patients with Kawasaki disease may establish diagnosis before day 4 in rare cases.

[‡] See differential diagnosis (Table 191.2).

[§] Some infants present with thrombocytopenia and disseminated intravascular coagulation.

From McCrindle BW, Rowley A, Newburger JW et al: Diagnosis, treatment, and long-term management of Kawasaki disease: a scientific statement for health professionals from the American Heart Association, Circulation 135(17):e927–e999, 2017.)

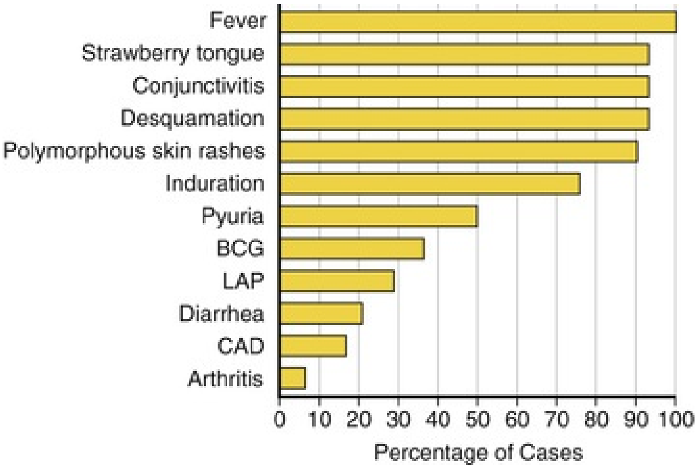


FIG. 191.2 Clinical symptoms and signs of Kawasaki disease. Summary of clinical features from 110 cases of Kawasaki disease seen in Kaohsiung, Taiwan. LAP, Lymphadenopathy in head and neck area; BCG, reactivation of bacille Calmette-Guérin inoculation site; CAD, coronary artery *dilation,* defined by an internal diameter >3 mm. Symptoms other than the principal clinical criteria are common in the 10 days before diagnosis of KD, which may be explained in part by the finding that up to a third of patients with KD have confirmed, concurrent infections. Gastrointestinal (GI) symptoms (vomiting, diarrhea, or abdominal pain) occur in >60% of patients, and at least 1 respiratory symptom (rhinorrhea or cough) occurs in 35%. Other clinical findings include significant irritability that is especially prominent in infants and likely caused by aseptic meningitis, mild hepatitis, hydrops of the gallbladder, urethritis and meatitis with sterile pyuria, and arthritis. Arthritis may occur early in the illness or may develop in the 2nd or 3rd wk. Small or large joints may be affected, and the arthralgias may persist for several weeks. Clinical features that are *not consistent* with KD include exudative conjunctivitis, exudative pharyngitis, generalized lymphadenopathy, discrete oral lesions (ulceration or exudative pharyngitis), splenomegaly, and bullous, petechial, or vesicular rashes.

Cardiac involvement is the most important manifestation of KD. Myocarditis occurs in most patients with acute KD and manifests as tachycardia disproportionate to fever, along with diminished left ventricular systolic function. Occasionally, patients with KD present in cardiogenic shock (**KD shock syndrome**), with greatly diminished left ventricular function. Case series of KD shock syndrome indicate that these patients may be at higher risk for coronary artery dilation. Pericarditis with a small pericardial effusion can also occur during the acute illness. Mitral regurgitation of at least mild severity is evident on echocardiography in 10–25% of patients at presentation but diminishes over time, except among rare patients with coronary aneurysms and ischemic heart disease. Up to 25% of untreated patients develop CAA in the 2nd to 3rd week of illness; initially these are usually asymptomatic and detected by echocardiography. Almost all the morbidity and mortality in KD occur in patients with **large or giant coronary artery aneurysms** , defined by the 2017 American Heart Association (AHA) scientific statement on the diagnosis and treatment of KD as having a *z* score ≥10 or an absolute dimension of ≥8 mm. Specifically, large or giant aneurysms are associated with the greatest risk of thrombosis or stenosis, angina, and myocardial infarction (Figs. 191.7 and 191.8*A*). Rupture of a giant aneurysm is a rare complication that generally occurs in the 1st months after illness onset and may present as hemopericardium with tamponade. Axillary, popliteal, iliac, or other arteries may also become aneurysmal, but always in the setting of giant coronary aneurysms (Fig. 191.8*B*).

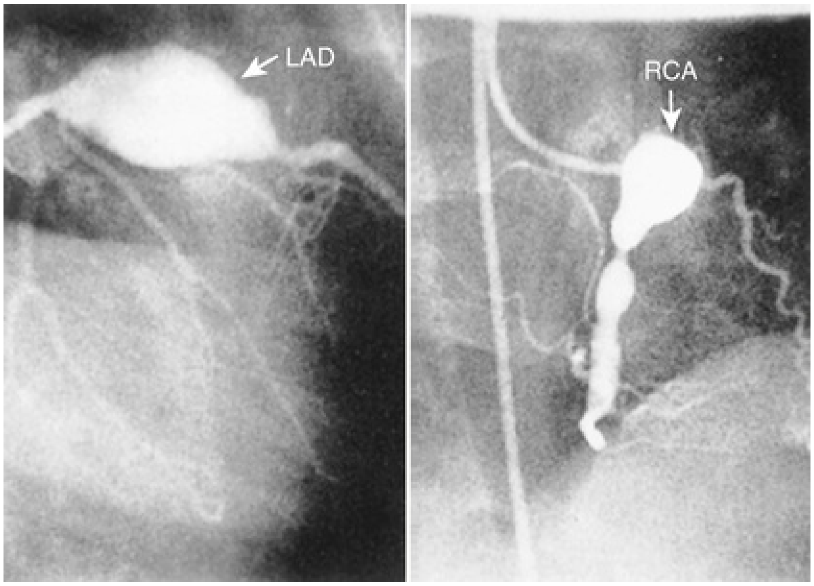

FIG. 191.7 **Coronary angiograms in 6 yr old boy with Kawasaki disease. *Left,* Giant aneurysm of the left anterior descending coronary artery (LAD) with obstruction. *Right,* Giant aneurysm of the right coronary artery (RCA) with an area of severe narrowing. (From Newburger JW, Takahashi M, Gerber MA, et al: Diagnosis, treatment, and long-term management of Kawasaki disease, *Pediatrics* 114:1708–1733, 2004.)**

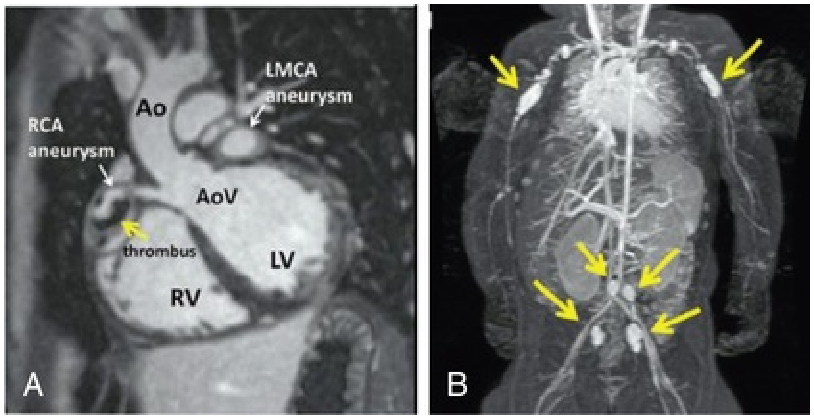

FIG. 191.8 MRI of coronary and peripheral artery aneurysms in Kawasaki disease. A, Image of left ventricular outflow tract showing a giant right coronary artery (RCA) aneurysm with nonocclusive thrombus *(yellow arrow)* and a giant left main coronary artery (LMCA) aneurysm. Ao, Aorta; AoV, aortic valve; LV, left ventricle; RV, right ventricle. B, Aneurysms in the axillary and subclavian arteries and the iliac and femoral arteries *(yellow arrows)* . (From McCrindle BW, Rowley A, Newburger JW et al: Diagnosis, treatment, and long-term management of Kawasaki disease: a scientific statement for health professionals from the American Heart Association, *Circulation* 135(17):e927-e999, 2017, Fig 2GH, p e935.)

Occasionally KD initially presents with only fever and lymphadenopathy (**node-first KD**). This presentation may be confused with bacterial or viral cervical lymphadenopathy or lymphadenitis and may delay the diagnosis of KD. Persistence of high fever, lack of response to antibiotics, and subsequent development of other signs of KD suggest the diagnosis. Children with node-first KD tend to be older (4 vs 2 yr) and have more days of fever and higher CRP levels. In addition to cervical adenopathy, many had retropharyngeal and peritonsillar inflammation on CT scans (Fig. 191.9).

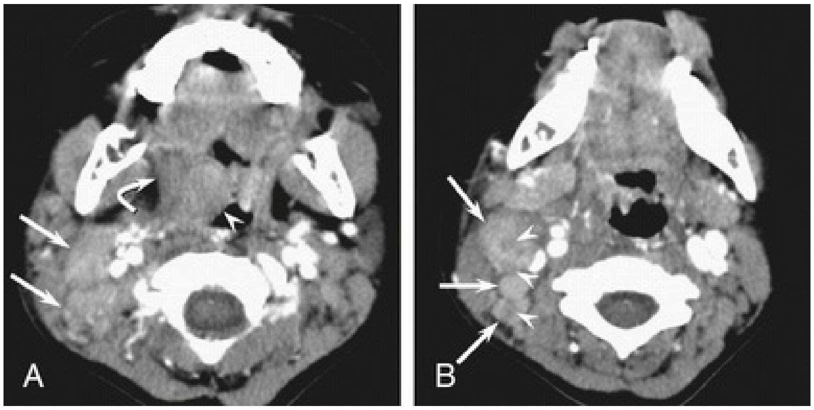

FIG. 191.9 Contrast-enhanced CT in 3 yr old boy with Kawasaki disease. A, Right-sided cervical lymphadenopathy *(arrows),* peritonsillar hypodense area *(curved arrow),* and swelling of right palatine tonsil *(arrowhead).* B, Right-sided cervical lymphadenopathy

with perinodal infiltration *(arrows)* and intranodal focal low attenuation *(arrowheads).* (From Kato H, Kanematsu M, Kato Z, et al: Computed tomographic findings of Kawasaki disease with cervical lymphadenopathy, *J Comput Assist Tomogr* 36(1):138–142, 2012, Fig 1, p 139.)

KD can be divided into 3 clinical phases. The **acute febrile phase** is characterized by fever and the other acute signs of illness and usually lasts 1-2 wk. The **subacute phase** is associated with desquamation, thrombocytosis, development of CAA, and the highest risk of sudden death in patients who develop aneurysms; it generally lasts 3 wk. The **convalescent phase** begins when all clinical signs of illness have disappeared and continues until the erythrocyte sedimentation rate (ESR) returns to normal, typically 6-8 wk after the onset of illness.

Laboratory and Radiology Findings

There is no diagnostic test for KD, but patients usually have characteristic laboratory findings. The leukocyte count is often elevated, with a predominance of neutrophils and immature forms. Normocytic, normochromic anemia is common. The platelet count is generally normal in the 1st wk of illness and rapidly increases by the 2nd to 3rd wk of illness, sometimes exceeding 1 million/mm^3 . An elevated ESR or CRP value is universally present in the acute phase of illness. The ESR may remain elevated for weeks, in part from the effect of IVIG. Sterile pyuria, mild elevations of the hepatic transaminases, hyperbilirubinemia, and cerebrospinal fluid pleocytosis may also be present. KD is unlikely if the ESR, CRP, and platelet counts are normal after 7 days of fever.

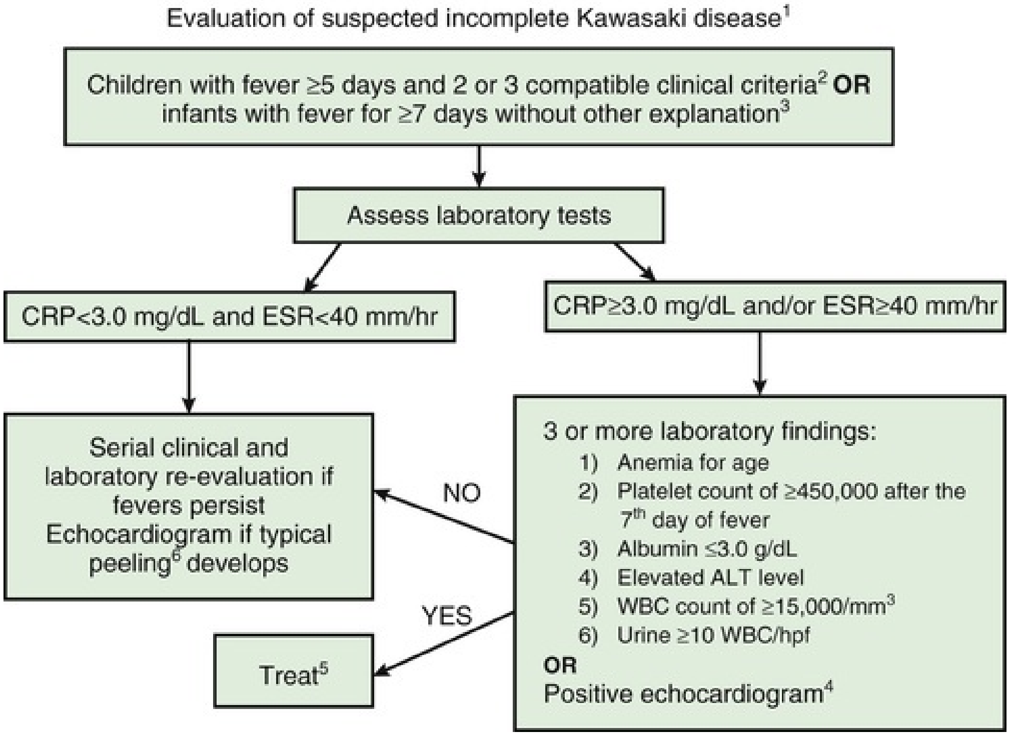
Two-dimensional echocardiography is the most useful test to monitor for development of CAA. Although frank aneurysms are rarely detected in the 1st week of illness, coronary arteries are commonly ectatic. Moreover, coronary artery dimensions, adjusted for BSA (*z* scores), may be increased in the 1st 5 wk after presentation, and as previously noted, baseline *z* scores may offer prognostic information regarding ultimate coronary artery dimensions. Children with non-KD febrile illnesses also have mildly increased *z* scores compared with nonfebrile controls, but not to the same degree as patients with KD. Aneurysms have been defined with use of absolute dimensions by the Japanese Ministry of Health and are classified as small (≤4 mm internal diameter [ID]), medium (>4 to ≤8 mm ID), or giant (>8 mm ID). Some experts believe that a *z* -score–based system for classification of aneurysm size may be more discriminating, because it adjusts the coronary dimension for BSA. The AHA *z* -score classification system is as follows:

1. No involvement: always <2
2. Dilation only: 2 to <2.5; or if initially <2, a decrease in *z* score during follow-up ≥1
3. Small aneurysm: ≥2.5 to <5
4. Medium aneurysm: ≥5 to <10, and absolute dimension <8 mm
5. Large or giant aneurysm: ≥10, or absolute dimension ≥8 mm

Echocardiography should be performed at diagnosis and again after 1-2 wk of illness. If the results are normal, a repeat study should be performed 6-8 wk after onset of illness. If results of either of the initial studies are abnormal or the patient has recurrent fever or symptoms, more frequent echocardiography or other studies may be necessary. In patients without CCA at any time during the illness, echocardiography and a lipid profile are recommended 1 yr later. After this time, periodic evaluation for preventive cardiology counseling is warranted, and some experts recommend cardiologic follow-up every 5 yr. For patients with CAA, the type of testing and the frequency of cardiology follow-up visits are tailored to the patient's coronary status.

Diagnosis

The diagnosis of KD is based on the presence of characteristic clinical signs. For **classic KD** the diagnostic criteria require the presence of fever for at least 4 days and at least 4 of 5 of the other principal characteristics of the illness (see Table 191.1). The diagnosis of KD should be made within 10 days, and ideally within 7 days, of fever onset to improve coronary artery outcomes. In **atypical or incomplete KD** , patients have persistent fever but <4 of the 5 characteristic clinical signs. In these patients, laboratory and echocardiographic data can assist in the diagnosis (Fig. 191.10). Incomplete cases occur most frequently in infants, who also have the highest likelihood of development of CAA. Ambiguous cases should be referred to a center with experience in the diagnosis of KD. Establishing the diagnosis with prompt institution of treatment is essential to prevent potentially devastating coronary artery disease. For this reason, *it is recommended that any infant age ≤6 mo with fever for ≥7 days* *without explanation undergo echocardiography to assess the coronary arteries.*



Evaluation of suspected incomplete Kawasaki disease[1]
Children with fever ≥5 days and 2 or 3 compatible clinical criteria[2] OR infants with fever for ≥7 days without other explanation[3]
Assess laboratory tests
CRP<3.0 mg/dL and ESR<40 mm/hr
CRP≥3.0 mg/dL and/or ESR≥40 mm/hr
Serial clinical and laboratory re-evaluation if fevers persist
Echocardiogram if typical peeling[6] develops
NO
YES
Treat[5]
3 or more laboratory findings:
1) Anemia for age
2) Platelet count of ≥450,000 after the 7th day of fever
3) Albumin ≤3.0 g/dL
4) Elevated ALT level
5) WBC count of ≥15,000/mm3
6) Urine ≥10 WBC/hpf
OR
Positive echocardiogram[4]

FIG. 191.10 Evaluation of suspected incomplete Kawasaki disease (KD). [1] In the absence of a gold standard for diagnosis of KD, this algorithm cannot be evidence based but rather represents the informed opinion of the expert committee. Consultation with an expert should be sought any time assistance is needed. [2] Clinical findings of KD are listed in Table 191.1 . Characteristics suggesting that another diagnosis should be considered include exudative conjunctivitis, exudative pharyngitis, ulcerative intraoral lesions, bullous or vesicular rash, generalized adenopathy, and splenomegaly. [3] Infants ≤6 mo of age are most likely to develop prolonged fever without other clinical criteria for KD; these infants are at particularly high risk of developing coronary artery abnormalities. [4] Echocardiography is considered positive for purposes of this algorithm if any of 3 conditions are met: z score of left anterior descending coronary artery or right coronary artery ≥2.5; coronary artery aneurysm is observed; or ≥3 other suggestive features exist, including decreased left ventricular function, mitral regurgitation, pericardial effusion, or z scores in left anterior descending coronary artery or right coronary artery of 2-2.5. [5] If the echocardiogram is positive, treatment should be given within 10 days of fever onset or after the 10th day of fever in the presence of clinical and laboratory signs (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) of ongoing inflammation. [6] Typical peeling begins under the nail beds of fingers and toes. ALT, Alanine transaminase; WBC, white blood cell. (From McCrindle BW, Rowley A, Newburger JW et al: Diagnosis, treatment, and long-term management of Kawasaki disease: a scientific statement for health professionals from the American Heart Association, *Circulation* 135(17):e927–e999, 2017, Fig 2, p e937.)

Differential Diagnosis

Adenovirus, measles, and scarlet fever lead the list of common childhood infections that mimic KD (Table 191.2). Children with **adenovirus** typically have exudative pharyngitis and exudative conjunctivitis, allowing differentiation from KD. A common clinical problem is the differentiation of **scarlet fever** from KD in a child who is a group A streptococcal carrier. Patients with scarlet fever typically have a rapid clinical response to appropriate antibiotic therapy. Such treatment for 24-48 hr with clinical reassessment generally clarifies the diagnosis. Furthermore, ocular findings are quite rare in group A streptococcal pharyngitis and may assist in the diagnosis of KD.

Table 191.2

Differential Diagnosis of Kawasaki Disease

Viral Infections*

- Adenovirus
- Enterovirus
- Measles
- Epstein-Barr virus
- Cytomegalovirus

Bacterial Infections

- Scarlet fever
- Rocky Mountain spotted fever
- Leptospirosis
- Bacterial cervical lymphadenitis ± retropharyngeal phlegmon
- Meningococcemia
- Urinary tract infection

Rheumatologic Disease

- Systemic-onset juvenile idiopathic arthritis
- Behçet disease
- Rheumatic fever

Other

- Toxic shock syndromes
- Serum sickness
- Staphylococcal scalded skin syndrome
- Macrophage activation syndrome
- Drug hypersensitivity reactions
- Stevens-Johnson syndrome
- Aseptic meningitis

---

[*] Detection of a virus does not exclude Kawasaki disease in the presence of the principal clinical features (see Table 191.1).

Features of **measles** that distinguish it from KD include exudative conjunctivitis, Koplik spots, rash that begins on the face and hairline and behind the ears, and leukopenia. **Cervical lymphadenitis** can be the initial diagnosis in children who are ultimately recognized to have KD. Less common infections such as Rocky Mountain spotted fever and leptospirosis are occasionally confused with KD. **Rocky Mountain spotted fever** is a potentially lethal bacterial infection, and appropriate antibiotics should not be withheld if the diagnosis is under consideration. Its distinguishing features include pronounced myalgias and headache at onset, centripedal rash, and petechiae on the palms and soles. **Leptospirosis** can also be an illness of considerable severity. Risk factors include exposure to water contaminated with urine from infected animals. The classic description of leptospirosis is of a biphasic illness with a few asymptomatic days between an initial period of fever and headache and a late phase with renal and hepatic failure. In contrast, patients with KD have consecutive days of fever at diagnosis and rarely have renal or hepatic failure.

Children with KD and pronounced myocarditis may demonstrate hypotension with a clinical picture similar to that of toxic shock syndrome. Features of **toxic shock syndrome** that are not usually seen in KD include renal insufficiency, coagulopathy, pancytopenia, and myositis. Drug hypersensitivity reactions, including Stevens-Johnson syndrome, share some characteristics with KD. Drug reaction features such as the presence of periorbital edema, oral ulcerations, and a normal or minimally elevated ESR are not seen in KD. Systemic-onset

juvenile idiopathic arthritis (sJIA) is also characterized by fever and rash, but physical findings include diffuse lymphadenopathy and hepatosplenomegaly. Arthritis is required to develop at some point in the disease course to make the diagnosis, but may not be present in the 1st few wk of illness. Laboratory findings may include coagulopathy, elevated fibrin degradation product values, and hyperferritinemia. Interestingly, there are reports of children with sJIA who have echocardiographic evidence of CAA. Coronary aneurysms have also been reported in Behçet disease, primary cytomegalovirus infection, and meningococcemia.

Treatment

Patients with acute KD should be treated with 2 g/kg of IVIG as a single infusion, usually administered over 10-12 hr within 10 days of disease onset, and ideally as soon as possible after diagnosis (Table 191.3). In addition, moderate (30-50 mg/kg/day divided every 6 hr) to high-dose aspirin (80-100 mg/kg/day divided every 6 hr) should be administered until the patient is afebrile, then lowered to antiplatelet doses. Other NSAIDs should not be given during therapy with aspirin because they may block the action of aspirin. The mechanism of action of IVIG in KD is unknown, but treatment results in defervescence and resolution of clinical signs of illness in approximately 85% of patients. The prevalence of coronary disease, in 20–25% in children treated with aspirin alone, is <5% in those treated with IVIG and aspirin within the 1st 10 days of illness. Strong consideration should be given to treating patients with persistent fever, abnormal dimensions of the coronary arteries, or signs of systemic inflammation who are diagnosed after the 10th day of fever. The dose of aspirin is usually decreased from antiinflammatory to antithrombotic doses (3-5 mg/kg/day as a single dose) after the patient has been afebrile for 48 hr. Aspirin is continued for its antithrombotic effect until 6-8 wk after illness onset and is then discontinued in patients who have had normal echocardiography findings throughout the course of their illness. Patients with CAA continue with aspirin therapy and may require anticoagulation, depending on the degree of coronary dilation (see later).

Table 191.3

Treatment of Kawasaki Disease

Acute Stage

Intravenous immune globulin 2 g/kg over 10-12 hr
and
Aspirin 30-50 mg/kg/day or 80-100 mg/kg/day divided every 6 hr orally until patient is afebrile for at least 48 hr

Convalescent Stage

Aspirin 3-5 mg/kg once daily orally until 6-8 wk after illness onset if normal coronary findings throughout course

Long-Term Therapy for Patients With Coronary Abnormalities

Aspirin 3-5 mg/kg once daily orally
Clopidogrel 1 mg/kg/day (maximum 75 mg/day)
Most experts add warfarin or low-molecular-weight heparin for those patients at particularly high risk of thrombosis

Acute Coronary Thrombosis

Prompt fibrinolytic therapy with tissue plasminogen activator or other thrombolytic agent under supervision of a pediatric cardiologist

Corticosteroids have been used as primary therapy with the 1st dose of IVIG in hopes of improving coronary outcomes. A North American trial using a single pulse dose of intravenous methylprednisolone (30 mg/kg) with IVIG as primary therapy did not improve coronary outcomes. However, a trial in Japan utilizing the Kobayashi score to identify high-risk children demonstrated improved coronary outcomes with a regimen of prednisolone (2 mg/kg) plus IVIG as primary therapy. Furthermore, a systematic review and meta-analysis of 16 comparative studies demonstrated that early treatment with corticosteroids improved coronary artery outcomes in children with KD. Despite these promising results, administration of corticosteroids as primary therapy to all children with KD awaits the development of a risk score that identifies high-risk children in a multiracial population.

IVIG-resistant KD occurs in approximately 15% of patients and is defined by persistent or recrudescent fever 36 hr after completion of the initial IVIG infusion. Patients with IVIG resistance are at increased risk for CAA. Therapeutic options for the child with IVIG resistance include a 2nd dose of IVIG (2 g/kg), a tapering course of corticosteroids, and/or infliximab (Table 191.4). For the most severely affected patients with enlarging coronary aneurysms, additional therapies such as cyclosporine or cyclophosphamide may be administered, with consultation from specialists in pediatric rheumatology and cardiology.

Table 191.4

Treatment Options for IVIG-Resistant Patients With Kawasaki Disease[*]

AGENT	DESCRIPTION	DOSE
MOST FREQUENTLY ADMINISTERED		
IVIG: 2nd infusion	Pooled polyclonal IG	2 g/kg IV
IVIG + prednisolone	IVIG + corticosteroid	IVIG: 2 g/kg IV + prednisolone 2 $mg \cdot kg^{-1} \cdot d^{-1}$ IV divided every 8 hr until afebrile, then prednisone orally until CRP normalized, then taper over 2-3 wk
Infliximab	Monoclonal antibody against TNF-α	Single infusion: 5 mg/kg IV given over 2 hr
ALTERNATIVE TREATMENTS		
Cyclosporine	Inhibitor of calcineurin-NFAT pathway	IV: 3 $mg \cdot kg^{-1} \cdot d^{-1}$ divided every 12 hr PO: 4-8 $mg \cdot kg^{-1} \cdot d^{-1}$ divided every 12 hr Adjust dose to achieve trough 50-150 ng/mL; 2 hr peak level 300-600 ng/mL
Anakinra	Recombinant IL-1β receptor antagonist	2-6 $mg \cdot kg^{-1} \cdot d^{-1}$ given by subcutaneous injection
Cyclophosphamide	Alkylating agent blocks DNA replication	2 $mg \cdot kg^{-1} \cdot d^{-1}$ IV
Plasma exchange	Replaces plasma with albumin	Not applicable

[*] IVIG resistance is defined as persistent or recrudescent fever at least 36 hours and <7 days after completion of 1st IVIG infusion. The top 3 treatments have been most frequently used, although no comparative effectiveness trial has been performed. Pulsed high-dose corticosteroid treatment is not recommended. The alternative treatments have been used in a limited number of patients with KD.

CRP, C-reactive protein; IG, immunoglobulin; IL, interleukin; IV, intravenous(ly); IVIG, intravenous immune globulin; NFAT, nuclear factor of activated T cells; PO, oral; TNF, tumor necrosis factor.

Complications

Patients with KD and aneurysms may experience myocardial infarction, angina, and sudden death. For this reason, antithrombotic medications are the cornerstone of therapy for the child with coronary disease. Aspirin is continued indefinitely in children with coronary aneurysms. When aneurysms are moderate sized, dual-antiplatelet therapy is sometimes administered. For those with large or giant aneurysms, anticoagulation with warfarin or low-molecular-weight heparin is added to aspirin. For acute thrombosis that occasionally occurs in an aneurysmal or stenotic coronary artery, thrombolytic therapy may be lifesaving.

Long-term follow-up of patients with coronary artery aneurysms is tailored to the past (i.e., worst-ever) and current coronary status, with a schedule of testing recommended in the 2017 AHA scientific statement on KD. Testing may include echocardiography, assessment for inducible ischemia, advanced imaging (CT, MRI, or invasive angiography), physical activity counseling, and cardiovascular risk factor assessment and management. Patients with coronary artery stenosis and inducible ischemia may be managed with coronary artery bypass grafting (CABG) or catheter interventions, including percutaneous transluminal coronary rotational ablation, directional coronary atherectomy, and stent implantation.

Patients undergoing long-term aspirin therapy should receive annual influenza vaccination to reduce the risk of Reye syndrome. A different antiplatelet agent can be substituted for aspirin during the 6 wk after varicella vaccination. IVIG may interfere with the immune response to live-virus vaccines as a result of specific antiviral antibody, so the measles-mumps-rubella and varicella vaccinations should generally be deferred until 11 mo after IVIG administration. Nonlive vaccinations do not need to be delayed.

Prognosis

The vast majority of patients with KD return to normal health; timely treatment reduces the risk of coronary aneurysms to <5%. Acute KD recurs in 1–3% of cases. The prognosis for patients with CCA depends on the severity of coronary disease; therefore, recommendations for follow-up and management are stratified according to coronary artery status. Published fatality rates are very low, generally <1.0%. Overall, 50% of coronary artery aneurysms regress to normal lumen diameter by 1-2 yr after the illness, with smaller aneurysms being more likely to regress. Intravascular ultrasonography has demonstrated that regressed aneurysms are associated with marked myointimal thickening and abnormal functional behavior of the vessel wall. Giant aneurysms are less likely to regress to normal lumen diameter and are most likely to lead to thrombosis or stenosis. CABG may be required if there is inducible ischemia; it is best accomplished with the use of arterial grafts, which grow with the child and are more likely than venous grafts to remain patent over the long-term. Heart transplantation has been required in rare cases where revascularization is not feasible because of distal coronary stenoses, distal aneurysms, or severe ischemic cardiomyopathy. A study from Japan reported outcomes in adult patients with a history of KD and giant aneurysms. These patients required multiple cardiac and surgical procedures, but the 30-yr survival rate approached 90%.

Whether children who have had KD and normal echocardiography findings throughout their course are at higher risk for the development of atherosclerotic heart disease in adulthood remains unclear. Studies of endothelial dysfunction in children with a history of KD and normal coronary dimensions have produced conflicting results. However, reassuring data suggest that the standardized mortality ratio among adults in Japan who had KD in childhood without aneurysms is indistinguishable from that of the general population. All children with a history of KD should be counseled regarding a heart-healthy diet, adequate amounts of exercise, tobacco avoidance, and intermittent lipid monitoring. Among children with coronary aneurysms, the AHA recommends treatment thresholds for risk factors for atherosclerotic heart disease that are lower than those for the normal population.

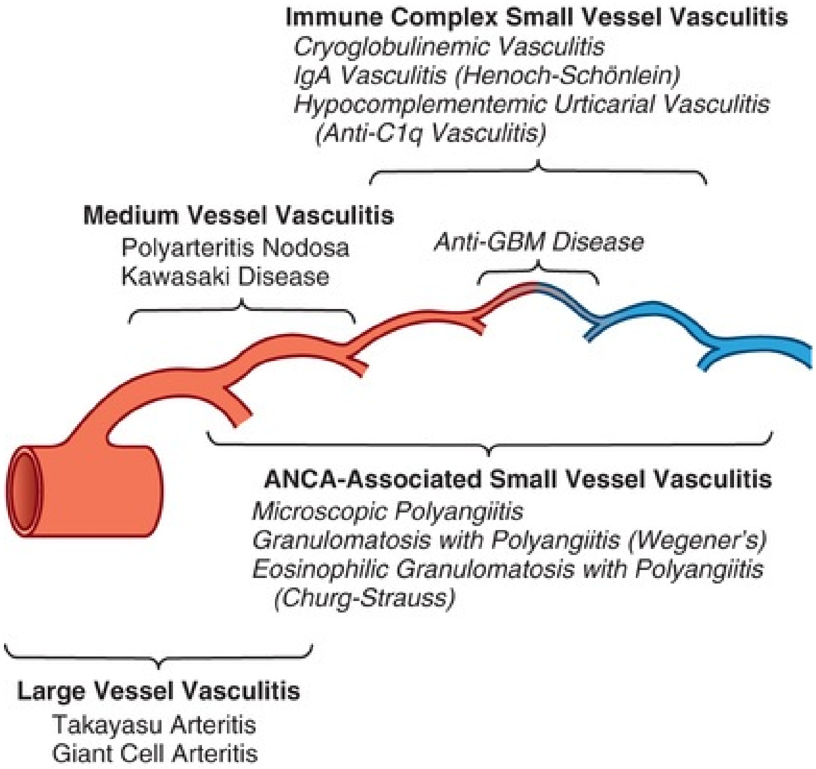
CHAPTER 192

Vasculitis Syndromes

Vidya Sivaraman, Edward C. Fels, Stacy P. Ardoin

Childhood vasculitis encompasses a broad spectrum of diseases that share inflammation of the blood vessels as the central pathophysiology. The pathogenesis of the vasculitides is generally idiopathic. Some forms of vasculitis are associated with infectious agents and medications, whereas others may occur in the setting of preexisting autoimmune disease. The pattern of vessel injury provides insight into the form of vasculitis and serves as a framework to delineate the different vasculitic syndromes. The distribution of vascular injury includes *small vessels* (capillaries, arterioles, and postcapillary venules), *medium vessels* (renal arteries, mesenteric vasculature, and coronary arteries), and *large vessels* (the aorta and its proximal branches) (Fig. 192.1). Additionally, some forms of small vessel vasculitis are characterized by the presence of **antineutrophil cytoplasmic antibodies (ANCAs)** , whereas others are associated with **immune complex** deposition in affected tissues. A combination of clinical features, histologic appearance of involved vessels, and laboratory data is used to classify vasculitis (Tables 192.1 to 192.3). A nomenclature system from the 2012 International Chapel Hill Consensus Conference has proposed using the pathologic diagnosis rather than eponyms for vasculitis nomenclature. For example, Henoch-Schönlein purpura would be referred to as IgA vasculitis. Additionally, the classification criteria endorsed by the European League Against Rheumatism, Pediatric Rheumatology International Trial Organization, and Pediatric Rheumatology European Society (EULAR/PRINTO/PRES) have been validated in childhood vasculitis. (Table 192.1).



Immune Complex Small Vessel Vasculitis
Cryoglobulinemic Vasculitis
IgA Vasculitis (Henoch-Schönlein)
Hypocomplementemic Urticarial Vasculitis
(Anti-C1q Vasculitis)
Medium Vessel Vasculitis
Polyarteritis Nodosa
Kawasaki Disease
Anti-GBM Disease
ANCA-Associated Small Vessel Vasculitis
Microscopic Polyangiitis
Granulomatosis with Polyangiitis (Wegener's)
Eosinophilic Granulomatosis with Polyangiitis
(Churg-Strauss)
Large Vessel Vasculitis
Takayasu Arteritis
Giant Cell Arteritis

FIG. 192.1 **Distribution of vessel involvement in large, medium, and small vessel vasculitis. There is substantial overlap with respect to arterial involvement, and all 3 major categories of vasculitis can affect any-size artery. Large vessel vasculitis affects large arteries more often than other vasculitides. Medium vessel vasculitis predominantly affects medium arteries. Small vessel vasculitis predominantly affects small vessels, but medium arteries and veins may be affected, although immune complex small vessel vasculitis rarely affects arteries. Not shown is *variable vessel vasculitis* , which can affect any type of vessel, from aorta to veins. The diagram depicts (from *left* to *right*) aorta, large artery, medium artery, small artery/arteriole, capillary, venule, and vein. ANCA, Antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane. (From Jennette JC, Falk RJ, Bacon PA, et al: 2012 Revised International Chapel Hill Consensus Conference Nomenclature of Vasculitides, *Arthritis Rheum* 65(1):1–11, 2013, Fig 2, p 4.)**

Table 192.2

Features That Suggest a Vasculitic Syndrome

Clinical Features

Fever, weight loss, fatigue of unknown origin
Skin lesions (palpable purpura, fixed urticaria, livedo reticularis, nodules, ulcers)
Neurologic lesions (headache, mononeuritis multiplex, focal central nervous system lesions)
Arthralgia or arthritis, myalgia, or myositis, serositis
Hypertension, hematuria, renal failure
Pulmonary infiltrates or hemorrhage
Myocardial ischemia, arrhythmias

Laboratory Features

Increased erythrocytes sedimentation rate or C-reactive protein level
Leukocytosis, anemia, thrombocytosis
Eosinophilia
Antineutrophil cytoplasmic antibodies
Elevated factor VIII–related antigen (von Willebrand factor)
Cryoglobulinemia
Circulating immune complexes
Hematuria

From Petty RE, Laxer RM, Lindsley CB, Wedderburn LR: *Textbook of pediatric rheumatology,* ed 7, Philadelphia, 2016, Elsevier Saunders.

Table 192.3

Clinicopathologic Characteristics of Vasculitides in Childhood

SYNDROME	FREQUENCY	VESSELS AFFECTED	CHARACTERISTIC PATHOLOGY
Polyarteritis			
Polyarteritis nodosa	Rare	Medium-size and small muscular arteries and sometimes arterioles	Focal segmental (often near bifurcations); fibrinoid necrosis; gastrointestinal, renal microaneurysms; lesions at various stages of evolution
Kawasaki disease	Common	Coronary and other muscular arteries	Thrombosis, fibrosis, aneurysms, especially of coronary vessels
Leukocytoclastic Vasculitis			
Henoch-Schönlein purpura (IgA vasculitis)	Common	Arterioles and venules, often small arteries and veins	Leukocytoclasis; mixed cells, eosinophils, IgA deposits in affected vessels
Hypersensitivity angitis	Rare	Arterioles and venules	Leukocytoclastic or lymphocytic, varying eosinophils, occasionally granulomatous; widespread lesions at same stage of evolution
Granulomatous Vasculitis			
Granulomatosis with polyangiitis (Wegener granulomatosis)	Rare	Small arteries and veins, occasionally larger vessels	Upper and lower respiratory tract, necrotizing granulomata glomerulonephritis
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)	Rare	Small arteries and veins, often arterioles and venules	Necrotizing extravascular granulomata; lung involvement; eosinophilia
Giant Cell Arteritis			
Takayasu arteries	Uncommon	Large arteries	Granulomatous inflammation, giant cells; aneurysms, dissection
Temporal arteritis	Rare	Medium-size and large arteries	Granulomatous inflammation, giant cell arteries

Adapted from Cassidy JT, Petty RE: *Textbook of pediatric rheumatology,* ed 6, Philadelphia, 2011, Elsevier Saunders.

Childhood vasculitis varies from a relatively benign and self-limited disease such as Henoch-Schönlein purpura to catastrophic disease with end-organ damage, as seen in granulomatosis with polyangiitis (formerly Wegener granulomatosis). Vasculitis generally manifests as a heterogeneous multisystem disease. Although some features, such as purpura, are easily identifiable, others, such as hypertension secondary to renal artery occlusion or glomerulonephritis, can be subtler. Ultimately, the key to recognizing vasculitis relies heavily on *pattern recognition.* Demonstration of vessel injury and inflammation on biopsy or vascular imaging is required to confirm a diagnosis of vasculitis.

192.1

Henoch-Schönlein Purpura

Vidya Sivaraman, Edward C. Fels, Stacy P. Ardoin

Henoch-Schönlein purpura (**HSP**) is the most common vasculitis of childhood and is characterized by leukocytoclastic vasculitis and immunoglobulin A deposition in the small vessels in the skin, joints, gastrointestinal tract, and kidney. According to the 2012 International Chapel Hill Consensus Conference nomenclature, HSP is also referred to as **IgA vasculitis** , based on the presence of vasculitis with predominance of IgA deposits affecting small vessels.

Epidemiology

HSP occurs worldwide and affects all ethnic groups but is more common in white and Asian populations. The incidence of HSP is estimated at 14-20 per 100,000 children per year and affects males more than females, with a 1.2-1.8 : 1 male/female ratio. Approximately 90% of HSP cases occur in children, usually between ages 3 and 10 yr. HSP is distinctly less common in adults, who often have severe and chronic complications. HSP is more common in the winter and spring and is unusual in summer months. Many cases of HSP follow a documented upper respiratory infection.

Pathology

Skin biopsies demonstrate **leukocytoclastic vasculitis** of the dermal capillaries and postcapillary venules. The inflammatory infiltrate includes neutrophils and monocytes. Renal histopathology typically shows endocapillary proliferative glomerulonephritis, ranging from a focal segmental process to extensive crescentic involvement. In all tissues, immunofluorescence identifies IgA deposition in walls of small vessels (Fig. 192.2), accompanied to a lesser extent by deposition of C3, fibrin, and IgM.

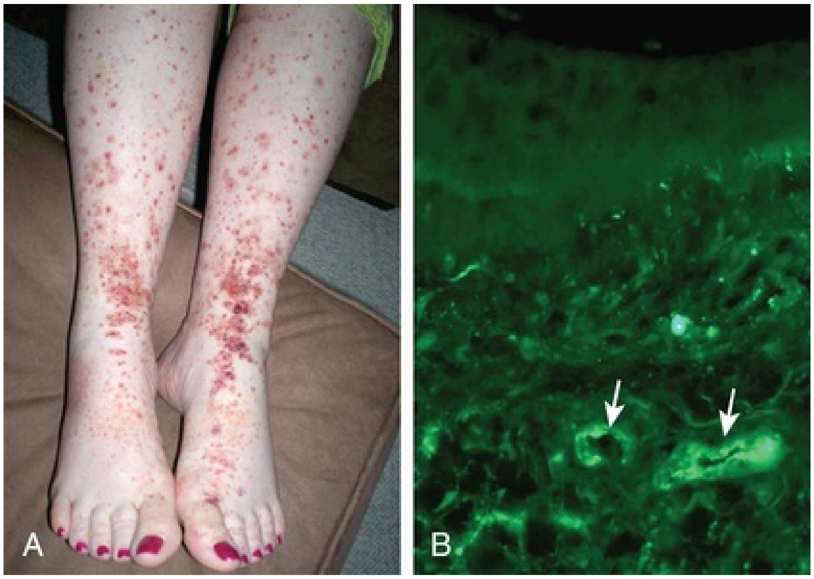

FIG. 192.2 **Girl with Henoch-Schönlein purpura. A, Typical palpable purpura in lower extremities. B, Skin biopsy of lesion shows direct immunofluorescence of IgA *(arrows)* within the walls of dermal capillaries.**

Pathogenesis

The exact pathogenesis of HSP remains unknown. Given the seasonality of HSP and the frequency of preceding upper respiratory infections, infectious triggers such as group A β-hemolytic streptococcus, *Staphylococcus aureus,* mycoplasma, and adenovirus have been suspected. The common finding of deposition of IgA, specifically IgA_1 , suggests that HSP is a disease mediated by IgA and IgA immune complexes. HSP occasionally clusters in families, suggesting a genetic component. HLA-B34 and HLA-DRB1*01 alleles have been linked to HSP nephritis. Patients with familial Mediterranean fever, hereditary periodic fever syndromes, and complement deficiencies are at increased risk for developing HSP, suggesting that genetically determined immune dysregulation may contribute.

Clinical Manifestations

The hallmark of HSP is its **rash** : palpable purpura starting as pink macules or wheals and developing into petechiae, raised purpura, or larger ecchymoses. Occasionally, bullae and ulcerations develop. The skin lesions are usually symmetric and occur in gravity-dependent areas (lower extremities), extensor aspect of the upper extremities or on pressure points (buttocks) (Figs. 192.2 and 192.3). The skin lesions often evolve in groups, typically lasting 3-10 days, and may recur up to 4 mo after initial presentation. Subcutaneous edema localized to the dorsa of hands and feet, periorbital area, lips, scrotum, or scalp is also common.

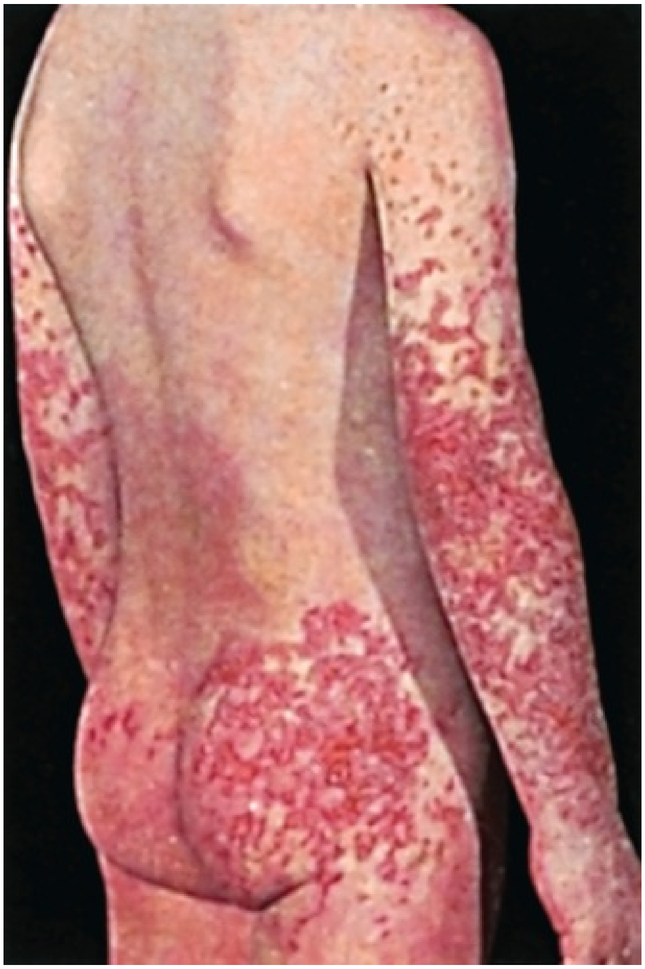

FIG. 192.3 **Henoch-Schönlein purpura. (From Korting GW: *Hautkrankheiten bei Kindern und Jungendlichen,* ed 3, Stuttgart, 1982, FK Schattaur Verlag.)**

Musculoskeletal involvement, including arthritis and arthralgias, is common, occurring in up to 75% of children with HSP. The arthritis tends to be self-limited and oligoarticular, with a predilection for large joints such as the knees and ankles, and does not lead to deformities. Periarticular swelling and tenderness without erythema or effusions are common. The arthritis usually resolves within 2 wk but can recur.

Gastrointestinal (GI) manifestations occur in up to 80% of children with HSP and include abdominal pain, vomiting, diarrhea, paralytic ileus, and melena. Intussusception, mesenteric ischemia, and intestinal perforation are rare but serious complications. Endoscopic evaluation is usually not needed but may identify vasculitis of the intestinal tract.

Renal involvement occurs in up to 30% of children with HSP, manifesting as microscopic hematuria, proteinuria, hypertension, frank nephritis, nephrotic syndrome, and acute or chronic renal failure. However, progression to end-stage renal disease (ESRD) is uncommon in children (1–2%) (see Chapter 538.3). Renal manifestations can be delayed for several months after the initial illness, so close follow-up with serial urinalyses and blood pressure monitoring is necessary.

Neurologic manifestations of HSP, caused by hypertension (posterior reversible encephalopathy syndrome) or central nervous system (CNS) vasculitis, may also occur, including intracerebral hemorrhage, seizures, headaches, depressed level of consciousness, cranial or peripheral neuropathies, and behavior changes. Other, less common potential manifestations of HSP are inflammatory eye disease, carditis, pulmonary hemorrhage, orchitis, and testicular torsion.

Diagnosis

The diagnosis of HSP is clinical and often straightforward when the typical rash is present. However, in at least 25% of cases, the rash appears after other manifestations, making early diagnosis challenging. Table 192.4 summarizes the EULAR/PRES classification criteria for HSP. Most patients are afebrile.

Table 192.4

Classification Criteria for Henoch-Schönlein Purpura*

European League Against Rheumatism/Pediatric Rheumatology European Society Criteria [†]

Palpable purpura (in absence of coagulopathy or thrombocytopenia) and 1 or more of the following criteria must be present:

- Abdominal pain (acute, diffuse, colicky pain)
- Arthritis or arthralgia
- Biopsy of affected tissue demonstrating predominant IgA deposition
- Renal involvement (proteinuria >3 g/24 hr), hematuria or red cell casts

---

[*] Classification criteria are developed for use in research and not validated for clinical diagnosis.

[†] Developed for use in pediatric populations only.

Adapted from Ozen S, Pistorio A, Iusan SM, et al: EULAR/PRINTO/PRES criteria for Henoch-Schönlein purpura, childhood polyarteritis nodosa, childhood Wegener granulomatosis and childhood Takayasu arteritis: Ankara 2008. Part II. Final classification criteria, *Ann Rheum Dis* 69:798–806; 2010.

The **differential diagnosis** for HSP depends on specific organ involvement but usually includes other small vessel vasculitides, infections, acute poststreptococcal glomerulonephritis, hemolytic-uremic syndrome, coagulopathies, and other acute intraabdominal processes. Additional disorders in the differential include papular-purpuric glove and sock syndrome, systemic lupus erythematosus (SLE), other vasculitides (urticarial, hypersensitivity), and thrombocytopenia.

Infantile acute hemorrhagic edema (AHE) , an isolated cutaneous leukocytoclastic vasculitis that affects infants <2 yr of age, resembles HSP clinically. AHE manifests as fever; tender edema of the face, scrotum, hands, and feet; and ecchymosis (usually larger than the purpura of HSP) on the face and extremities (Fig. 192.4). The trunk is spared, but petechiae may be seen in mucous membranes. The patient usually appears well except for the rash. The platelet count is normal or elevated, and the urinalysis results are normal. The younger age, the nature of the lesions, absence of other organ involvement, and a biopsy may help distinguish infantile AHE from HSP.

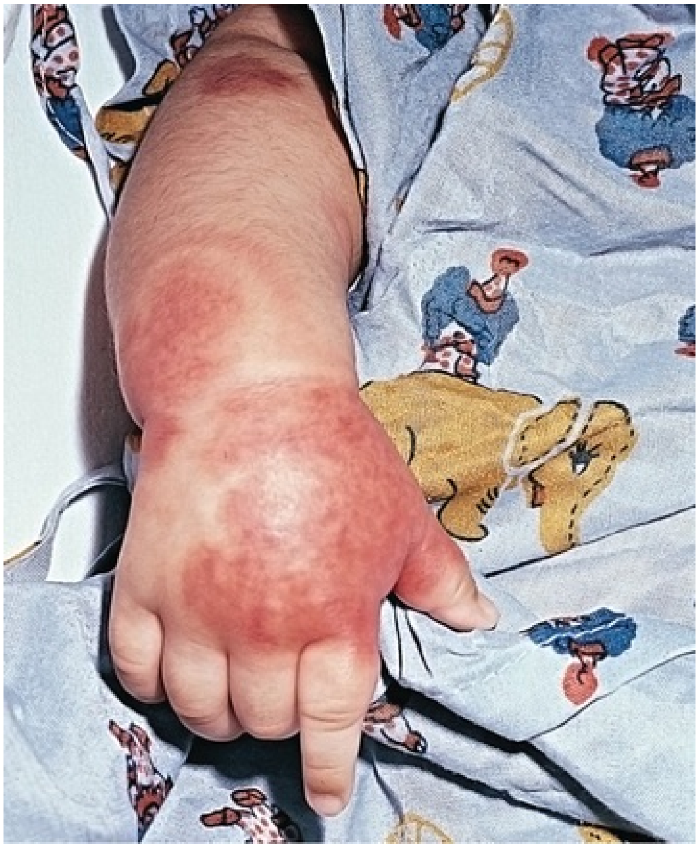

FIG. 192.4 **Infantile acute hemorrhagic edema. Typical lesions on the arm of an infant. (From Eichenfield LF, Frieden IJ, Esterly NB: *Textbook of neonatal dermatology,* Philadelphia, 2001, WB Saunders.)**

Laboratory Findings

No laboratory finding is diagnostic of HSP. Common but nonspecific findings include leukocytosis, thrombocytosis, mild anemia, and elevations of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). *The platelet count is normal in HSP* . Occult blood is frequently found in stool specimens. Serum albumin levels may be low because of renal or intestinal protein loss. Autoantibody testing such as antinuclear antibody (ANA) is not useful diagnostically except to exclude other diseases. Serum IgA values are often elevated but are not routinely measured. Assessment of renal involvement with blood pressure, urinalysis, and serum creatinine is necessary.

Ultrasound is often used in the setting of GI complaints to look for bowel wall edema or the rare occurrence of an associated intussusception. Barium enema can also be used to both diagnose and treat intussusception. Although often unnecessary in typical HSP, biopsies of skin and kidney can provide important diagnostic information, particularly in atypical or severe cases, and characteristically show leukocytoclastic vasculitis with IgA deposition in affected tissues.

Treatment

Treatment for mild and self-limited HSP is *supportive,* with an emphasis on ensuring adequate hydration, nutrition, and analgesia. Corticosteroids are most often used to treat significant GI involvement or other life-threatening manifestations. Glucocorticoids such as oral prednisone (1-2 mg/kg/day), or in severe cases, intravenous (IV) methylprednisolone for 1-2 wk, followed by taper, reduce abdominal and joint pain but do not alter overall prognosis. Corticosteroids are not routinely recommended for prevention of complications such as nephritis. Rapid tapering of corticosteroids may lead to a flare of HSP symptoms. Although few data are available to demonstrate efficacy, intravenous immune globulin (IVIG) and plasma exchange are sometimes used for severe disease. In some patients, chronic HSP renal disease is managed with a variety of immunosuppressants, including azathioprine, cyclophosphamide, cyclosporine, and mycophenolate mofetil. ESRD develops in <5% of children with HSP nephritis.

Complications

Acutely, serious GI involvement, including intussusception and intestinal perforation, imparts significant morbidity and mortality. Renal disease is the major long-term complication, occurring in 1–2% of children with HSP. Renal disease can develop up to 6 mo after diagnosis but rarely does so if the initial urinalysis findings are normal. Therefore, it is recommended that children with HSP undergo serial monitoring of blood pressure and urinalysis for at least 6 mo after diagnosis to monitor for development of nephritis.

Prognosis

Overall, the prognosis for childhood HSP is excellent, and most children experience an acute, self-limited course lasting on average 4 wk. However, 15–

60% of children with HSP experience 1 or more recurrences, typically within 4-6 mo of diagnosis. With each relapse, symptoms are usually milder than at presentation. Children with a more severe initial course are at higher risk for relapse. The long-term prognosis usually depends on the severity and duration of GI or renal involvement. Chronic renal disease develops in 1–2% of children with HSP, and <5% of those with HSP nephritis go on to have ESRD. The risk of HSP recurrence and graft loss following renal transplantation is estimated at 7.5% after 10 yr.

192.2

Takayasu Arteritis

Vidya Sivaraman, Edward C. Fels, Stacy P. Ardoin

Takayasu arteritis (**TA**), also known as **pulseless disease** , is a chronic large vessel vasculitis of unknown etiology that predominantly involves the aorta and its major branches.

Epidemiology

Although TA occurs worldwide and can affect all ethnic groups, the disease is most common in Asians. Age of onset is typically between 10 and 40 yr. Most children are diagnosed as adolescents, on average at age 13 yr. Up to 20% of individuals with TA are diagnosed before 19 yr. Younger children may be affected, but diagnosis in infancy is rare. TA preferentially affects females, with a reported 2-4 : 1 female/male ratio in children and adolescents and a 9 : 1 ratio among adults. Occlusive complications are more common in the United States, Western Europe, and Japan, whereas aneurysms predominate in Southeast Asia and Africa.

Pathology

TA is characterized by inflammation of the vessel wall, starting in the vasa vasorum. Involved vessels are infiltrated by T cells, natural killer cells, plasma cells, and macrophages. Giant cells and granulomatous inflammation develop in the media. Persistent inflammation damages the elastic lamina and muscular media, leading to blood vessel dilation and the formation of aneurysms. Progressive scarring and intimal proliferation can result in stenotic or occluded vessels. The subclavian, renal, and carotid arteries are the most commonly involved aortic branches; pulmonary, coronary, and vertebral arteries may also be affected.

Pathogenesis

The etiology of TA remains unknown. The presence of abundant T cells with a restricted repertoire of T-cell receptors in TA vascular lesions points to the importance of cellular immunity and suggests the existence of a specific but unknown aortic tissue antigen. Expression of interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α is reported to be higher in patients with active TA than in patients with inactive TA and in healthy controls. In some patient populations, IL-1 genetic polymorphisms are linked to TA. Some individuals with TA have elevated serum values of antiendothelial antibodies. The increased prevalence of TA in certain ethnic populations and its occasional occurrence in monozygotic twins and families suggest a genetic predisposition to the disease.

Clinical Manifestations

The diagnosis of TA is challenging, because early disease manifestations are often nonspecific. As a result, diagnosis can be delayed for several months, and the time to diagnosis is usually longer in children than in adults. Fever, malaise, weight loss, headache, hypertension, myalgias, arthralgias, dizziness, and abdominal pain are common early complaints in the *pre-pulseless* phase of the disease. Among children, hypertension and headache are particularly common presenting manifestations and should prompt consideration of TA when present without alternative explanation. Some individuals with TA report no systemic symptoms and instead present with vascular complications. It is only after substantial vascular injury that evidence of hypoperfusion becomes clinically evident. Later manifestations of disease include diminished pulse, asymmetric blood pressure, claudication, Raynaud phenomenon, renal failure, and symptoms of pulmonary or cardiac ischemia. Inflammation can extend to the aortic valve, resulting in valvular insufficiency. Other findings may include pericardial effusion, pericarditis, pleuritis, splenomegaly, and arthritis.

Supradiaphragmatic (aortic arch) disease often manifests with CNS (stroke, transient ischemic attack) and cardiac (heart failure, palpitations) symptoms.

Infradiaphragmatic (mid-aortic syndrome) disease may produce hypertension, abdominal bruits, and pain. Most patients have involvement in both areas.

Diagnosis

Specific pediatric criteria for TA have been proposed (Table 192.5). *Radiographic demonstration of large vessel vasculitis is necessary* . A thorough physical examination is required to detect an aortic murmur, diminished or asymmetric pulses, and vascular bruits. Four extremity blood pressures should be measured; >10 mm Hg asymmetry in systolic pressure is indicative of disease.

Table 192.5

Proposed Classification Criteria for Pediatric-Onset Takayasu Arteritis

Angiographic abnormalities (conventional, CT, or magnetic resonance angiography) of the aorta or its main branches and at least 1 of the following criteria:

- Decreased peripheral artery pulse(s) and/or claudication of extremities
- Blood pressure difference between arms or legs of >10 mm Hg
- Bruits over the aorta and/or its major branches
- Hypertension (defined by childhood normative data)
- Elevated acute-phase reactant (erythrocyte sedimentation rate or C-reactive protein)

Adapted from Ozen S, Pistorio A, Iusan SM, et al: EULAR/PRINTO/PRES criteria for Henoch-Schönlein purpura, childhood polyarteritis nodosa, childhood Wegener granulomatosis and childhood Takayasu arteritis: Ankara 2008. Part II. Final classification criteria, *Ann Rheum Dis* 69:798–806; 2010.

Differential Diagnosis

In the early phase of TA, when nonspecific symptoms predominate, the differential diagnosis includes a wide array of systemic infections, autoimmune conditions, and malignancies. Although **giant cell arteritis** , also known as *temporal arteritis,* is a common large vessel vasculitis in older adults, this entity is rare in childhood. Noninflammatory conditions that can cause large vessel compromise include fibromuscular dysplasia, Marfan syndrome, and Ehlers-Danlos syndrome.

Laboratory Findings

The laboratory findings in TA are nonspecific, and there is no specific diagnostic laboratory test. ESR and CRP value are typically elevated, and other nonspecific markers of chronic inflammation may include leukocytosis, thrombocytosis, anemia of chronic inflammation, and hypergammaglobulinemia. Autoantibodies, including ANA and ANCA, are not useful in diagnosing TA except to help exclude other autoimmune diseases.

Radiographic assessment is essential to establish large vessel arterial involvement. Conventional arteriography of the aorta and major branches, including carotid, subclavian, pulmonary, renal, and mesenteric branches, can identify luminal defects, including dilation, aneurysms, and stenoses, even in smaller vessels such as the mesenteric arteries. Fig. 192.5 shows a conventional arteriogram in a child with TA. Although not yet thoroughly validated in TA, magnetic resonance angiography (MRA) and computed tomography angiography (CTA) also provide important information about vessel wall thickness and enhancement, although they may not image smaller vessels as well as conventional angiography. Positron emission tomography (PET) may detect vessel wall inflammation but has not been studied extensively. Ultrasound with duplex color flow Doppler imaging may identify vessel wall thickening and assesses arterial flow. Echocardiography is recommended to assess for aortic valvular involvement. Serial vascular imaging is usually necessary to assess response to treatment and to detect progressive vascular damage.

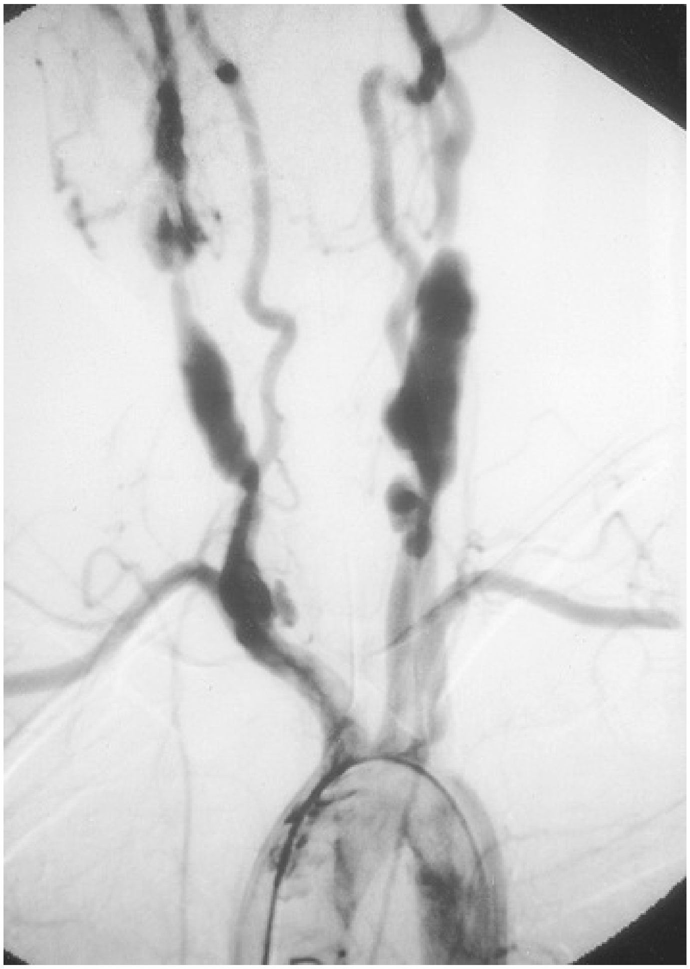

FIG. 192.5 Child with Takayasu arteritis. Conventional angiogram shows massive bilateral carotid dilation, stenosis, and poststenotic dilation.

Treatment

Glucocorticoids are the mainstay of therapy, typically starting with high doses (1-2 mg/kg/day of prednisone or methylprednisolone IV) followed by gradual dosage tapering. When TA progresses or recurs, steroid-sparing therapy is often required, usually involving methotrexate or azathioprine. *Cyclophosphamide* is reserved for severe or refractory disease. Results of small case series also suggest that *mycophenolate mofetil* or anti–TNF-α therapy may be beneficial in select patients. Anti–IL-6 therapy with tocilizumab has shown promising results in a small case series of children with TA. Antihypertensive medications are often necessary to control blood pressure caused by renovascular disease.

Complications

Progressive vascular damage can result in arterial stenoses, aneurysms, and occlusions, which produce ischemic symptoms and can be organ or life threatening. Potential ischemic complications include stroke, renal impairment or failure, myocardial infarction, mesenteric ischemia, and limb-threatening arterial disease. When these complications occur or are imminent, intervention with surgical vascular grafting or catheter-based angioplasty and stent placement may be necessary to restore adequate blood flow. A high rate of recurrent stenosis has been reported after angioplasty and stent placement. Aortic valve replacement may be required if significant aortic insufficiency develops.

Prognosis

Although up to 20% of individuals with TA have a monophasic course and achieve sustained remission, most suffer relapses. Survival for individuals with TA has improved considerably over the decades, although higher mortality rates are reported in children and adolescents. The overall estimated survival for individuals with TA is 93% at 5 yr and 87% at 10 yr. However, morbidity from vascular complications remains high, particularly when there is evidence of ongoing active inflammation as detected by elevated CRP or ESR. Given the chronic endothelial insult and inflammation, children and adolescents with TA are probably at high risk for accelerated atherosclerosis. Early detection and treatment are critical to optimizing outcome in TA.

192.3

Polyarteritis Nodosa and Cutaneous Polyarteritis Nodosa

Vidya Sivaraman, Edward C. Fels, Stacy P. Ardoin

Polyarteritis nodosa (**PAN**) is a systemic necrotizing vasculitis affecting small and medium-size arteries. Aneurysms and stenoses form at irregular intervals throughout affected arteries. Cutaneous PAN is limited to the skin.

Epidemiology

PAN is rare in childhood. Boys and girls are equally affected, and the mean age at presentation is 9 yr. The cause is unknown, but the development of PAN following infections, including group A streptococcus and chronic hepatitis B, suggests that PAN may represent a postinfectious autoimmune response. Infections with other organisms, including Epstein-Barr virus, *Mycobacterium tuberculosis* , cytomegalovirus, parvovirus B19, and hepatitis C virus, have also been associated with PAN. There is a possible association between PAN and familial Mediterranean fever.

Pathology

Biopsies show **necrotizing vasculitis** with granulocytes and monocytes infiltrating the walls of small and medium-size arteries (Fig. 192.6). Involvement is usually segmental and tends to occur at vessel bifurcations. Granulomatous inflammation is not present, and deposition of complement and immune complexes is rarely observed. Different stages of inflammation are found, ranging from mild inflammatory changes to panmural fibrinoid necrosis associated with aneurysm formation, thrombosis, and vascular occlusion.

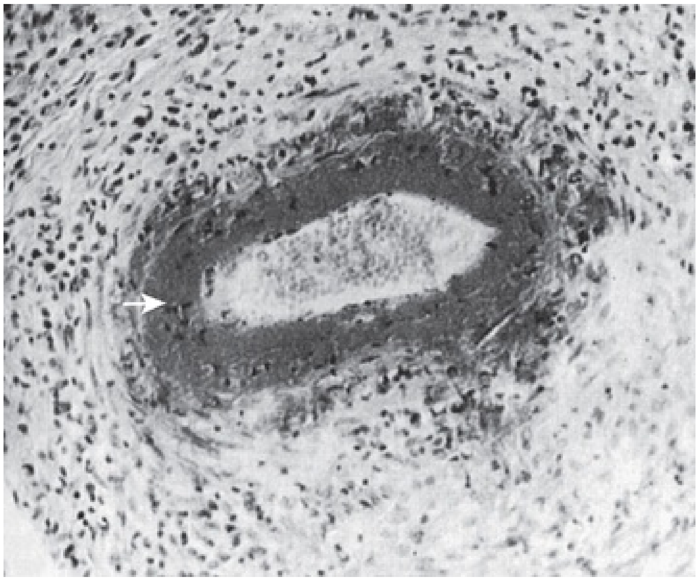

FIG. 192.6 **Polyarteritis nodosa. Biopsy specimen from a medium-size muscular artery that exhibits marked fibrinoid necrosis of the vessel wall *(arrow)* . (From Cassidy JT, Petty RE: Polyarteritis and related vasculitides. In *Textbook of pediatric rheumatology,* ed 5, Philadelphia, 2005, Elsevier/Saunders.)**

Pathogenesis

Immune complexes are believed to be pathogenic, but the mechanism is poorly understood. It is not known why PAN has a predilection for small and medium-size blood vessels. The inflamed vessel wall becomes thickened and narrowed, impeding blood flow and contributing to end-organ damage characteristic of this disease. Although there is no clear genetic association with PAN, PAN-like vasculitis is a component of 3 recently described monogenic autoinflammatory conditions.

Deficiency in **adenosine deaminase 2 (DADA2)** , caused by mutations in the *CECR1* gene, causes a familial form of vasculitis in Georgian Jewish patients with an autosomal recessive inheritance (see Chapter 188).

Clinical Manifestations

The clinical presentation of PAN is variable but generally reflects the distribution of inflamed vessels. Constitutional symptoms are present in most children at disease onset. Weight loss and severe abdominal pain suggest mesenteric arterial inflammation and ischemia. Renovascular arteritis can cause hypertension, hematuria, or proteinuria, although glomerulonephritis is not typical. Cutaneous manifestations include purpura, livedo reticularis, ulcerations, digital ischemia, and painful nodules. Arteritis affecting the nervous system can result in cerebrovascular accidents, transient ischemic attacks, psychosis, and ischemic motor or sensory peripheral neuropathy (**mononeuritis multiplex**). Myocarditis or coronary arteritis can lead to heart failure and myocardial ischemia; pericarditis and arrhythmias have also been reported. Arthralgias, arthritis, or myalgias are frequently present. Less common symptoms include testicular pain that mimics testicular torsion, bone pain, and vision loss as a result of retinal arteritis. The pulmonary vasculature is usually spared in PAN.

Diagnosis

The diagnosis of PAN requires demonstration of vessel involvement on biopsy or angiography (Table 192.6). Biopsy of cutaneous lesions shows small or medium vessel vasculitis (see Fig. 192.6). Kidney biopsy in patients with renal manifestations may show necrotizing arteritis. Electromyography in children with peripheral neuropathy identifies affected nerves, and sural nerve biopsy may reveal vasculitis. Conventional arteriography is the gold standard diagnostic imaging study for PAN and reveals areas of aneurysmal dilation and segmental stenosis, the classic “beads on a string” appearance (Fig. 192.7). MRA and CTA, less invasive imaging alternatives, are gaining acceptance, but may not be as effective in identifying small vessel disease or in younger children.

Table 192.6

Proposed Classification Criteria for Pediatric-Onset Polyarteritis Nodosa*

CRITERION	FINDINGS
Histopathology	Necrotizing vasculitis in medium or small arteries
Angiographic abnormalities	Angiography showing aneurysm, stenosis, or occlusion of medium or small artery not from noninflammatory cause
Cutaneous	Livedo reticularis, tender subcutaneous nodules, superficial skin ulcers, deep skin ulcers,

findings	digital necrosis, nail bed infarctions, or splinter hemorrhages
Muscle involvement	Myalgia or muscle tenderness
Hypertension	Systolic or diastolic blood pressure >95th percentile for height
Peripheral neuropathy	Sensory peripheral neuropathy, motor mononeuritis multiplex
Renal involvement	Proteinuria (>300 mg/24 hr equivalent), hematuria or red blood cell casts, impaired renal function (glomerular filtration rate <50% normal)

[*] The presence of 5 criteria provides 89.6% sensitivity and 99.6% specificity for the diagnosis of childhood-onset polyarteritis nodosa.

Adapted from Ozen S, Pistorio A, Iusan SM, et al: EULAR/PRINTO/PRES criteria for Henoch-Schönlein purpura, childhood polyarteritis nodosa, childhood Wegener granulomatosis and childhood Takayasu arteritis: Ankara 2008. Part II. Final classification criteria, *Ann Rheum Dis* 69:798–806; 2010.

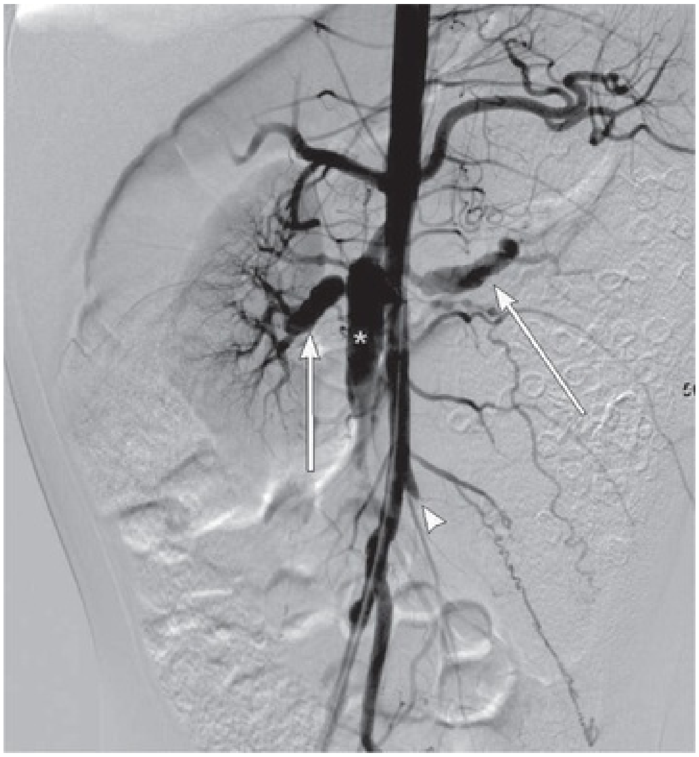

FIG. 192.7 **Child with polyarteritis nodosa. Abdominal aortogram shows bilateral renal artery aneurysms *(arrows)* , superior mesenteric artery aneurysm *(asterisk)* , and left common iliac artery occlusion *(arrowhead)* . (Courtesy of Dr. M. Hogan.)**

Differential Diagnosis

Early skin lesions may resemble those of HSP, although the finding of nodular lesions and presence of systemic features help distinguish PAN. Because pulmonary vascular involvement is very rare in PAN, pulmonary lesions suggest ANCA-associated vasculitis or Goodpasture disease. Other rheumatic diseases, including SLE, have characteristic target-organ involvement and associated autoantibodies distinguishing them from PAN. Prolonged fever and weight loss should also prompt consideration of inflammatory bowel disease or malignancy.

Laboratory Findings

Nonspecific laboratory findings include elevations of ESR and CRP, anemia, leukocytosis, and hypergammaglobulinemia. Abnormal urine sediment, proteinuria, and hematuria indicate renal disease. Laboratory findings may be normal in cutaneous PAN or similar to those of systemic PAN. Elevated hepatic enzyme values may suggest hepatitis B or C infection. Serologic tests for hepatitis (hepatitis B surface antigen and hepatitis C antibody) should be performed in all patients.

Treatment

Oral *prednisone* (1-2 mg/kg/day) or IV pulse *methylprednisolone* (30 mg/kg/day) are the mainstay of therapy. Oral or IV cyclophosphamide are often used as adjunctive therapy, and plasma exchange may be warranted for life-threatening disease. If hepatitis B is identified, appropriate antiviral therapy should be initiated (see Chapter 385). Most cases of cutaneous PAN can be treated with less intense therapy such as corticosteroids alone, nonsteroidal antiinflammatory drugs (NSAIDs), and methotrexate. Azathioprine, mycophenolate mofetil, IVIG, thalidomide, cyclosporine, and anti-TNF agents such as infliximab have all been reported as successful in treatment of refractory cutaneous or systemic PAN, although clinical trials are lacking. If an infectious trigger for PAN is identified, antibiotic prophylaxis can be considered.

Complications

Cutaneous nodules may ulcerate and become infected. Hypertension and chronic renal disease may develop from renovascular involvement in PAN. Cardiac involvement may lead to decreased cardiac function or coronary artery disease.

Mesenteric vasculitis can predispose to bowel infarction, rupture, and malabsorption. Stroke and rupture of hepatic arterial aneurysm are uncommon complications of this disorder.

Prognosis

The course of PAN varies from mild disease with few complications to a severe, multiorgan disease with high morbidity and mortality. Poor prognostic factors in PAN include elevated serum creatinine, proteinuria, severe GI involvement, cardiomyopathy, and CNS involvement. Early and aggressive immunosuppressive therapy increases the likelihood of clinical remission. Compared with disease in adults, childhood PAN is associated with less mortality. Cutaneous PAN is unlikely to transition to systemic disease. Early recognition and treatment of the disease are important to minimizing potential long-term vascular complications.

192.4

Antineutrophilic Cytoplasmic Antibody–Associated Vasculitis

Vidya Sivaraman, Edward C. Fels, Stacy P. Ardoin

The ANCA-associated vasculitides are characterized by small vessel involvement, circulating ANCAs, and paucity of immune complex deposition in affected tissues, thus the term **pauci-immune vasculitis** . ANCA-associated vasculitis is categorized into 3 distinct forms: **granulomatosis with polyangiitis (GPA)** , formerly Wegener granulomatosis; **microscopic polyangiitis (MPA)** ; and **eosinophilic granulomatosis with polyangiitis** , formerly Churg-Strauss syndrome (**CSS**) (see Table 192.1).

Epidemiology

GPA is a necrotizing granulomatous small and medium vessel vasculitis that occurs at all ages and targets the upper and lower respiratory tracts and the kidneys. Although most cases of GPA occur in adults, the disease also occurs in children with a mean age at diagnosis of 14 yr. There is a female predominance of 3-4 : 1, and pediatric GPA is most prevalent in Caucasians.

MPA is a small vessel necrotizing vasculitis with clinical features similar to those of GPA, but without granulomas and upper airway involvement. CSS is a small vessel necrotizing granulomatous (allergic granulomatosis) vasculitis associated with a history of refractory asthma and peripheral eosinophilia. MPA and CSS are rare in children, and there does not appear to be a gender predilection in either disease.

Pathology

Necrotizing vasculitis is the cardinal histologic feature in both GPA and MPA. Kidney biopsies typically demonstrate crescentic glomerulonephritis with little or no immune complex deposition (“pauci-immune”), in contrast to biopsies from patients with SLE. Although granulomatous inflammation is common in GPA and CSS, it is typically not present in MPA. Biopsies showing perivascular eosinophilic infiltrates distinguish CSS syndrome from both MPA and GPA (Table 192.7).

Table 192.7

Differential Diagnostic Features of Small Vessel Vasculitis

FEATURE	HENOCH-SCHÖNLEIN PURPURA	GRANULOMATOSIS WITH POLYANGIITIS	CHURG-STRAUSS SYNDROME*	MICROSCOPIC POLYANGIITIS
Signs and symptoms of	+	+	+	+

small vessel vasculitis [†]				
IgA-dominant immune deposits	+	−	−	−
Circulating antineutrophil cytoplasmic antibodies	−	+ (PR3)	+ (MPO > PR3)	+ (MPO)
Necrotizing vasculitis	−	+	+	+
Granulomatous inflammation	−	+	+	−
Asthma and eosinophilia	−	−	+	−

[*] Eosinophilic granulomatosis with polyangiitis.

[†] Signs and symptoms of small vessel vasculitis include purpura, other rash, arthralgias, arthritis, and constitutional symptoms.

MPO, Myeloperoxidase-reactive antibodies; PR3, proteinase-3–reactive antibodies; +, present; −, absent.

Adapted from Jeannett JC, Falk RJ: Small-vessel vasculitis, *N Engl J Med* 337:1512–1523, 1997.

Pathogenesis

The etiology of ANCA-associated vasculitis remains unknown, although neutrophils, monocytes, and endothelial cells are involved in disease pathogenesis. Neutrophils and monocytes are activated by ANCAs, specifically by the ANCA-associated antigens proteinase-3 (PR3) and myeloperoxidase (MPO), and release proinflammatory cytokines such as TNF-α and IL-8. Localization of these inflammatory cells to the endothelium results in vascular damage characteristic of the ANCA vasculitides. Why the respiratory tract and kidneys are preferential targets in GPA and MPA is unknown.

Clinical Manifestations

Early disease course is characterized by nonspecific constitutional symptoms, including fever, malaise, weight loss, myalgias, and arthralgias. In GPA, upper airway involvement can manifest as sinusitis, nasal ulceration, epistaxis, otitis media, and hearing loss. Lower respiratory tract symptoms in GPA include cough, wheezing, dyspnea, and hemoptysis. Pulmonary hemorrhage can cause rapid respiratory failure. Compared with adults, childhood GPA is more frequently complicated by subglottic stenosis (Fig. 192.8). Inflammation-induced damage to the nasal cartilage can produce a saddle nose deformity (Fig. 192.8). Ophthalmic involvement includes conjunctivitis, scleritis, uveitis, optic neuritis, and invasive orbital pseudotumor (causing proptosis). Perineural vasculitis or direct compression on nerves by granulomatous lesions can cause cranial and peripheral neuropathies. Hematuria, proteinuria, and hypertension in GPA signal renal disease. Cutaneous lesions include palpable purpura and ulcers. Venous thromboembolism is a rare but potentially fatal complication of GPA. The frequencies of organ system involvement throughout the disease course in GPA follow: respiratory tract, 74%; kidneys, 83%; joints, 65%; eyes, 43%; skin, 47%; sinuses, 70%; and nervous system, 20%. Table 192.8 lists the classification criteria for pediatric-onset GPA.

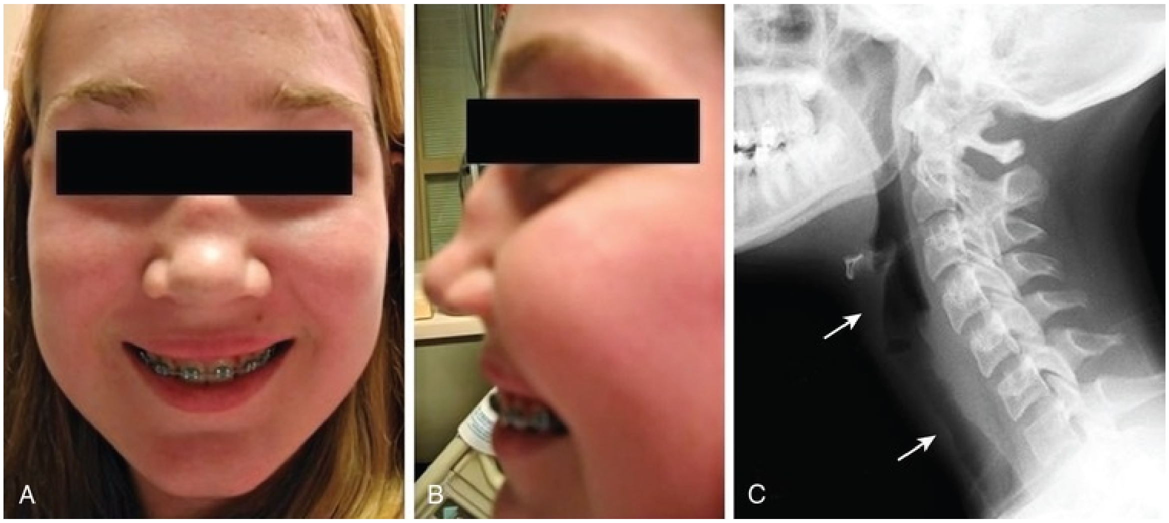

FIG. 192.8 Adolescent girl with granulomatosis with polyangiitis. A and B, Anterior and lateral views of saddle nose deformity. C, Segment of subglottic posterior tracheal irregularity (between *arrows*) on lateral neck radiograph.

Table 192.8

EULAR/PReS Classification Criteria for Pediatric-Onset Granulomatosis with Polyangiitis*

Histopathology showing granulomatous inflammation
Upper airway involvement
Laryngeal, tracheal or bronchial involvement
Antineutrophil cytoplasmic antibody (ANCA) positivity
Renal involvement

Proteinuria, hematuria, red blood cell casts, necrotizing pauci-immune glomerulonephritis

---

[*] Diagnosis requires 3 of 6 criteria.

Adapted from: Ozen S, Pistorio A, Iusan SM, et al: EULAR/PRINTO/PRES criteria for Henoch-Schönlein purpura, childhood polyarteritis nodosa, childhood Wegener granulomatosis and childhood Takayasu arteritis: Ankara 2008. Part II. Final classification criteria, *Ann Rheum Dis* 69:798–806; 2010.

The clinical presentation of MPA closely resembles that of GPA, although sinus disease is less common; systemic features of fever, malaise, weight loss, myalgias, and arthralgias may be dominant. MPA predominantly affects the kidney and lungs; other organ systems include skin, CNS, muscle, heart, and eyes.

CSS frequently causes inflammation of the upper and lower respiratory tracts, but cartilage destruction is rare. CSS may initially demonstrate chronic or recurrent rhinitis/sinusitis, nasal polyposis, nonfixed pulmonary lesions, and difficult-to-treat asthma. Eosinophilia (>10% of leukocytes) with pulmonary infiltrates may precede a vasculitic phase. Other organ involvement includes skin, cardiac, peripheral neuropathy, GI tract, and muscle. Renal involvement in CSS is uncommon.

Diagnosis

GPA should be considered in children who have recalcitrant sinusitis, pulmonary infiltrates, and evidence of nephritis. Chest radiography often fails to detect pulmonary lesions, and chest CT may show nodules, ground-glass opacities, mediastinal lymphadenopathy, and cavitary lesions (Fig. 192.9). The diagnosis is confirmed by the presence of c-ANCA with anti-PR3 specificity (PR3-ANCAs) and the finding of necrotizing granulomatous vasculitis on pulmonary, sinus, or renal biopsy. The ANCA test result is positive in approximately 90% of children with GPA, and the presence of anti-PR3 increases the specificity of the test.

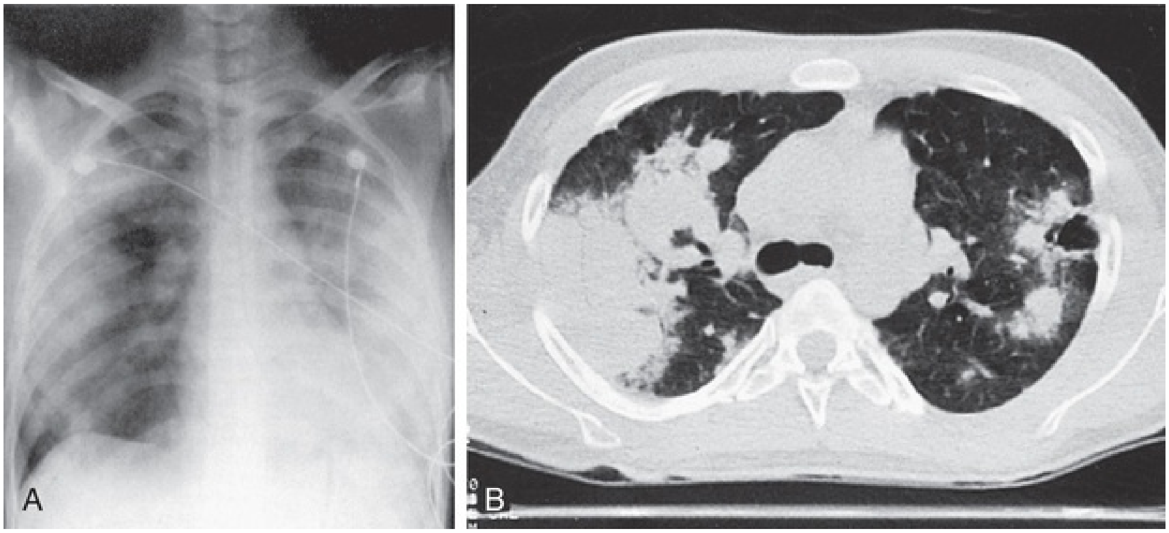

FIG. 192.9 Radiographs of lower respiratory tract disease in granulomatosis with polyangiitis (GPA). A, Chest radiograph of 14 yr old girl with GPA and pulmonary hemorrhage. Extensive bilateral, fluffy infiltrates are visualized. B, Chest CT scan in 17 yr old boy with GPA. Air space consolidation, septal thickening, and a single cavitary lesion are present. (A from Cassidy JT, Petty RE: Granulomatous vasculitis, giant cell arteritis and sarcoidosis. In *Textbook of pediatric rheumatology,* ed 3, Philadelphia, 1995, Saunders; B from Kuhn JP, Slovis TL, Haller JO: *Caffey's pediatric diagnostic imaging,* ed 10, vol 1, Philadelphia, 2004, Mosby.)

In MPA, ANCAs are also frequently present (70% of patients) but are usually p-ANCA with reactivity to MPO (MPO-ANCAs). MPA can be distinguished from PAN by the presence of ANCAs and the tendency for small vessel involvement. The ANCA test result is positive in 50–70% of cases of CSS, and MPO-ANCAs are more common than PR3-ANCAs. In addition, the presence of chronic asthma and peripheral eosinophilia suggests the diagnosis of CSS.

Differential Diagnosis

ANCAs are absent in other granulomatous diseases, such as sarcoidosis and tuberculosis. **Goodpasture syndrome** is characterized by antibodies to glomerular basement membrane. Medications such as propylthiouracil, hydralazine, and minocycline are associated with drug-induced ANCA (usually perinuclear ANCA) vasculitis. SLE and HSP can manifest as pulmonary hemorrhage and nephritis.

Laboratory Findings

Nonspecific laboratory abnormalities include elevated ESR and CRP values, leukocytosis, and thrombocytosis, which are present in most patients with an ANCA-associated vasculitis but are nonspecific. Anemia may be caused by chronic inflammation or pulmonary hemorrhage. ANCA antibodies show 2 distinct immunofluorescence patterns: *perinuclear* (p-ANCA) and *cytoplasmic* (c-ANCA). In addition, ANCAs can also be defined by their specificity for PR3 or MPO antigen. GPA is strongly associated with c-ANCAs/anti-PR3 antibodies, whereas 75% of patients with MPA have a positive p-ANCA (see Table 192.7). There is no clear correlation between ANCA titers and disease activity or relapse.

Treatment

When the lower respiratory tract or kidneys are significantly involved, initial induction therapy usually consists of prednisone (oral 2 mg/kg/day oral or IV methylprednisolone 30 mg/kg/day × 3 days) in conjunction with daily oral or monthly IV cyclophosphamide. *Rituximab* , a monoclonal antibody to CD20 on activated B cells, is an option for induction therapy in ANCA-positive vasculitides, although it has been studied primarily in adults. *Plasmapheresis* in conjunction with methylprednisolone has a role in the therapy of patients with severe disease manifestations such as pulmonary hemorrhage or ESRD, with the potential for reducing dialysis dependency. Patients are transitioned to a less toxic maintenance medication (usually methotrexate, azathioprine, or mycophenolate mofetil) within 3-6 mo once remission is achieved. Trimethoprim-sulfamethoxazole (one 180 mg/800 mg tablet 3 days/wk) is often prescribed both for prophylaxis against *Pneumocystis jiroveci* infection and to reduce upper respiratory bacterial colonization with *S. aureus,* which may trigger disease activity. If disease is limited to the upper respiratory tract, corticosteroids (1-2 mg/kg/day) and methotrexate (0.5-1.0 mg/kg/wk) may be first-line treatment.

Mepolizumab , an anti–IL-5 monoclonal antibody, may have a role in the treatment of eosinophilic granulomatosis with polyangiitis (CSS).

Complications

Upper respiratory tract lesions can invade the orbit and threaten the optic nerve, and lesions in the ear can cause permanent hearing loss. Respiratory complications include potentially life-threatening pulmonary hemorrhage and upper airway obstruction caused by subglottic stenosis. Chronic lung disease secondary to granulomatous inflammation, cavitary lesions, and scarring can predispose to infectious complications. Chronic glomerulonephritis may progress to ESRD in a subset of patients with advanced or undertreated disease.

Prognosis

The course is variable, but disease relapse occurs in up to 60% of patients. Mortality has been reduced with the introduction of cyclophosphamide and other immunosuppressive agents. Compared with adults, children are more likely to develop multiorgan involvement, renal involvement, and subglottic stenosis.

192.5

Other Vasculitis Syndromes

Vidya Sivaraman, Edward C. Fels, Stacy P. Ardoin

Other vasculitic conditions can occur in childhood; the most common is **Kawasaki disease** (see Chapter 191). **Behçet disease** is a rare form of vasculitis seen in children of Turkish and Mediterranean descent, characterized by the triad of recurrent aphthous stomatitis, genital ulcers, and uveitis (see Chapter 186).

Hypersensitivity vasculitis is a cutaneous vasculitis triggered by medication or toxin exposure. The rash consists of palpable purpura or other, nonspecific rash. Skin biopsies reveal characteristic changes of **leukocytoclastic vasculitis**

(small vessels with neutrophilic perivascular or extravascular neutrophilic infiltration) (Table 192.9). **Hypocomplementemic urticarial vasculitis** involves small vessels and manifests as recurrent urticaria that resolves over several days but leaves residual hyperpigmentation. This condition is associated with low levels of complement component C1q and systemic findings that include fever, GI symptoms, arthritis, and glomerulonephritis. Some patients with urticarial vasculitis have normal complement levels. **Cryoglobulinemic vasculitis** can complicate mixed essential cryoglobulinemia and is a small vessel vasculitis affecting skin, joints, kidneys, and lungs.

Table 192.9

Criteria for Diagnosis of Hypersensitivity Vasculitis*

CRITERION	DEFINITION
Age at onset >16 yr	Development of symptoms after 16 yr of age
Medication at disease onset	Medication that may have been a precipitating factor was taken at the onset of symptoms
Palpable purpura	Slightly elevated purpuric rash over 1 or more areas; does not blanch with pressure and is not related to thrombocytopenia
Maculopapular rash	Flat and raised lesions of various sizes over 1 or more areas of the skin
Biopsy, including arteriole and venule	Histologic changes showing granulocytes in a perivascular or extravascular location

* For purposes of classification, a patient is said to have hypersensitivity vasculitis if at least 3 of these criteria are present. The presence of ≥3 criteria has a diagnostic sensitivity of 71.0% and specificity of 83.9%. The age criterion is not applicable for children.

Adapted from Calabrese LH, Michel BA, Bloch DA, et al: The American College of Rheumatology 1990 criteria for the classification of hypersensitivity vasculitis, *Arthritis Rheum* 33:1108–1113, 1990 (Table 2, p 1110); and *Textbook of pediatric rheumatology,* ed 7, Philadelphia, 2016, Elsevier (Table 38.2, p 511).

Primary angiitis of the central nervous system represents vasculitis confined to the CNS and requires exclusion of other systemic vasculitides. **Large vessel disease** (angiography positive) may be progressive or nonprogressive and may manifest with focal deficits similar to an occlusive stroke, with hemiparesis, focal gross or fine motor deficits, language disorders, or cranial nerve deficits. Diffuse cognitive, memory, and concentration deficits as well as behavioral disorders are seen in 30–40% of patients. **Small vessel disease** (angiography negative, biopsy positive) more often results in language problems and diffuse deficits, such as cognitive, memory, behavior, and concentration problems, as well as focal seizures. In both types of cerebral angiitis, patients may have an elevated ESR or CRP and abnormal CSF findings (increased protein, pleocytosis), although these are not consistent findings in all patients. Diagnosis remains a challenge, and brain biopsy is often indicated to confirm the diagnosis and exclude vasculitis mimics such as infections that could worsen with immunosuppressive therapy (Table 192.10).

Table 192.10

Differential Diagnosis of Small Vessel Primary Central Nervous System (CNS) Vasculitis in Children

CNS Vasculitis Complicating Other Diseases

Infections

- Bacterial: *Mycobacterium tuberculosis, Mycoplasma pneumoniae, Streptococcus pneumoniae*
- Viral: Epstein-Barr virus, cytomegalovirus, enterovirus, varicella-zoster virus, hepatitis C virus, parvovirus B19, West Nile virus
- Fungal: *Candida albicans, Actinomyces, Aspergillus*
- Spirochetal: *Borrelia burgdorferi, Treponema pallidum*

Rheumatic and Inflammatory Diseases

- Systemic vasculitis such as granulomatosis with polyangiitis, microscopic polyangiitis, Henoch-Schönlein purpura, Kawasaki disease, polyarteritis nodosa, Behçet disease
- Systemic lupus erythematosus, juvenile dermatomyositis, morphea
- Inflammatory bowel disease
- Autoinflammatory syndromes
- Hemophagocytic lymphohistiocytosis
- Neurosarcoidosis
- Adenosine deaminase-2 deficiency

Other

- Drug-induced vasculitis
- Malignancy-associated vasculitis

Nonvasculitis Inflammatory Brain Diseases

Demyelinating Diseases

- Multiple sclerosis, acute demyelinating encephalomyelitis (ADEM), optic neuritis, transverse myelitis

Antibody-Mediated Inflammatory Brain Disease

- Anti–NMDA receptor encephalitis, neuromyelitis optica (NMO), antibody-associated limbic encephalitis (antibodies against LGI, AMP, AMP-binding protein), Hashimoto encephalopathy, celiac disease, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS)

T-Cell–Associated Inflammatory Brain Disease

- Rasmussen encephalitis

Other

- Febrile infection-related epilepsy syndrome (FIRES)

Noninflammatory Vasculopathies

- Hemoglobinopathies (sickle cell disease), thromboembolic disease
- Radiation vasculopathy, graft-versus-host disease
- Metabolic and genetic diseases such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), mitochondrial encephalopathy lactic acidosis and stroke-like episodes (MELAS), CARASIL (cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy), moyamoya disease,

Fabray disease

- Malignancy (lymphoma)

Modified from Gowdie P, Twilt M, Benseler SM: Primary and secondary central nervous system vasculitis. *J Child Neurol* 27:1448–1459, 2012.

Nonprogressive angiography-positive CNS vasculitis, also known as *transient CNS angiopathy,* represents a more benign variant and can be seen after varicella infection. **Cogan syndrome** is rare in children; its potential clinical manifestations include constitutional symptoms; inflammatory eye disease such as uveitis, episcleritis, or interstitial keratitis; vestibuloauditory dysfunction (vertigo, hearing loss, tinnitus); arthritis; and large vessel vasculitis or aortitis. Cerebral autosomal **dominant** arteriopathy with subcortical infarcts and leukoencephalopathy (**CADASIL**) is caused by mutations in the *NOTCH3* gene and manifests with stroke, mood changes, cognitive decline, and migraines; it is a vasculitis mimic and demonstrates osmophilic granules in cerebral arteries. **CARASIL** (cerebral autosomal **recessive** arteriopathy with subcortical infarcts and leukoencephalopathy) is another mimic of angiitis caused by mutations in the *HTRA1* gene. It manifests with early-onset hair loss, spasticity, stroke, memory loss, and personality changes.

Identification of these vasculitis syndromes requires a comprehensive history and physical examination. Table 192.11 outlines other diagnostic considerations. Although tailored to disease severity, treatment generally includes prednisone (up to 2 mg/kg/day). Potent immunosuppressive medications, such as cyclophosphamide, are often indicated, particularly in primary angiitis of the CNS to prevent rapid neurologic decline. For hypersensitivity vasculitis, withdrawal of the triggering medication or toxin is indicated if possible.

Table 192.11

Diagnostic Considerations for Other Vasculitis Syndromes

VASCULITIS SYNDROME	APPROACH TO DIAGNOSIS
Hypersensitivity vasculitis	Skin biopsy demonstrating leukocytoclastic vasculitis
Hypocomplementemic urticarial vasculitis	Biopsy of affected tissue demonstrating small vessel vasculitis Low levels of circulating C1q
Cryoglobulinemic vasculitis	Biopsy of affected tissue demonstrating small vessel vasculitis Measurement of serum cryoglobulins

	Exclusion of hepatitides B and C infections
Primary angiitis of CNS	Conventional, CT, or MRA evidence of CNS vasculitis Consideration of dura or brain biopsy
Nonprogressive angiography-positive CNS vasculitis	Conventional, CT, or MRA evidence of CNS vasculitis
Cogan syndrome	Ophthalmology and audiology evaluations Conventional, CT, or MRA evidence of CNS or aortic vasculitis

CNS, Central nervous system; CT, computed tomography; MRA, magnetic resonance angiography.

CHAPTER 193

Musculoskeletal Pain Syndromes

Kelly K. Anthony, Laura E. Schanberg

Musculoskeletal pain is a frequent complaint of children presenting to general pediatricians and is the most common presenting problem of children referred to pediatric rheumatology clinics. Prevalence estimates of persistent musculoskeletal pain in community samples range from 10–30%. Although diseases such as juvenile idiopathic arthritis (JIA) and systemic lupus erythematosus (SLE) may manifest as persistent musculoskeletal pain, the majority of musculoskeletal pain complaints in children are benign in nature and attributable to trauma, overuse, and normal skeletal growth variations. In a subset of children, chronic pain complaints develop in the absence of physical or laboratory abnormalities. Children with idiopathic musculoskeletal pain syndromes also typically develop marked subjective distress and functional impairment. Therefore the treatment of children with musculoskeletal pain syndromes optimally includes both pharmacologic and nonpharmacologic interventions.

Clinical Manifestations

Chronic musculoskeletal pain syndromes involve pain complaints at least 3 mo in duration in the absence of objective abnormalities on physical examination or laboratory screening. Additionally, children and adolescents with musculoskeletal pain syndromes often complain of persistent pain despite previous treatment with nonsteroidal antiinflammatory drugs (NSAIDs) and analgesic agents. The location varies, with pain complaints either localized to a single extremity or more diffuse and involving multiple extremities. The pain may start in a single area of the body before intensifying and radiating to other areas over time. The prevalence of musculoskeletal pain syndromes increases with age and is higher in females, thus rendering adolescent girls at highest risk.

The somatic complaints of children and adolescents with musculoskeletal pain syndromes are typically accompanied by psychological distress, sleep difficulties, and functional impairment across home, school, and peer domains. **Psychological distress** may include symptoms of anxiety and depression, such as frequent crying spells, fatigue, sleep disturbance, feelings of worthlessness, poor concentration, and frequent worry. Indeed, a substantial number of children with musculoskeletal pain syndromes display the full range of psychological symptoms, warranting an additional diagnosis of a comorbid mood or anxiety disorder (e.g., major depressive episode, generalized anxiety disorder). **Sleep disturbance** in children with musculoskeletal pain syndromes may include difficulty falling asleep, multiple night awakenings, disrupted sleep–wake cycles with increased daytime sleeping, nonrestorative sleep, and fatigue.

For children and adolescents with musculoskeletal pain syndromes, the constellation of pain, psychological distress, and sleep disturbance often leads to a high degree of functional impairment. Poor school attendance is common, and children may struggle to complete other daily activities relating to self-care and participation in household chores. Decreased physical fitness can also occur, as well as changes in gait and posture, as children avoid contact with or use of the body area affected by pain. Peer relationships may also be disrupted by decreased opportunities for social interaction because of pain. As such, children and adolescents with musculoskeletal pain syndromes often report loneliness and social isolation characterized by few friends and lack of participation in extracurricular activities.

Diagnosis and Differential Diagnosis

The diagnosis of a musculoskeletal pain syndrome is typically one of exclusion when careful, repeated physical examinations and laboratory testing do not reveal an etiology. At initial presentation, children with pain complaints require a thorough clinical history and a complete physical examination to look for an obvious etiology (sprains, strains, or fractures), characteristics of the pain (localized or diffuse), and evidence of systemic involvement. A comprehensive history can be particularly useful in providing clues to the possibility of underlying illness or systemic disease. The presence of current or recent fever can be indicative of an inflammatory or neoplastic process if the pain is also accompanied by worsening symptoms over time or weight loss.

Subsequent, *repeated* physical examinations of children with musculoskeletal pain complaints may reveal eventual development and manifestations of rheumatic or other diseases. The need for additional testing should be individualized, depending on the specific symptoms and physical findings. Laboratory screening and radiography should be pursued if there is suspicion of certain underlying disease processes. Possible indicators of a serious, vs a benign, cause of musculoskeletal pain include pain present at rest, pain that may be relieved by activity, objective joint swelling on physical examination, stiffness or limited range of motion in joints, bony tenderness, muscle weakness, poor growth and/or weight loss, and constitutional symptoms (e.g., fever, malaise) (Table 193.1). In the case of laboratory screenings, a complete blood count (CBC) and erythrocyte sedimentation rate (ESR) are likely to be abnormal in children whose pain is secondary to a bone or joint infection, SLE, or a malignancy. Bone tumors, fractures, and other focal pathology resulting from infection, malignancy, or trauma can often be identified through imaging studies, including plain radiographs, MRI, and less often technetium-99m bone scans.

Table 193.1

Potential Indicators of Benign vs Serious Causes of Musculoskeletal Pain

CLINICAL FINDING	BENIGN CAUSE	SERIOUS CAUSE
Effects of rest vs activity on pain	Relieved by rest and worsened by activity	Present at rest and may be relieved by activity
Time of day pain occurs	End of the day and nights	Morning*
Objective joint swelling	No	Yes
Joint characteristics	Hypermobile/normal	Stiffness, limited range of motion
Bony tenderness	No	Yes
Muscle strength	Normal	Muscle weakness
Gait	Normal	Limp or refusal to walk
Growth	Normal growth pattern or weight gain	Poor growth and/or weight loss
Constitutional symptoms (e.g., fever, malaise)	Fatigue without other constitutional symptoms	Yes
Lab findings	Normal CBC, ESR, CRP	Abnormal CBC, raised ESR and CRP
Imaging findings	Normal	Effusion, osteopenia, radiolucent metaphyseal lines, joint space loss, bony destruction

* Cancer pain is often severe and worst at night.

CBC, Complete blood count; CRP, C-reactive protein level; ESR, erythrocyte sedimentation rate.

Adapted from Malleson PN, Beauchamp RD: Diagnosing musculoskeletal pain in children, *CMAJ* 165:183–188, 2001.

The presence of persistent pain, accompanied by psychological distress, sleep disturbance, and/or functional impairment, in the absence of objective laboratory or physical examination abnormalities, suggests the diagnosis of an **idiopathic** musculoskeletal pain syndrome. All pediatric musculoskeletal pain syndromes share this general constellation of symptoms at presentation. Several more specific pain syndromes routinely seen by pediatric practitioners can be differentiated by anatomic region and associated symptoms. Table 193.2 outlines pediatric musculoskeletal pain syndromes, including growing pains (see Chapter 193.1), fibromyalgia (Chapter 193.3), complex regional pain syndrome (Chapter 193.4), localized pain syndromes, low back pain, and chronic sports-related pain syndromes (e.g., Osgood-Schlatter disease).

Table 193.2

Common Musculoskeletal Pain Syndromes in Children by Anatomic Region

ANATOMIC REGION	**PAIN SYNDROMES**	
Shoulder	Impingement syndrome	
Elbow	"Little League elbow" Avulsion fractures Osteochondritis dissecans	Tennis elbow Panner disease
Arm	Localized hypermobility syndrome Complex regional pain syndrome	
Pelvis and hip	Avulsion injuries Legg-Calvé-Perthes syndrome	Slipped capital femoral epiphysis Congenital hip dysplasia
Knee	Osteochondritis dissecans Osgood-Schlatter disease Sinding-Larsen syndrome	Patellofemoral syndrome Malalignment syndromes
Leg	Growing pains Complex regional pain syndrome Localized hypermobility syndrome	Shin splints Stress fractures Compartment syndromes
Foot	Plantar fasciitis Tarsal coalition Stress fractures	Achilles tendonitis Juvenile bunion
Spine	Musculoskeletal strain Spondylolisthesis Spondylolysis	Scoliosis Scheuermann disease (kyphosis) Low back pain
Generalized	Hypermobility syndrome Juvenile fibromyalgia Generalized pain syndrome	

Adapted from Anthony KK, Schanberg LE: Assessment and management of pain syndromes and arthritis pain in children and adolescents, *Rheum Dis Clin North Am* 33:625–660, 2007 (Box 1).

Treatment

The primary goal of treatment for pediatric musculoskeletal pain syndromes is to improve function rather than relieve pain, and these 2 desirable outcomes may not occur simultaneously. Indeed, it is common for children with musculoskeletal pain syndromes to continue complaining of pain even as they resume normal function (e.g., increased school attendance and participation in extracurricular activities). For all children and adolescents with pediatric musculoskeletal pain syndromes, regular school attendance is crucial, because this is a hallmark of normal functioning in this age-group. The dual nature of treatment, targeting both *function* and *pain*, needs to be clearly explained to children and their families to outline better the goals by which treatment success will be measured. Indeed, children and families need to be supported in disengaging from the sole pursuit of pain relief and embracing broader treatment goals of improved functioning.

Recommended treatment modalities typically include physical and/or occupational therapy, pharmacologic interventions, and cognitive-behavioral and/or other psychotherapeutic interventions. The overarching goal of **physical therapy** is to improve children's physical function and should emphasize participation in aggressive but graduated aerobic exercise. **Pharmacologic** interventions should be used judiciously. Low-dose tricyclic antidepressants (amitriptyline, 10-50 mg orally 30 min before bedtime) are indicated for treatment of sleep disturbance; selective serotonin reuptake inhibitors (sertraline, 10-20 mg daily) may prove useful in treating symptoms of depression and anxiety if present. Referral for psychological evaluation is warranted if these symptoms do not resolve with initial treatment efforts or if suicidal ideation is present. **Cognitive-behavioral therapy (CBT)** and/or other **psychotherapeutic** interventions are typically designed to teach children and adolescents coping skills for controlling the behavioral, cognitive, and physiologic responses to pain. Specific components often include cognitive restructuring, relaxation, distraction, and problem-solving skills; additional targets of therapy include sleep hygiene and activity scheduling, all with the goal of restoring normal sleep patterns and activities of daily living. Parent education and involvement in the psychological intervention is important to ensure maintenance of progress. More intensive family-based approaches are warranted if barriers to treatment success are identified at the family level. These could include parenting strategies or family dynamics that serve to maintain children's pain complaints, such as overly solicitous responses to the child's pain and maladaptive models for pain coping.

Complications and Prognosis

Musculoskeletal pain syndromes can negatively affect the child's development and future role functioning. Worsening pain and the associated symptoms of depression and anxiety can lead to substantial school absences, peer isolation, and developmental delays later in adolescence and early adulthood. Specifically, adolescents with musculoskeletal pain syndromes may fail to achieve the level of autonomy and independence necessary for age-appropriate activities, such as attending college, living away from home, and maintaining a job. Fortunately, not all children and adolescents with musculoskeletal pain syndromes experience this degree of impairment, but many children experience pain that persists for 1 yr or more. Factors that contribute to the persistence of pain are increasingly understood and include female gender, pubertal stage at pain onset, older age of pain onset, increased psychological distress associated with the pain, joint hypermobility, and greater functional impairment. The likelihood of positive health outcomes is increased with multidisciplinary treatment.

193.1

Growing Pains

Kelly K. Anthony, Laura E. Schanberg

More appropriately termed **benign nocturnal pains of childhood** , growing pains affect 10–20% of children, with peak incidence between age 4 and 12 yr. Pain does not occur during periods of rapid growth or at growth sites. The most common cause of recurrent musculoskeletal pain in children, growing pains are intermittent and bilateral, predominantly affecting the anterior thigh, shin, and calf, but not joints. Occasionally, bilateral upper extremity pain may be associated with leg pain; isolated upper extremity pain does not occur. Children typically describe cramping or aching that occurs in the late afternoon or evening. Pain may wake the child from sleep and may last a few minutes to hours, but resolves quickly with massage or analgesics; pain is never present the following morning (Table 193.3). Pain often follows a day with exercise or other physical activities. Physical findings are normal, and gait is not impaired.

Table 193.3

Inclusion and Exclusion Criteria for Growing Pains Including Features of Restless Leg Syndromes (RLS)

	INCLUSIONS	EXCLUSIONS	RLS FEATURES
Nature of pain	Intermittent; some pain-free days and nights, deep aching, cramping	Persistent; increasing intensity, pain during the day	Urge to move legs often accompanied by unpleasant sensations in legs, but may not be painful
Unilateral or bilateral	Bilateral	Unilateral	
Location of pain	Anterior thigh, calf, posterior knee—in muscles not the joints	Articular, back, or groin pain	Urge to move and discomfort throughout leg
Onset of pain	Late afternoon or evening	Pain still present next morning	Worse later in day or night but also present at periods of rest or inactivity throughout the day
Physical findings	Normal	Swelling, erythema, tenderness; local trauma or infection; reduced joint range of motion; limping, fever, weight loss, mass	
Laboratory findings	Normal	Objective evidence of abnormalities; increased erythrocyte sedimentation rate or C-reactive protein; abnormal complete blood count, radiography, bone scan, or MRI	

Adapted from Evans AM, Scutter SD: Prevalence of “growing pains” in young children, *J Pediatr* 145:255–258, 2004; and Walters AS, Gabelia D, Frauscher B: Restless legs syndrome (Willis-Ekbom disease) and growing pains: are they the same thing? A side-by-side comparison of the diagnostic criteria for both and recommendations for future research, *Sleep Med* 14:1247–1252, 2013.

Although growing pains are generally considered a benign, time-limited condition, evidence suggests they represent a **pain amplification syndrome** . Indeed, growing pains persist in a significant percentage of children, with some children developing other pain syndromes such as abdominal pain and headaches. Growing pains are more likely to persist in children with a parent who has a history of a pain syndrome and in children who have lower pain thresholds not just at the site of pain, but throughout their body. Disordered somatosensory testing, lower bone strength, and lower calcium intake have also been shown to be present in children with growing pains.

Treatment should also focus on reassurance, education, and healthy sleep hygiene. Massage during the episode is very effective, and physical therapy and muscle stretching may also be important parts of treatment. NSAIDs agents may be useful for frequent episodes. CBT may be indicated if the pain persists.

Restless legs syndrome (**RLS** , Willis-Ekbom disease), seen more frequently among adolescents and adults, is a sensorimotor disturbance that may be confused with growing pains (see Chapter 31). Often familial, RLS is a difficult-to-control *urge* to move the leg that is exacerbated during rest and at night and is relieved by movement (Table 193.3). There is significant overlap in the diagnostic features of growing pains and RLS, leading to diagnostic confusion. Moreover, these conditions can be comorbid, and there is a high incidence of RLS in the parents of children with growing pains. RLS appears to be best distinguished from growing pains by the *urge* to move the legs, associated uncomfortable leg sensations that may not be described as painful; the worsening with periods of rest; and relief through movement. Iron supplementation may benefit pediatric patients with RLS.

193.2

Small Fiber Polyneuropathy

Kelly K. Anthony, Laura E. Schanberg

Many patients with juvenile-onset widespread pain syndromes, as well as patients with pediatric fibromyalgia (Chapter 193.3), complex regional pain syndrome type I (Chapter 193.4), and erythromelalgia (Chapter 193.5), have evidence of a small fiber polyneuropathy causing dysfunctional or degeneration of small-diameter unmyelinated C fibers and thinly myelinated A delta fibers that mediate nociception and the autonomic nervous system. Fibromyalgia includes **chronic widespread pain** , defined as ≥3 mo duration of axial pain that is often bilateral and that also affects the upper and lower extremities. In addition, many patients have associated chronic cardiovascular (dizziness, postural orthostasis syndrome) symptoms, as well as chronic abdominal pain and ileus, headaches, fatigue, and erythromelalgia, suggestive of **dysautonomia** .

There are no typical findings on physical examination or standard laboratory tests. The diagnosis of small fiber polyneuropathy requires distal leg immunolabeled skin biopsy to identify epidermal nociceptive fibers and autonomic function testing to examine cardiovagal, adrenergic, and sudomotor small fiber function.

Treatment of patients with small fiber polyneuropathy and isolated juvenile-onset widespread pain syndrome, or those subsets of patients with small fiber polyneuropathy and fibromyalgia, complex regional pain syndrome, or erythromelalgia, is evolving and has included prednisone or intravenous immune globulin.

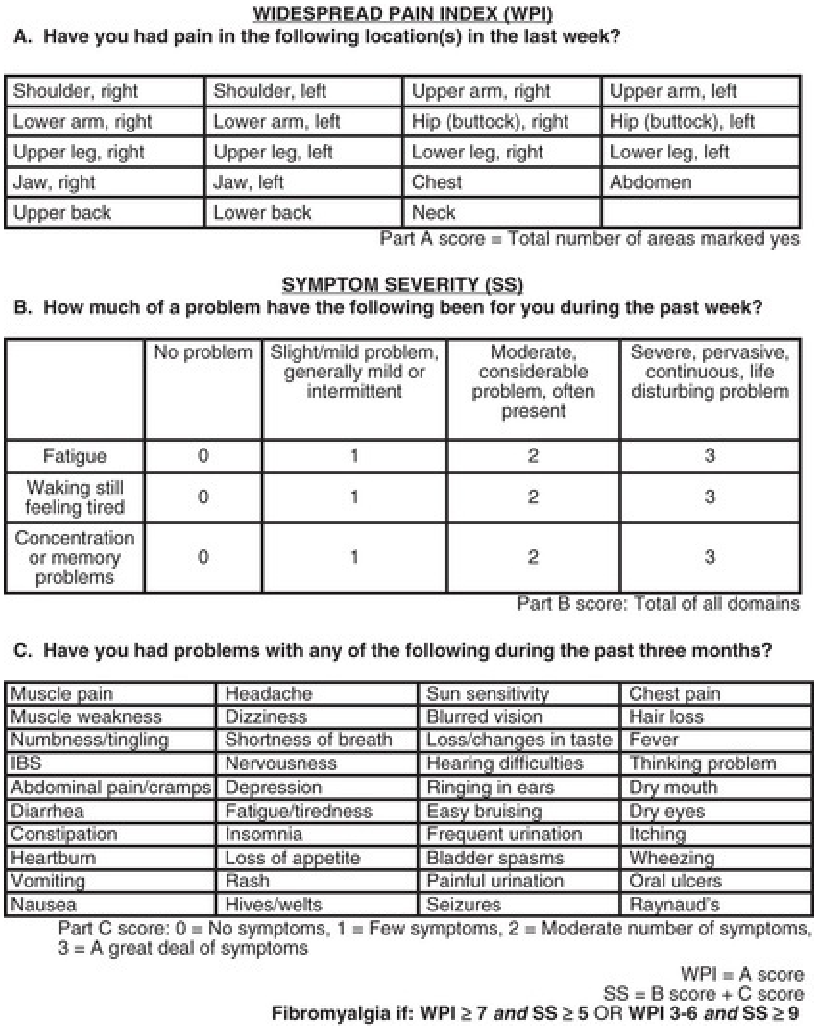
193.3

Fibromyalgia

Kelly K. Anthony, Laura E. Schanberg

Juvenile primary fibromyalgia syndrome (JPFS) is a common pediatric musculoskeletal pain syndrome. Approximately 25–40% of children with chronic pain syndromes can be diagnosed with JPFS. Although specific diagnostic criteria for JPFS have not been determined, the adult criteria set forth by the American College of Rheumatology (ACR) in 2010 have been shown to have a high degree of sensitivity and specificity in the diagnosis of JPFS (Fig. 193.1 and Table 193.4). Previous studies describing children and adolescents with JPFS noted diffuse, multifocal, waxing and waning, and at times migratory musculoskeletal pain in at least 3 areas of the body persisting for at least 3 mo in the absence of an underlying condition. Results of laboratory tests were normal, and physical examination revealed at least 5 well-defined tender points (Fig. 193.2). There is considerable overlap among symptoms associated with JPFS and complaints associated with other **functional disorders** (e.g., irritable bowel disease, migraines, temporomandibular joint disorder, premenstrual syndrome, mood and anxiety disorders, chronic fatigue syndrome), suggesting that these disorders may be part of a larger spectrum of related syndromes.



WIDESPREAD PAIN INDEX (WPI)

A. Have you had pain in the following location(s) in the last week?

Shoulder, right	Shoulder, left	Upper arm, right	Upper arm, left
Lower arm, right	Lower arm, left	Hip (buttock), right	Hip (buttock), left
Upper leg, right	Upper leg, left	Lower leg, right	Lower leg, left
Jaw, right	Jaw, left	Chest	Abdomen
Upper back	Lower back	Neck	

Part A score = Total number of areas marked yes

SYMPTOM SEVERITY (SS)

B. How much of a problem have the following been for you during the past week?

	No problem	Slight/mild problem, generally mild or intermittent	Moderate, considerable problem, often present	Severe, pervasive, continuous, life disturbing problem
Fatigue	0	1	2	3
Waking still feeling tired	0	1	2	3
Concentration or memory problems	0	1	2	3

Part B score: Total of all domains

C. Have you had problems with any of the following during the past three months?

Muscle pain	Headache	Sun sensitivity	Chest pain
Muscle weakness	Dizziness	Blurred vision	Hair loss
Numbness/tingling	Shortness of breath	Loss/changes in taste	Fever
IBS	Nervousness	Hearing difficulties	Thinking problem
Abdominal pain/cramps	Depression	Ringing in ears	Dry mouth
Diarrhea	Fatigue/tiredness	Easy bruising	Dry eyes
Constipation	Insomnia	Frequent urination	Itching
Heartburn	Loss of appetite	Bladder spasms	Wheezing
Vomiting	Rash	Painful urination	Oral ulcers
Nausea	Hives/welts	Seizures	Raynaud's

Part C score: 0 = No symptoms, 1 = Few symptoms, 2 = Moderate number of symptoms, 3 = A great deal of symptoms

WPI = A score
SS = B score + C score
Fibromyalgia if: WPI ≥ 7 *and* SS ≥ 5 OR WPI 3-6 *and* SS ≥ 9

FIG. 193.1 **Fibromyalgia questionnaire. American College of Rheumatology criteria. IBS, Irritable bowel syndrome. (Adapted from Wolfe F, Clauw DJ, Fitzcharles MA, et al. The American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity. *Arthritis Care Res* 62:600–610, 2010.)**

Table 193.4

American College of Rheumatology Fibromyalgia Diagnostic Criteria

The following 3 conditions must be met:

1. Widespread pain index (WPI) ≥7 and symptom severity (SS) scale score ≥5 *or* WPI 3-6 and SS scale score ≥9.
2. Symptoms have been present at a similar level for at least 3 mo.
3. The patient does not have a disorder that would otherwise explain the pain.

Ascertainment of WPI

The WPI is the number of areas in which a patient has had pain over the last week. The score will be between 0 and 19: left shoulder girdle left, right shoulder girdle, left upper arm, right upper arm, left lower arm, right lower arm, left hip (buttock, trochanter), right hip (buttock, trochanter), left upper leg, right upper leg, left lower leg, right lower leg, left jaw, right jaw, chest, abdomen, upper back, lower back, and neck.

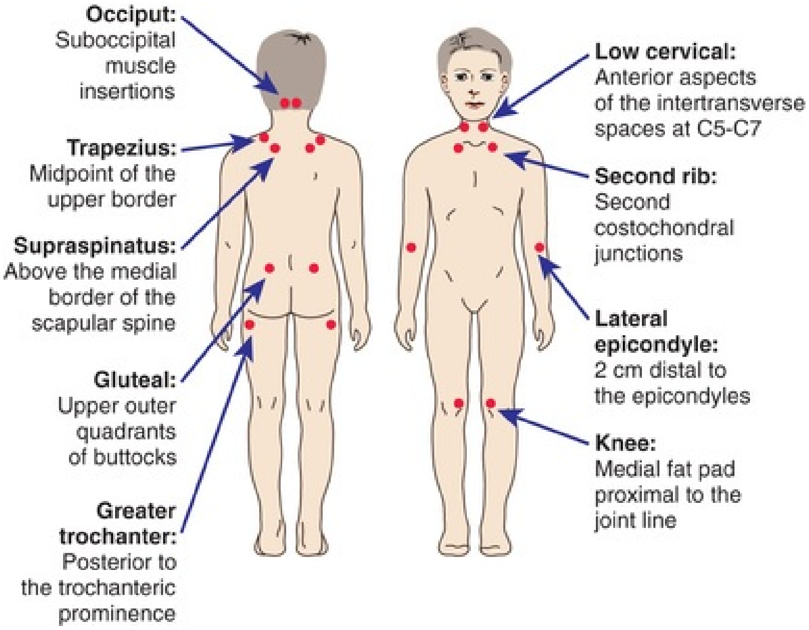
Ascertainment of Ss Scale Score

The SS scale score is the sum of the severity of 3 symptoms (fatigue, waking unrefreshed, and cognitive symptoms) *plus* the severity of somatic symptoms in general. The final score is between 0 and 12.

- For each of the 3 symptoms, the level of severity over the past week is rated using the following scale:
  0 = No problem
  1 = Slight or mild problems, generally mild or intermittent
  2 = Moderate, considerable problems, often present and/or at a moderate level
  3 = Severe: pervasive, continuous, life-disturbing problems
- Considering somatic symptoms in general, the following scale is used to indicated the number of symptoms:
  0 = No symptoms
  1 = Few symptoms
  2 = Moderate number of symptoms
  3 = Great deal of symptoms
- Somatic symptoms that can be considered include muscle pain, irritable bowel syndrome, fatigue, thinking problems, muscle weakness, headache, abdominal pain, numbness/tingling, dizziness, insomnia, depression,

constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

Adapted from Wolfe F, Clauw DJ, Fitzcharles MA, et al: The American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity, *Arthritis Care Res* 62: 600–610, 2010.



Occiput:
Suboccipital muscle insertions
Trapezius:
Midpoint of the upper border
Supraspinatus:
Above the medial border of the scapular spine
Gluteal:
Upper outer quadrants of buttocks
Greater trochanter:
Posterior to the trochanteric prominence
Low cervical:
Anterior aspects of the intertransverse spaces at C5-C7
Second rib:
Second costochondral junctions
Lateral epicondyle:
2 cm distal to the epicondyles
Knee:
Medial fat pad proximal to the joint line

FIG. 193.2 **Fibromyalgia tender points.**

Although the precise cause of JPFS is unknown, there is an emerging understanding that the development and maintenance of JPFS are related both to biologic and psychological factors. JPFS is an abnormality of central pain processing characterized by disordered sleep physiology, enhanced pain perception with abnormal levels of substance P in cerebrospinal fluid, disordered mood, and dysregulation of hypothalamic-pituitary-adrenal and other neuroendocrine axes, resulting in lower tender-point pain thresholds and increased pain sensitivity. Evolving evidence also suggests that up to 50% of patients with fibromyalgia may have a small fiber polyneuropathy (see Chapter

193.2), and that patients with JPFS may also have chronotropic incompetence (inability to increase heart rate commensurate with activity) and autonomic dysfunction at diagnosis. Children and adolescents with fibromyalgia often find themselves in a vicious cycle of pain, where symptoms build on one another and contribute to the onset and maintenance of new symptoms (Fig. 193.3).

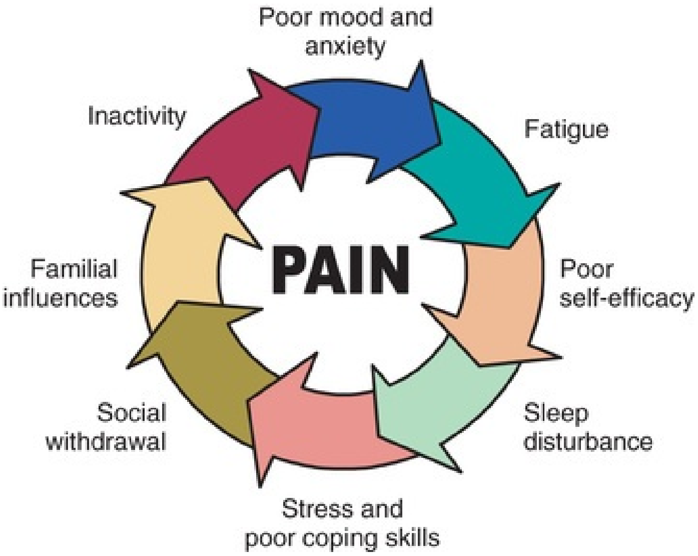


FIG. 193.3 **Juvenile primary fibromyalgia syndrome. Vicious cycle promoting symptom maintenance. (Adapted from Anthony KK, Schanberg LE: Juvenile primary fibromyalgia syndrome, *Curr Rheumatol Rep* 3:167–171, 2001, Fig. 1.)**

JPFS has a chronic course that can detrimentally affect child health and development. Adolescents with JPFS who do not receive treatment or who are inadequately treated may withdraw from school and the social milieu, complicating their transition to adulthood. **Treatment** of JPFS generally follows consensus statements of the American Pain Society. The major goals are to restore function and alleviate pain, as well as improve comorbid mood and sleep disorders. Treatment strategies include parent/child education, pharmacologic interventions, exercise-based interventions, and psychological interventions. Graduated aerobic exercise is the recommended exercise-based intervention, whereas psychological interventions should include training in pain coping skills, stress management skills, emotional support, and sleep hygiene. CBT is particularly effective in reducing symptoms of depression in children and adolescents with JPFS and also helps to reduce functional disability.

Drug therapies , although largely unsuccessful in isolation, may include tricyclic antidepressants (amitriptyline, 10-50 mg orally 30 min before bedtime), selective serotonin reuptake inhibitors (sertraline, 10-20 mg daily), and anticonvulsants. Pregabalin and duloxetine hydrochloride are approved by the U.S. Food and Drug Administration (FDA) for treatment of fibromyalgia in adults (≥18 yr of age). The safety and efficacy of *pregabalin* in adolescents age 12-17 yr was recently demonstrated in a 15 wk randomized controlled trial and 6 mo open-label study. Safety was consistent with that shown in adults, with preliminary evidence for improvement in secondary pain outcomes, impressions of change, and better sleep. *Duloxetine* has not been studied in children with JPFS. Muscle relaxants are generally not used in children because they affect school performance.

193.4

Complex Regional Pain Syndrome

Kelly K. Anthony, Laura E. Schanberg

Complex regional pain syndrome (CRPS) is characterized by ongoing burning limb pain subsequent to an injury, immobilization, or another noxious event affecting the extremity. **CRPS1** , formerly called *reflex sympathetic dystrophy* , has no evidence of nerve injury, whereas **CRPS2** , formerly called *causalgia* , follows a prior nerve injury. Key associated features are pain disproportionate to the inciting event, persisting **allodynia** (a heightened pain response to normally nonnoxious stimuli), **hyperalgesia** (exaggerated pain reactivity to noxious stimuli), swelling of distal extremities, and indicators of **autonomic dysfunction** (cyanosis, mottling, hyperhidrosis).

There are currently no gold standard diagnostic criteria for pediatric CPRS;

although in adults, the **Budapest criteria** have been shown to be more sensitive and specific than previous diagnostic guidelines (Table 193.5). The diagnosis requires an initiating noxious event or immobilization; continued pain, allodynia, and hyperalgesia out of proportion to the inciting event; evidence of edema, skin blood flow abnormalities, or sudomotor activity; and exclusion of other disorders. Associated features include atrophy of hair or nails; altered hair growth; loss of joint mobility; weakness, tremor, dystonia; and sympathetically maintained pain.

Table 193.5

Budapest Clinical Diagnostic Criteria for Complex Regional Pain Syndrome

All the following criteria must be met:

1. Continuing pain, which is disproportionate to any inciting event
2. Must report at least 1 symptom in each of the following 4 categories:
    - *Sensory* : Hyperesthesia and/or allodynia
    - *Vasomotor* : Temperature asymmetry, skin color changes, and/or skin color asymmetry
    - *Sudomotor/edema* : Edema, sweating changes, and/or sweating asymmetry
    - *Motor/trophic* : Decreased range of motion, motor dysfunction (tremor, weakness, dystonia) and/or trophic changes (hair, nail, skin)
3. Must display at least 1 sign at time of evaluation in ≥2 of the following 4 categories:
    - *Sensory* : Evidence of hyperesthesia (to pin prick) and/or allodynia (to light touch, temperature sensation, deep somatic pressure, and/or joint movement)
    - *Vasomotor* : Evidence of temperature asymmetry (>1°C), skin color changes, and/or skin color asymmetry
    - *Sudomotor/edema* : Edema, sweating changes, and/or sweating asymmetry
    - *Motor/trophic* : Decreased range of motion, motor dysfunction (tremor, weakness, dystonia) and/or trophic changes (hair, nail, skin)
4. There is no other diagnosis that better explains the signs and symptoms.

Adapted from Harden RN, Bruel S, Stanton-Hicks, et al: Proposed new diagnostic criteria for complex regional pain syndrome, Pain Med 8:326–331, 2007.

Although the majority of pediatric patients with CRPS present with a history of minor trauma or repeated stress injury (e.g., caused by competitive sports), a sizable proportion are unable to identify a precipitating event. Usual age of onset is between 8 and 16 yr, and girls outnumber boys with the disease by as much as 6 : 1. Childhood CRPS differs from the adult form in that lower extremities, rather than upper extremities, are most often affected. The incidence of CRPS in children is unknown, largely because it is often undiagnosed or diagnosed late, with the diagnosis frequently delayed by almost 1 yr. Left untreated, CRPS can have severe consequences for children, including bone demineralization, muscle wasting, and joint contractures.

An evidence-based approach to the **treatment** of CRPS continues to suggest a multistage approach. Aggressive *physical therapy* (PT) should be initiated as soon as the diagnosis is made and CBT added as needed. PT is recommended 3-4 times/wk, and children may need analgesic premedication at the onset, particularly before PT sessions. PT is initially limited to desensitization and then moves to weight-bearing, range-of-motion, and other functional activities. CBT used as an adjunctive therapy targets psychosocial obstacles to fully participating in PT and provides pain-coping skills training. Sympathetic and epidural *nerve blocks* should be attempted only under the auspices of a pediatric pain specialist. The goal of both pharmacologic and adjunctive treatments for CRPS is to provide sufficient pain relief to allow the child to participate in aggressive physical rehabilitation. If CRPS is identified and treated early, the majority of children and adolescents can be treated successfully with low-dose *amitriptyline* (10-50 mg orally 30 min before bedtime), aggressive PT, and CBT interventions. Opioids and anticonvulsants such as gabapentin can also be helpful. Notably, multiple studies have shown that noninvasive treatments, particularly PT and CBT, are at least as efficacious as nerve blocks in helping children with CRPS achieve resolution of their symptoms.

There is growing evidence that some patients with CRPS I have a small fiber polyneuropathy (see Chapter 193.2).

193.5

Erythromelalgia

Laura E. Schanberg

Children with **erythromelalgia** experience episodes of intense pain, erythema, and heat in their hands and feet (Fig. 193.4). Less frequently involved are the face, ears, or knees. Symptoms may be triggered by exercise and exposure to heat, lasting for hours and occasionally for days. It is more common in girls and in the teenage years, and diagnosis is often delayed for years. Although most cases are sporadic, an autosomal dominant hereditary form results from mutations of the *SCN9A* gene on chromosome 2q31-32, causing a painful channelopathy. **Secondary** erythromelalgia is associated with an array of disorders, including myeloproliferative diseases, peripheral neuropathy, frostbite, hypertension, and rheumatic disease. Treatment includes avoidance of heat exposure and other precipitating situations and utilization of cooling techniques that do not cause tissue damage during attacks. NSAIDs, narcotics, anesthetic agents (lidocaine patch), anticonvulsants (oxcarbazepine, carbamazepine, gabapentin), and antidepressants, as well as biofeedback and hypnosis, may help manage pain. Drugs acting on the vascular system (aspirin, sodium nitroprusside, magnesium, misoprostol) may also be somewhat effective. However, a reliably efficacious treatment is not available, resulting in substantial negative impact on physical and mental health.

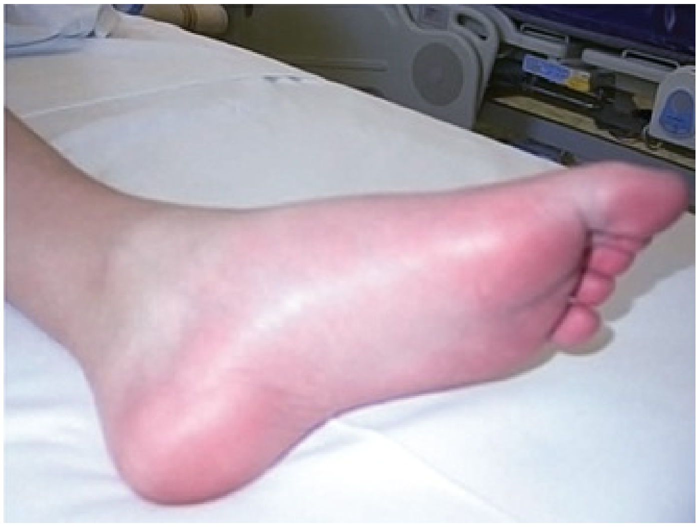

FIG. 193.4 **Erythromelalgia. Typical redness and edema of the foot. (From Pfund Z, Stankovics J, Decsi T, Illes Z: Childhood steroid-responsive acute erythromelalgia with axonal neuropathy of large myelinated fibers: a dysimmune neuropathy? *Neuromuscul Disord* 19:49–52, 2009, Fig 1A, p 50.)**

There is growing evidence that some patients with erythromelalgia have a small fiber polyneuropathy (see Chapter 193.2).

CHAPTER 194

Miscellaneous Conditions Associated With Arthritis

Angela Byun Robinson, C. Egla Rabinovich

Relapsing Polychondritis

Relapsing polychondritis (RP) is a rare condition characterized by episodic chondritis causing cartilage destruction and deformation of the ears (sparing the earlobes), nose, larynx, and tracheobronchial tree. Antibodies to matrillin-1 and collagen (type II, IX and XI) are present in approximately 60% of patients with RP, suggesting an autoimmune pathogenesis. Patients may experience arthritis, uveitis, and hearing loss resulting from inflammation near the auditory and vestibular nerves. Children may initially relate episodes of intense erythema over the outer ears. Other dermatologic manifestations may include erythema nodosum, maculopapular rash, and purpura. Cardiac involvement, including conduction defects and coronary vasculitis, has been reported. Severe, progressive, and potentially fatal disease resulting from destruction of the tracheobronchial tree and airway obstruction is unusual in childhood. **Diagnostic criteria** established for adults are useful guidelines for evaluating children with suggestive symptoms (Table 194.1). The clinical course of RP is variable; flares of disease are often associated with elevations of acute-phase reactants and may remit spontaneously. Although seen more often in the adult population, RP may coexist with other rheumatic disease (e.g., systemic lupus erythematosus, Sjögren syndrome, Henoch-Schönlein purpura) in up to 30% of patients. The differential diagnosis includes **ANCA-associated vasculitis** (granulomatosis with polyangiitis) (see Chapter 192.4) and **Cogan syndrome** , which is characterized by auditory nerve inflammation and keratitis but not chondritis. Many children respond to nonsteroidal antiinflammatory drugs, but some require corticosteroids or other immunosuppressive agents (azathioprine, methotrexate, hydroxychloroquine, colchicine, cyclophosphamide, cyclosporine, and anti–tumor necrosis factor [TNF] agents), as reported in small series and case reports.

Table 194.1

Suggested Criteria for Relapsing Polychondritis*

MAJOR

- Typical inflammatory episodes of ear cartilage
- Typical inflammatory episodes of nose cartilage
- Typical inflammatory episodes of laryngotracheal cartilage

MINOR

- Eye inflammation (conjunctivitis, keratitis, episcleritis, uveitis)
- Hearing loss
- Vestibular dysfunction
- Seronegative inflammatory arthritis

[*] The diagnosis is established by the presence of 2 major or 1 major and 2 minor criteria. Histologic examination of affected cartilage is required when the presentation is atypical.

Data from Michet CJ Jr, McKenna CH, Luthra HS, et al: Relapsing polychondritis: survival and predictive role of early disease manifestations, *Ann Intern Med* 104:74-78, 1986.

Mucha-Habermann Disease/Pityriasis Lichenoides Et Varioliformis Acuta

Pityriasis lichenoides et varioliformis acuta (**PLEVA**) is a benign, self-limited cutaneous vasculitis characterized by episodes of macules, papules, and papulovesicular lesions that can develop central ulceration, necrosis, and crusting (Fig. 194.1). Different stages of development are usually seen at once. **PLEVA fulminans** or febrile ulceronecrotic Mucha-Habermann disease (**FUMHD**) is the severe, life threatening form of PLEVA. Large, coalescing, ulceronecrotic lesions are seen, accompanied by high fever and elevated erythrocyte sedimentation rate (ESR). Systemic manifestations can include interstitial pneumonitis, abdominal pain, malabsorption, arthritis, and neurologic manifestations. PLEVA has a male predominance and occurs more frequently in childhood. The diagnosis is confirmed by biopsy of skin lesions, which reveals perivascular and intramural lymphocytic inflammation affecting capillaries and venules in the upper dermis that may lead to keratinocyte necrosis. When disease is severe, corticosteroids have been used with questionable effect, and methotrexate has been reported to induce rapid remission in resistant cases. Cyclosporine and anti-TNF agents have also been efficacious in case reports.

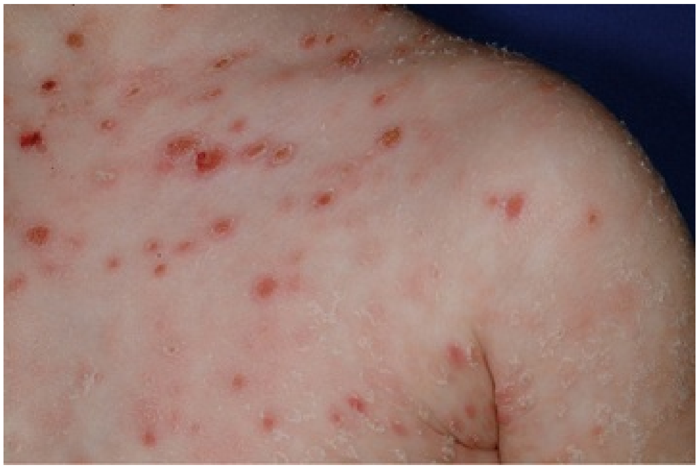

FIG. 194.1 **Pityriasis lichenoides et varioliformis acuta (PLEVA). Symmetric, oval and round, reddish brown macular, popular, necrotic, and crusted lesions on chest of 9 yr old boy. (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology,* ed 5, Philadelphia, 2016, Elsevier, Fig 4-33, p 87.)**

Sweet Syndrome

Sweet syndrome, or **acute febrile neutrophilic dermatosis** , is a rare entity in children. It is characterized by fever, elevated neutrophil count, and raised, tender erythematous plaques and nodules over the face, extremities, and trunk. Skin biopsy reveals neutrophilic perivascular infiltration in the upper dermis. Female predominance is seen in the adult population, whereas gender distribution is equal in children. Established criteria are useful for diagnosis (Table 194.2). Children can also have arthritis, sterile osteomyelitis, myositis, and other extracutaneous manifestations. Sweet syndrome may be idiopathic or secondary to malignancy (particularly acute myelogenous leukemia), drugs (granulocyte colony-stimulating factor, tretinoin or trimethoprim-sulfamethoxazole), or rheumatic diseases (Behçet disease, antiphospholipid antibody syndrome, systemic lupus erythematosus). The condition usually responds to treatment with corticosteroids, treatment of underlying disease, or removal of associated medication.

Table 194.2

Diagnostic Criteria for Classic Sweet Syndrome*

Major Criteria

- Abrupt onset of painful erythematous plaques or nodules
- Histopathologic evidence of dense neutrophilic infiltrate without evidence of leukocytoclastic vasculitis

Minor Criteria

- Pyrexia >38°C
- Association with underlying hematologic or visceral malignancy, inflammatory disease or pregnancy, *or* preceded by an upper respiratory or gastrointestinal infection or vaccination
- Excellent response to systemic corticosteroids or potassium iodide
- Abnormal laboratory values at presentation (3 of 4):
    - Erythrocyte sedimentation rate >20 mm/hr
    - Positive C-reactive protein test result
    - >8,000 leukocytes/mm^3
    - >70% neutrophils/mm^3

---

* The diagnosis is established by the presence of 2 major criteria *plus* 2 of the 4 minor criteria.

Adapted from Walker DC, Cohen PR: Trimethoprim-sulfamethoxazole-associated acute febrile neutrophilic dermatosis: case report and review of drug induced Sweet's syndrome. *J Am Acad Dermatol* 34:918–923, 1996.

Hypertrophic Osteoarthropathy

Children with chronic disease, especially pulmonary or cardiac disease, can demonstrate clubbing of the terminal phalanges and have associated periosteal reaction and arthritis. These findings characterize the classic presentation of hypertrophic osteoarthropathy. HOA can be **primary** (idiopathic) or secondary. Although rare, **secondary** HOA is more common in children and is seen in those with chronic pulmonary disease (cystic fibrosis), congenital heart disease, gastrointestinal disease (malabsorption syndromes, biliary atresia, inflammatory bowel disease), and malignancy (nasopharyngeal sarcoma, osteosarcoma, Hodgkin disease). It may precede diagnosis of cardiopulmonary disease or malignancy. The pathogenesis of secondary HOA is unknown; symptoms often improve if the underlying condition is treated successfully. HOA-related pain can be disabling; in adults, management with bisphosphonates has been reported. Evaluation of children presenting with HOA should include a chest radiograph to evaluate for pulmonary disease or intrathoracic mass. Autosomal recessive mutations in prostaglandin pathway genes have recently been described in primary HOA, also described as **pachydermoperiostosis** .

Plant Thorn Synovitis

A diagnosis of plant thorn synovitis should be considered in children with monoarticular arthritis nonresponsive to antiinflammatory therapy. Acute or chronic arthritis can occur after a plant thorn or other foreign object penetrates a joint. Unlike septic arthritis, children with plant thorn synovitis are usually afebrile. The most common organism seen with plant thorn synovitis is *Pantoea agglomerans* , although cultures are often negative. The initial injury may be unknown or forgotten, making diagnosis difficult. Ultrasound or MRI can be useful in identifying the foreign body. Removal of the foreign body using arthroscopy, followed by an antibiotic course, is the accepted therapy.

Pigmented Villonodular Synovitis

Proliferation of synovial tissue is seen in pigmented villonodular synovitis (PVNS). This proliferation is localized or diffuse and can affect the joint, tendon sheath, or bursa. Macrophages and multinucleated giant cells with brownish hemosiderin are present histologically. It is unclear if the etiology of PVNS is inflammatory or neoplastic in nature. Although findings are not pathognomonic, MRI with contrast is a useful diagnostic tool by which PVNS can be seen as a mass or bone erosion. Brown or bloody synovial fluid is seen with arthrocentesis, but the diagnosis is made by tissue biopsy. Surgical removal of the affected tissue is the therapeutic modality, and with diffuse disease, a total synovectomy is recommended.

Chapter 195 Diagnostic Microbiology
Chapter 196 The Microbiome and Pediatric Health

CHAPTER 195

Diagnostic Microbiology

Carey-Ann D. Burnham, Gregory A. Storch

Laboratory evidence to support the diagnosis of an infectious disease may be based on one or more of the following: direct examination of specimens using microscopic or antigen detection techniques, isolation of microorganisms in culture, serologic testing, host gene expression patterns, or molecular detection of an organism, resistance determinant, or virulence factor. Some additional roles of the clinical microbiology laboratory include performing antimicrobial susceptibility testing and supporting hospital infection prevention in the detection and characterization of pathogens associated with nosocomial infections.

Specimen Collection

The success of a diagnostic microbiology assay, that is, detection of a pathogen if present, is directly linked to specimen collection techniques. In general, this means collecting the correct specimen type for the disease or condition in question and promptly transporting the specimen to the laboratory for analysis. Although **swab specimens** may be necessary for some conditions, in general a swab is a suboptimal specimen. A swab is only able to hold a very small amount of specimen (approximately 100 µL), and, using a traditional swab, only a small fraction of organisms that are absorbed onto a swab will be released back into the culture. **Flocked swabs** coupled with transport medium improve organism recovery. However, when possible, fluid or tissue should be submitted to the laboratory for analysis. If anaerobic infection is suspected, the sample should be transported in appropriate medium to preserve viability of anaerobic bacteria. For the recovery of some organism types, such as viruses and *Neisseria gonorrhoeae* , specific transport media may be required. Considerations specific to the collection of blood cultures are addressed in the blood culture section.

Laboratory Diagnosis of Bacterial and Fungal Infections

Although the scope and availability of molecular methods for detection of bacterial and fungal pathogens have increased rapidly, the diagnosis of many of these infections depends on microscopic detection of organisms or cultivation of organisms on **culture media** .

Microscopy

The **Gram stain** is an extremely valuable diagnostic technique to provide rapid and inexpensive information regarding the absence or presence of inflammatory cells and organisms in clinical specimens. For some specimen types, the presence of inflammatory and epithelial cells is used to judge the suitability of a specimen for culture. For example, the presence of >10 epithelial cells per low-power field in a sputum specimen is highly suggestive of a specimen contaminated with oral secretions. In addition, a preliminary assessment of the etiologic agent can be made based on the morphology (e.g., cocci vs rods) and stain reaction (e.g., gram-positive isolates are purple; gram-negative isolates are red) of the microorganisms. However, a negative Gram stain does not rule out infection, since 10^4 to 10^5 microorganisms per milliliter (mL) in the specimen are required for detection by this method.

In addition to the Gram stain, many other stains are used in microbiology, both to detect organisms and to help infer their identity (Table 195.1).

Table 195.1

Stains Used for Microscopic Examination

TYPE OF STAIN	CLINICAL USE
Gram stain	Stains bacteria (with differentiation of gram-positive and gram-negative organisms), fungi, leukocytes, and epithelial cells.
Potassium hydroxide (KOH)	A 10% solution dissolves cellular and organic debris and facilitates detection of fungal elements in clinical specimens.
Calcofluor	Nonspecific fluorochrome that binds to cellulose and chitin in fungal cell walls, can be combined

white stain	with 10% KOH to dissolve cellular material.
Ziehl-Neelsen and Kinyoun stains	Acid-fast stains, using basic carbolfuchsin, followed by acid-alcohol decolorization and methylene blue counterstaining.
	Acid-fast organisms (e.g., *Mycobacterium*) resist decolorization and stain pink.
	A weaker decolorizing agent is used for partially acid-fast organisms (e.g., *Nocardia, Cryptosporidium, Cyclospora, Isospora*).
Auramine-rhodamine stain	Acid-fast stain using fluorochromes that bind to mycolic acid in mycobacterial cell walls and resist acid-alcohol decolorization; usually performed directly on clinical specimens.
	Acid-fast organisms stain orange-yellow against a black background.
Acridine orange stain	Fluorescent dye that intercalates into DNA, used to aid in differentiation of organisms from debris during direct specimen examination, and also for detection of organisms that are not visible with Gram stain.
	Bacteria and fungi stain orange, and background cellular material stains green.
Lugol iodine stain	Added to wet preparations of fecal specimens for ova and parasites to enhance contrast of the internal structures (nuclei, glycogen vacuoles).
Wright and Giemsa stains	Primarily for detecting blood parasites (*Plasmodium, Babesia,* and *Leishmania*), detection of amoeba in preparations of cerebrospinal fluid, and fungi in tissues (yeasts, *Histoplasma*)
Trichrome stain	Stains stool specimens for identification of protozoa.
Direct fluorescent-antibody stain	Used for direct detection of a variety of organisms in clinical specimens by using specific fluorescein-labeled antibodies (e.g., *Pneumocystis jiroveci,* many viruses).

Isolation and Identification

The approach to isolation of microorganisms in a clinical specimen will vary depending on the body site and pathogen suspected. For body sites that are usually sterile, such as cerebrospinal fluid, **nutrient-rich media** such as sheep blood agar and chocolate agar are used to aid in the recovery of fastidious pathogens. In contrast, stool specimens contain abundant amounts of commensal bacteria, and thus to isolate pathogens, selective and differential media must be used. **Selective media** will inhibit the growth of some organisms to aid in isolation of suspect pathogens; **differential media** rely on growth characteristics or carbohydrate assimilation characteristics to impart a growth pattern that differentiates organisms. MacConkey agar supports growth of gram-negative rods while suppressing gram-positive organisms, and a color change in the media from clear to pink distinguishes lactose-fermenting organisms from other gram-negative rods. Special media, such as Sabouraud dextrose agar and inhibitory mold agar, are used to recover fungi in clinical specimens. Many pathogens, including *Bartonella* , *Bordetella pertussis* , *Legionella* , *Mycoplasma* , some *Vibrio* spp., and certain fungal pathogens such as *Malassezia furfur* , require specialized growth media or incubation conditions. Consultation with the laboratory is advised when these pathogens are suspected.

Once an organism is recovered in culture, additional testing is performed to identify the isolate. Confirmation of microbial identity has classically been performed using tests that rely on the phenotypic properties of an isolate; examples include coagulase activity, carbohydrate assimilation patterns, indole production, and motility. However, phenotypic methods are not able to resolve all organisms to species level, and they require incubation time. In some instances, sequence-based identification may be necessary. For bacteria, this is usually based on sequence analysis of the bacterial 16S rRNA gene. This gene is a molecular chronometer that is highly conserved within a species but variable between species; as such, it is an excellent resource for organism identification.

Matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (**MALDI-TOF MS**) is a rapid and accurate technique that is based on generating a protein fingerprint of an organism and comparing that fingerprint to a library of known organisms to produce an identification. This method can identify bacteria or yeast that have been recovered in culture within minutes, and the consumable costs for these analyses are minimal. However, this methodology currently lacks the ability to resolve polymicrobial samples, and the biomass required for successful MALDI-TOF MS analysis generally precludes analysis directly from clinical specimens.

Blood Culture

The detection of microbes in blood culture specimens of patients with bloodstream infection is one of the most important functions of the clinical microbiology laboratory. Most blood cultures are performed by collecting blood into bottles of nutrient-rich broth to facilitate the growth of bacteria or yeast. Blood cultures are frequently submitted as a set that includes an aerobic and an anaerobic bottle, although in children, especially neonates, typically only an aerobic bottle is used. Some blood culture media contain resins or other agents to help neutralize antibiotics that may be present in the patients’ blood. Blood culture bottles are then placed into an automated blood culture incubator that will monitor the blood culture bottle at regular intervals for evidence of growth. Once the instrument detects evidence of microbial growth, an alarm alerts the laboratory. Approximately 80% of blood cultures that will ultimately be positive are identified within the 1st 24 hr of incubation. A portion of broth from a blood culture bottle that has signaled positive is then gram-stained and subsequently inoculated onto appropriate growth media so that the organism can be isolated and identified. Numerous preanalytical variables can influence the accuracy of blood culture results. To facilitate accurate interpretation of a positive blood culture, a minimum of 2 blood cultures drawn from different sites should be collected whenever possible. Growth of an organism that is part of the normal skin flora from a single blood culture raises concern that the isolate resulted from contamination of the culture.

To maximize detection of bloodstream infection, up to 4 blood cultures should be collected over 24 -hr. Proper skin antisepsis is essential before blood collection. Chlorhexidine is frequently used for this purpose, but alcohol is also used. If blood is collected through an indwelling line, proper antisepsis before collection is also important. The practice of obtaining blood for culture from intravascular catheters without accompanying peripheral venous blood cultures should be discouraged, because it is difficult to determine the significance of coagulase-negative staphylococci and other skin flora or environmental organisms isolated from blood obtained from line cultures. Differential time to positivity of 2 hr or more between paired blood cultures drawn simultaneously from a catheter and peripheral vein has been cited as an indicator of catheter-related bloodstream infection.

The volume of blood collected is also an important factor in the recovery of bloodstream pathogens, especially as the number of organisms per milliliter of blood in sepsis may be low (<10 colony-forming units/mL). The optimal amount of blood to collect from a pediatric patient varies depending on the weight of the child. The **Clinical and Laboratory Standards Institute** (CLSI) and Cumitech provide guidance on the amount of blood that is safe to collect from children of different sizes. For children from 3 to <12 kg, 3-5 mL is suggested; from 12 to <36 kg, 5-10 mL; from 36-50 kg, 10-15 mL, and >50 kg, 20 mL.

A number of **rapid diagnostic assays** can be performed directly on positive blood culture broth to identify pathogens frequently associated with bacteremia and some antimicrobial resistance determinants. Most of these rapid diagnostic assays are based on nucleic acid detection techniques. For example, the Verigene system can identify staphylococcal, streptococcal, and enterococcal species, as well as *mecA* and *vanA* genes, in positive blood culture broth in approximately 2 hr using the gram-positive blood culture panel. After specimen preparation to concentrate microorganisms and remove residual broth and blood from the blood culture specimen, MALDI-TOF MS can also be performed on blood culture broth that is positive for growth of microorganisms. These assays can help shorten the interval between a positive blood culture and definitive organism identification, with the goal of early optimization of antimicrobial therapy.

Detection of mycobacteria and some filamentous fungi (e.g., *Histoplasma* *capsulatum*) from the bloodstream is maximized using lysis-centrifugation techniques, such as the Isolator system (Wampole, Cranbury, NJ).

Cerebrospinal Fluid Culture

Cerebrospinal fluid (CSF) should be transported quickly to the laboratory and then cytocentrifuged to concentrate organisms for microscopic examination. CSF is routinely cultured on blood agar and chocolate agar, which support the growth of common pathogens causing meningitis. If tuberculosis is suspected, cultures for mycobacteria should be specifically requested. Culture of larger volumes of CSF (>10 mL) significantly improves yield of mycobacteria.

Historically, rapid antigen detection tests for bacterial pathogens such as *Haemophilus influenzae* type b and *Streptococcus pneumoniae* were used to attempt to detect organisms in CSF without the need for culture. These techniques lack sensitivity and in some cases specificity. A cytospin Gram stain is as sensitive as bacterial antigen tests for detection of microorganisms in CSF. In contrast, the cryptococcal antigen test can be useful when cryptococcal meningitis is suspected. Historically, India ink preparations were used to detect *Cryptococcus* in CSF, but this method is insensitive compared with the antigen detection assay.

In the postvaccine era, the epidemiology of infectious meningitis is rapidly changing, and acute bacterial meningitis is now a relatively infrequent event in North America. Many CSF infections are associated with shunts or other hardware, and *Propionibacterium* and coagulase-negative staphylococci are the organisms most frequently isolated from shunt infections. The laboratory should include media to facilitate the growth of *Propionibacterium* in CSF specimens received from neurosurgery patients.

Urine Culture

Urine for culture (including colony count) can be obtained by collecting clean-voided midstream specimens, by catheterization, or by suprapubic aspiration. Urine samples collected by placing bags on the perineum are unacceptable for culture because samples are often contaminated. Rapid transport of unpreserved urine to the laboratory (<2 hr) is imperative, and delay in transport or plating of specimens renders colony counts unreliable. Refrigeration or urine transport devices with boric acid preservative may be used when delay is unavoidable.

The specific colony counts used to define growth in a urine culture as *significant* are somewhat controversial and vary by laboratory. Urine obtained by suprapubic aspirate is normally sterile, and thus any organism growth is typically considered significant. Urine collected by catheterization is likely to reflect infection if there are $\geq 10^3$ to 10^4 organisms/mL. In general, clean-voided urine is considered abnormal if $\geq 10^4$ to 10^5 organisms/mL are present, although culture interpretation can be variable depending on the patient's age and the clinical setting.

Genital Culture

Neisseria gonorrhoeae is a fragile organism, and collection and transport in special medium are essential for efficient recovery. Selective agar, such as modified Thayer-Martin medium, should be used to enhance recovery of *N. gonorrhoeae* in clinical specimens, such as genital, anorectal, and pharyngeal swabs. Antimicrobial resistance is increasing in *N. gonorrhoeae* and is cited as an Urgent Threat by the U.S. Centers for Disease Control and Prevention (CDC), although few clinical laboratories have the ability to perform antimicrobial susceptibility testing for this organism. In pediatric patients, the identification of an organism as *N. gonorrhoeae* should be confirmed using 2 independent methods.

Specimens for ***Chlamydia trachomatis*** culture are obtained by cotton-tipped, aluminum-shafted urethral swabs. Endocervical specimens, using swabs with aluminum or plastic shafts, should be collected by rubbing the swab vigorously against the endocervical wall to obtain as much cellular material as possible. *C. trachomatis* is an obligate intracellular organism and is cultured by inoculation into cell culture systems, followed by immunofluorescent staining with monoclonal antibody against the organism. Nonculture methods such as DNA amplification methods are widely used and are more cost-effective than culture.

Although **nucleic acid amplification test (NAAT) assays** for *N. gonorrhoeae* and *C. trachomatis* are not approved by the U.S. Food and Drug Administration (FDA) for use in children, these assays are frequently used in this population to detect these organisms in urine specimens, endocervical and vaginal swabs, and penile swabs. The NAAT assays exhibit superior sensitivity compared to culture-based techniques. Some laboratories take the approach of confirming all NAAT-positive specimens with an alternative NAAT test that detects an alternative genetic target.

Throat and Respiratory Culture

Streptococcal pharyngitis and tonsillitis is a common diagnosis in pediatric patients; vigorous swabbing of the tonsillar area and posterior pharynx can be done to obtain a specimen for detection of group A streptococcus *(Streptococcus pyogenes).* Rapid antigen detection assays or rapid nucleic acid detection assays are frequently used when group A streptococcus pharyngitis is suspected. Negative rapid antigen assays should be confirmed using culture-based techniques. Rapid NAAT assays for detection of group A streptococcus are also being used with increasing frequency. These assays have increased sensitivity, but clinical experience with them is still limited and there are not yet recommendations regarding whether backup culture is required. Most laboratories screen throat cultures exclusively for the presence of group A streptococci. However, large colony variants of group C and group G streptococci (*Streptococcus dysgalactiae*) have also been associated with pharyngitis but are not associated with the same postinfectious sequelae attributed to group A streptococcus; laboratory practices for detecting and reporting group C and group G streptococci are variable and an area of controversy.

In addition to the detection of pathogenic streptococci, the clinical laboratory may query for diphtheria, gonococcal pharyngitis, or infection with *Arcanobacterium haemolyticum* in pharyngeal specimens. The laboratory should be notified if any of these pathogens is suspected, to ensure that appropriate methods are used to recover these organisms if present.

Cultures for *Bordetella pertussis* can be obtained by aspiration or swabbing of the nasopharynx using a Dacron or calcium alginate swab. The aspirate or swab is inoculated onto special charcoal-blood (Regan-Lowe) or Bordet-Gengou media, although molecular assays are now frequently used for detection of *B. pertussis* in these specimens.

The cause of lower respiratory tract disease in children is frequently difficult to confirm microbiologically because of the challenge of obtaining adequate sputum specimens. Gram-stained smears of specimens should be performed to assess the adequacy of sputum samples; specimens with large numbers of epithelial cells (>10 per high-power field) or with few neutrophils are unsuitable for culture, because correlation is lacking between upper respiratory tract flora and organisms causing lower respiratory tract disease. For patients with **cystic fibrosis** , special media should be used to detect pathogens important in cystic fibrosis, such as *Burkholderia cepacia* complex.

Endotracheal aspirates from intubated patients may be useful if the Gram stain shows abundant neutrophils and bacteria, although pathogens recovered from such specimens might still reflect only contamination from the endotracheal tube or upper airway. Quantitative cultures of bronchoalveolar lavage fluid may be valuable for distinguishing upper respiratory tract contamination from lower respiratory disease.

If infection with *Legionella* is suspected, the laboratory should be alerted so that the specimen can be inoculated to special media (e.g., buffered charcoal–yeast extract agar) to facilitate the recovery of this pathogen. The *Legionella* urinary antigen test is a noninvasive, sensitive and specific method for rapid detection of *L. pneumophila* serogroup 1.

The diagnosis of pulmonary **tuberculosis** in young children is best made by culture of early-morning gastric aspirates, obtained on 3 consecutive days. Sputum induction for obtaining specimens for mycobacterial culture has also proved useful in young children but requires skilled personnel and containment facilities to prevent exposure of healthcare workers. Cultures for *Mycobacterium tuberculosis* should be processed only in laboratories equipped with appropriate biologic safety cabinets and containment facilities. NAATs for detection of *M. tuberculosis* in respiratory specimens (e.g., Cepheid Xpert MTB assay) are becoming widely available and have very high sensitivity when performed on smear-positive sputum specimens.

Detection of Enteric Pathogens

In pediatric patients with diarrheal illnesses, culture of stool for enteric pathogens may be requested. A fresh stool specimen is preferred but is not always possible to obtain. If there is an unavoidable delay in specimen transport, the specimens should be placed in an appropriate transport medium, such as Cary-Blair. Rectal swabs for enteric culture are also acceptable specimens if the swab is visibly soiled. In general, enteric cultures should be performed on specimens from outpatients or patients who have been hospitalized for <3 days, since nosocomial acquisition of an enteric pathogen is extremely uncommon.

Stool specimens are typically plated on a series of selective and differential media to decrease the overgrowth of normal flora and recover pathogenic organisms if present. The specific pathogens queried vary by laboratory. Most laboratories in North America will routinely culture for *Salmonella* , *Shigella* , *Campylobacter,* and Shiga toxin–producing strains of *Escherichia coli* . The CDC recommends that all laboratories use an agar-based medium for recovery of

E. coli O157 in addition to an assay for detection of Shiga toxin production (e.g., immunoassay to detect Shiga toxin(s), nucleic acid detection assay for stx1/stx2). Practices surrounding the routine culture for *Yersinia enterocolitica* , *Vibrio cholerae* , *Edwardsiella* , *Aeromonas,* and *Plesiomonas* will vary with local epidemiology, and the laboratory should always be notified if one of these pathogens is specifically suspected.

Clostridium difficile is an important cause of antibiotic-associated diarrhea. *C. difficile* was long characterized as a nosocomial pathogen of older adults, but community-associated disease is emerging, and the incidence and severity of *C. difficile* infection in children are increasing. The optimal method for detection of *C. difficile* in fecal specimens is highly controversial; in general, however, detection of *C. difficile* toxin in fecal specimens has higher clinical specificity than toxigenic culture or nucleic acid detection methods. Testing for *C. difficile* in children <1 yr old should be discouraged because of the high incidence of colonization in this patient population.

Viruses are an important cause of **gastroenteritis** in pediatric patients. Methods for viral detection will vary but may include antigen detection (e.g., for rotavirus or adenovirus 40/41) or nucleic acid detection methods (e.g., for norovirus). In North America the burden of *parasitic* gastroenteritis is low. Complete microscopic exams for ova and parasite detection in stool samples is usually of low yield, and antigen detection assays for *Cryptosporidium* and *Giardia* , the most commonly encountered agents, are a sensitive and cost-effective method for detection of these pathogens.

Multiplex nucleic acid detection tests for simultaneous detection of a dozen or more enteric pathogens, including bacteria, viruses, and parasites, have been FDA-cleared and are available for clinical use. The deployment of these assays in clinical laboratories is variable, and the results of this testing can be difficult to interpret, especially when multiple targets are detected in a specimen (e.g., co-detection of *C. difficile* and an enteric bacterial pathogen in a young child).Culture-independent diagnostics may also challenge the public health response if bacterial isolates are not available for epidemiologic analysis. Although these assays have great promise to expedite the detection of the causative agent of diarrhea in children, laboratories and clinicians are still in the learning phase of how best to deploy this testing.

Culture of Other Fluids and Tissues

Abscesses, wounds, pleural fluid, peritoneal fluid, joint fluid, and other purulent fluids are cultured onto solid agar and, in some cases, broth media. Whenever possible, fluid and/or tissue rather than swabs from infected sites should be sent to the laboratory, because culture of a larger volume of fluid can detect organisms present in low concentration. **Anaerobic** organisms are involved in many abdominal and wound abscesses. These specimens should be collected and transported to the laboratory rapidly in anaerobic transport medium.

Although *Staphylococcus aureus* is the most common cause of bone and joint infections, *Kingella kingae* is an important cause of **septic arthritis** in children, especially in children <4 yr old. The detection of *K. kingae* is maximized by inoculation of synovial fluid into blood culture broth in addition to plating on solid medium. A number of studies suggest that molecular detection of *K. kingae* in specimens from young patients with suspected septic arthritis may be the most sensitive way to make this diagnosis.

Screening/Surveillance Cultures

Clinical laboratories may perform surveillance cultures for specific pathogens either to assist infection control in identifying patients requiring contact isolation or for outbreak investigation. Screening cultures for detection of methicillin-resistant *S. aureus* in the anterior nares or vancomycin-resistant enterococci in fecal specimens or rectal swabs may be routinely performed in certain patient populations. In addition, hospitals with carbapenem-resistant *Enterobacteriaceae* or a high prevalence of extended-spectrum β-lactamase–producing *Enterobacteriaceae* (ESBLs) may screen patients for fecal carriage of these organisms. Chromogenic media are frequently used for this purpose. These media contain proprietary compounds to select for the resistant organisms and result in growth of colored colonies to assist in the identification of the microbe of interest.

Antimicrobial Susceptibility Testing

Antimicrobial susceptibility tests are generally performed on organisms of clinical significance for which standards and interpretive criteria for susceptibility testing exist. In North America, most laboratories use commercial, automated systems for susceptibility testing. The output from these systems is a *minimum inhibitory concentration* (MIC) value and interpretation of that value as susceptible, intermediate, or resistant. The next most common technique is

Kirby-Bauer **disk diffusion** , in which a standardized inoculum of the organism is seeded onto an agar plate. Antibiotic-impregnated filter paper disks are then placed on the agar surface. After overnight incubation, the zone of inhibition of bacterial growth around each disk is measured and compared with nationally determined standards for susceptibility or resistance.

A less common technique is **broth or microbroth dilution** testing. A standard concentration of a microorganism is inoculated into serially diluted concentrations of antibiotic, and the MIC in µg/mL, the lowest concentration of antibiotic required to inhibit growth of the microorganism, is determined. The **gradient diffusion** method such as E-test is a hybrid of disk diffusion and broth dilution and can be used to determine the MIC of individual antibiotics on an agar plate. It uses a paper strip impregnated with a known continuous concentration gradient of antibiotic that diffuses across the agar surface, inhibiting microbial growth in an elliptical zone. The MIC is read off the printed strip at the point at which the zone intersects the strip. Major advantages of the gradient diffusion method are reliable interpretation, reproducibility, and applicability to organisms that require special media or growth conditions.

In addition to providing data to guide the treatment of individual patients, laboratories use aggregate susceptibility testing data to generate institution-specific **antibiogram** reports. These reports summarize susceptibility trends for common organisms and can be used to guide empirical therapy before the availability of specific susceptibility testing results.

Antimicrobial susceptibility patterns are rapidly changing as microbes evolve new resistance mechanisms. Recommendations for performance standards for antimicrobial susceptibility tests and their interpretation are regularly updated by groups such as the CLSI and **European Committee on Antimicrobial Susceptibility Testing** (EUCAST).

Fungal Cultures

Special growth media is used to recover fungi, both yeasts and molds, in clinical specimens. Since most fungi prefer reduced growth temperatures and some species grow slowly, fungal cultures are incubated at 30°C (86°F) for 4 wk. All manipulations of filamentous fungi should take place in the biologic safety cabinet to avoid infecting laboratory personnel and prevent laboratory contamination.

Most yeasts are identified using methods similar to those used for bacteria. In contrast, the standard of care for identification of filamentous fungi has not changed in nearly a century. The laboratory takes into consideration the growth rate, color, and colony characteristics of an isolate and then prepares the specimen in lactophenol alanine blue for microscopic evaluation. These features in aggregate are used to identify the isolate. In some cases, DNA sequencing is used for fungal identification, and MALDI-TOF MS is also emerging for identification of filamentous fungi. Antigen detection assays are also available for some fungal pathogens such as *Cryptococcus neoformans* and *Histoplasma capsulatum* . Assays to detect galactomannan, a molecule found in the cell wall of *Aspergillus* (in addition to some other filamentous fungi), are commercially available and increasingly used to assist in making the diagnosis of invasive aspergillosis in immunocompromised populations.

Point-of-Care Diagnostics

Some assays to detect infections may be performed in the office setting, provided the site is certified as meeting appropriate quality assurance standards specified by the **Clinical Laboratory Improvement Amendments** (CLIA) of 1988. These include procedures listed under the category of *provider-performed microscopy* such as wet mounts, potassium hydroxide preparations, pinworm examinations, and urinalysis.

Many pediatric offices perform rapid antigen and CLIA-waived nucleic acid detection assays for detection of group A streptococcal pharyngitis and common respiratory viruses such as influenza. The sensitivity of point-of-care testing depends on specimen collection technique, the type of kit used, and the concentration of target analyte present in the sample. In addition, some antigen detection assays for influenza lack sensitivity. Providers using point-of-care diagnostics should familiarize themselves with the analytical performance characteristics of these tests and seek alternative testing methods when clinically indicated.

Office laboratories licensed to perform waived tests are limited to performing these tests and avoid having to undergo inspections and proficiency testing, although they are still subject to CLIA certification requirements specific to these tests. Gram staining, culture inoculation, and isolation of bacteria are considered moderately to highly complex tests under CLIA specifications. Any office laboratory performing Gram stains or cultures must comply with the same requirements and inspections for quality assurance, proficiency testing, and personnel requirements as fully licensed microbiology laboratories.

Laboratory Detection of Parasitic Infections

Most parasites are detected by microscopic examination of clinical specimens. *Plasmodium* and *Babesia* can be detected in stained blood smears, *Leishmania* can be detected in stained bone marrow smears, and helminth eggs, *Entamoeba histolytica*, and *Giardia lamblia* can be detected in stained fecal smears (see Table 195.1). Serologic tests are important in documenting exposure to certain parasites that are not typically found in stool or blood, and thus are difficult to demonstrate in clinical specimens, such as *Trichinella* .

Pinworm is a relatively common parasitic infection in pediatric patients. A diagnosis of pinworm can be made by evaluating a pinworm prep. The best time to obtain this specimen is first thing in the morning, before the patient has bathed or had a bowel movement. A piece of clear tape is pressed onto the perianal region of the patient and then applied to a clear microscope slide. The slide is examined for recovery of pinworm eggs or worms.

Fecal specimens should not be contaminated with water or urine, because water can contain free-living organisms that can be confused with human parasites, and urine can destroy motile organisms. Mineral oil, barium, and bismuth interfere with the detection of parasites, and specimen collection should be delayed for 7-10 days after ingestion of these substances. Because *Giardia* and many worm eggs are shed intermittently into feces, a minimum of 3 specimens on nonconsecutive days are recommended to exclude the diagnosis of an enteric parasite. Because many protozoan parasites are easily destroyed, collection kits with appropriate stool preservatives should be used if a delay is anticipated between time of specimen collection and transport to the laboratory.

Ova and parasite examination of fecal specimens includes a wet mount (to detect motile organisms if fresh stool is received), concentration (to improve yield), and permanent staining (e.g., trichrome) for microscopic examination. *Cryptosporidium* , *Cyclospora*, and *Isospora* are detected by modified acid-fast stain, and microsporidia are detected by a modification of the trichrome stain. In addition, *Cyclospora* and *Isospora* autofluoresce under ultraviolet (UV) microscopy. The laboratory should be alerted if these parasites are suspected. Detection of certain intestinal parasites, especially *Giardia* and *Cryptosporidium*

, can be simplified by using antigen detection tests (immunoassays or direct fluorescent-antibody assays). In addition, *Giardia* and/or *Cryptosporidium* spp. may be targets included on multiplex molecular panels for detection of pathogens causing diarrhea.

Amebic encephalitis , caused by *Acanthamoeba* , *Balamuthia* , or *Naegleria* , is a rare but devastating and rapidly progressive disease. Special laboratory stains and procedures are required to detect these organisms. The laboratory should be notified if this infection is suspected.

Rapid antigen detection tests for *Plasmodium* spp. are available. The sensitivity and specificity of these tests vary depending on the burden of parasite in the sample and the specific *Plasmodium* species. In general, these tests are most sensitive for detecting *P. falciparum* and least sensitive for detecting *P. malariae* . These tests are particularly useful for laboratories lacking personnel trained in evaluation of thick and thin smears for malaria, or to provide a rapid preliminary result while awaiting microscopy. All positive and negative rapid malaria assays should be confirmed with blood smear analysis.

Trichomonas vaginalis is a sexually transmitted protozoan parasite that can also be transmitted on household fomites. Infected individuals may be asymptomatic or may have mild inflammation or severe inflammation and discomfort. *Trichomonas* may be detected using a wet mount, but this method is insensitive. Rapid antigen assays and culture-based methods are available. NAATs are a rapid and sensitive way to detect *Trichomonas* .

Serologic Diagnosis

Serologic tests are primarily used in the diagnosis of infectious agents that are difficult to culture in vitro or detect by direct examination, such as *Bartonella, Francisella, Legionella, Borrelia* (Lyme disease), *Treponema pallidum, Mycoplasma, Rickettsia,* some viruses (HIV, Epstein-Barr, hepatitis A), and some parasites *(Toxoplasma, Trichinella).*

Antibody tests may be specific for immunoglobulin (Ig) G or IgM or can measure antibody response regardless of immunoglobulin class. In very general terms, the IgM response occurs earlier in the illness, generally peaking at 7-10 days after infection, and usually disappears within a few weeks, but for some infections (e.g., hepatitis A, West Nile) it can persist for months. The IgG response peaks at 4-6 wk and often persists for life. Because the IgM response is transient, the presence of IgM antibody in most cases correlates with recent infection. Methods for IgM antibody detection are difficult to standardize, however, and false-positive results typically occur with some IgM assays. The presence of IgG antibody can indicate new seroconversion or past exposure to the pathogen. To confirm a new infection using IgG testing, it is essential to demonstrate either seroconversion or a rising IgG titer. A 4-fold increase in a convalescent titer obtained 3-4 wk after the acute titer is considered diagnostic in most situations. In neonates, interpretation of serologic tests is difficult because of passive transfer of maternal IgG that can persist for 6-18 mo after birth.

Context is extremely important in the interpretation of serologic findings. Important considerations are the ability of the host to mount an immune response, the background rate of seropositivity (especially for IgG detection assays), and for some diseases the antibody titer. In addition, interpretation of some serologic assays, such as those used to diagnose **Lyme disease** , are problematic because of lack of specificity of the immunoassays. A confirmatory immunoblot (Western blot) is required for all positive and equivocal enzyme immunoassay (EIA) results for Lyme disease.

Laboratory Diagnosis of Viral Infections

Viral diseases are extremely important in pediatrics, and **diagnostic virology** has long been important to pediatric practice, especially in the inpatient setting.

Specimens

Specimens for viral diagnosis are selected on the basis of knowledge of the site that is most likely to yield the suspected pathogen. When evaluating patients with acute viral infections, specimens should be collected early in the course of infection, when viral shedding tends to be maximal. Swabs should be rubbed vigorously against mucosal or skin surfaces to obtain as much cellular material as possible and sent in viral transport media that contain antibiotics to inhibit bacterial growth. Rectal swabs should contain visible fecal material. Flocked swabs have been shown to provide more material for the laboratory with consequent improvement in the performance of diagnostic tests. Fluids and respiratory secretions should be collected in sterile containers and promptly delivered to the laboratory. All specimens should be transported on ice if delay is anticipated. Freezing specimens, especially at −20°C (−4°F), can result in a significant decrease in culture sensitivity. Consultation with the laboratory is recommended, because some commercial diagnostic test kits used by laboratories may require specific collection devices.

Laboratory diagnosis of viral infections may be by electron microscopy, antigen detection, virus isolation in culture, serologic testing, or molecular techniques to detect viral nucleic acids. In the past few years, **molecular tests** have emerged as the primary means for detecting viral infections, with some virology laboratories abandoning the use of viral culture altogether. An exciting development is the availability of FDA-cleared multiplex assays that simultaneously detect multiple viruses as well as nonviral agents. Serologic testing still has an important role, especially for arboviral infections such as West Nile, Zika, chikungunya, and dengue; acute Epstein-Barr virus (EBV) infections; HIV; hepatitis A to E, and diseases of childhood such as measles, rubella, and mumps. Serology is also uniquely useful for defining immunity to specific viral infections.

Antigen Detection Tests

Immunofluorescent antibody (IFA) techniques or other methods, such as EIA, were the mainstay of the diagnosis of respiratory viral infections but are now being replaced by molecular tests. IFA assays of cellular material from respiratory secretions can identify the antigens of respiratory syncytial virus (RSV), adenovirus, influenza A and B viruses, parainfluenza virus types 1-3, and human metapneumovirus within 2-3 hr after the specimen is received. The sensitivity of IFA staining for RSV exceeds that of culture in many laboratories but is less than that of molecular tests. Sensitive IFA staining techniques are also commercially available for identifying varicella-zoster virus and herpes simplex virus. A method for detecting cytomegalovirus (CMV) pp65 antigen in blood of immunocompromised patients is also available but has been largely replaced by molecular testing. IFA is not useful for detecting viruses in specimens that do not contain an adequate number of infected cells.

Rapid antigen tests are usually based on lateral flow immunochromatography (similar to rapid tests for group A streptococcus) and have been approved by the FDA for detection of influenza A and B and RSV. Recent modifications that increase sensitivity include fluorescent labels and instrumented readers. Some rapid antigen tests have waived status under CLIA, meaning that they can be performed by personnel who are not trained laboratory technologists, with relatively little formal quality control other than controls that are incorporated into the test devices. Some require only 10 min to perform. Consequently, these tests can be performed in a physician's office or an emergency department. Sensitivity in children is 50–80%, generally higher for children than for adults. Rapid antigen tests can be useful in managing patients with acute respiratory infections, provided the caregiver keeps in mind that a negative test does not rule out the diagnosis of influenza or RSV. Positive tests that are properly read tend to be reliable, but the presence of a virus such as influenza or RSV does not rule out the presence of concomitant bacterial infection.

In addition to their role in respiratory virus infections, antigen detection EIA tests are often used for the diagnosis of viruses that are difficult to culture, such as rotavirus, enteric adenovirus, and hepatitis B virus. The detection of the p24 antigen of HIV along with HIV antibodies is included in fourth-generation EIA tests used in the diagnostic algorithm for HIV.

Viral Culture

Viruses require living cells for propagation; the cells used most often are human- or animal-derived tissue culture monolayers, such as human embryonic lung fibroblasts or monkey kidney cells. Historically, in vivo methods such as inoculation of suckling mice were also used but are rarely used today. Viral growth in susceptible cell culture is usually accomplished by detecting characteristic cytopathic effect that is visible by light microscopy under low magnification in the cultured cells. The most reliable confirmatory method for viral detection in cell culture involves fluorescein- or enzyme-labeled monoclonal antibody staining of infected cell monolayers. An important technical improvement in respiratory viral cultures is the development of cell culture systems that include more than 1 type of cell (R-Mix, Diagnostic Hybrids/Quidel, San Diego, CA) and employ IFA staining for virus detection. This system provides results in 16-40 hr from the time the specimen is received in the laboratory, compared to 2-10 days for conventional cultures. Cell culture methods are now being steadily replaced by molecular tests, which are faster, may be more sensitive, and have the potential to detect viruses that do not grow readily in cell cultures.

Molecular Diagnostics

Molecular tests to detect viruses use the polymerase chain reaction (PCR) and other comparable nucleic acid amplification methods. FDA-cleared multiplex tests have become available for the diagnosis of respiratory, gastrointestinal, and central nervous system (CNS) infections. Some of these tests detect 20 or more different agents at the same time and may require only about 65 min to perform. The infectious agents detected by multiplex panels may include bacteria, fungi, and parasites as well as viruses (Table 195.2).

Table 195.2

Multiplex Molecular Assays for Viral Diagnosis

TEST	MANUFACTURER	PATHOGENS DETECTED[*]
RESPIRATORY		
NxTag	Luminex, Austin, TX	Flu A, AH1, AH3, Flu B, RSV A/B, PIV 1-4, HMPV, RV/EV,[†] HCoV OC43/229E/NL63/HKU1, AdV, human bocavirus, *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*

[*] Cleared by the U.S. Food and Drug Administration (FDA) as of March 2017. Other versions that detect additional viruses are available outside the United States.

[†] Detects rhinoviruses and enteroviruses but does not distinguish between them.

AdV, Adenovirus; AH1, influenza A, hemagglutinin type 1; AH3, influenza A, hemagglutinin type 3; CMV, cytomegalovirus; CoV, coronavirus; EV, enterovirus; flu A, influenza A; flu B, influenza B;

HHV, human herpesvirus; HMPV, human metapneumovirus; HSV, herpes simplex virus; LT/ST, heat-labile; heat-stable toxins; PIV, parainfluenza virus; RSV, respiratory syncytial virus; RV, rhinovirus; VZV, varicella-zoster virus.

Herpes simplex virus (HSV) PCR of CSF was the first PCR-based test to become widely accepted dating to the mid-1990s. The first FDA-cleared test for this purpose was approved in 2014. Some laboratories still use laboratory-developed tests for which performance characteristics must be validated as specified by CLIA, resulting in testing that is not standardized and performance characteristics (sensitivity, specificity) that may vary from laboratory to laboratory. Well-performing CSF PCR assays for HSV have sensitivity and specificity exceeding 95% for the diagnosis of HSV encephalitis. PCR is also increasingly used to diagnose mucocutaneous HSV and varicella-zoster virus infections. Molecular testing is more sensitive than virus culture and provides a more rapid turnaround time. Because molecular tests detect nonviable as well as viable virus, they may detect virus from the healing phase of the illness, when cultures would be negative.

An FDA-cleared test for enterovirus in CSF (GeneXpert, Cepheid, Sunnyvale, CA) provides sensitive detection of enteroviruses in approximately 3 hr. Because this testing is simple, some hospital laboratories are able to perform testing around the clock, thus maximizing the clinical utility of the test. The **parechoviruses** , which may cause illnesses similar to those caused by enteroviruses, especially in infants <6 mo of age, must be detected by separate molecular assays.

Respiratory viruses detected by multiplex panels include influenza A and B, RSV, parainfluenza 1-4, human metapneumovirus, rhinovirus/enterovirus, coronaviruses OC43, 229E, NL63, and HKU1, and adenoviruses (Table 195.2). The specific viruses (and nonviral agents) included differ among tests produced by different manufacturers. In addition, rapid CLIA-waived molecular tests are available for the simultaneous detection of influenza A and B and the trio of influenza A/B and RSV. These tests are similar to cleared CLIA-waived molecular tests for group A streptococcus and have the potential to make sensitive molecular diagnosis available in emergency departments, urgent care centers, and physician offices. Molecular tests are more expensive than antigen-based tests, and studies of clinical utility and cost-effectiveness are not yet available.

Gastrointestinal multiplex panels recently FDA-approved may include tests for group A rotaviruses, noroviruses GI and GII, enteric adenoviruses (group F, serotypes 40 and 41), astrovirus, and sapovirus, but not all are included in each manufacturer's test. Tests for bacterial and parasitic causes are also included. For clinicians, these tests provide information about the presence of potential etiologic agents not previously available. Numerous questions arise about whether detected pathogens are actually clinically significant and how to sort out the detection of >1 pathogen in the same sample. For laboratories, these tests raise questions about whether they can replace previously used techniques such as bacterial culture. The clinical utility and cost-effectiveness of using these tests have not been determined.

A multiplex panel for viral and bacterial and 1 fungal agent of CNS infection was cleared by the FDA. This test provides information about the presence of diverse etiologic agents that challenged many laboratories in the past. As for the other multiplex molecular panels, clinical utility and cost-effectiveness remain to be determined. Susceptibility to contamination during performance of the assay has been a concern not yet fully resolved.

Another important area of application of molecular testing is the detection of viruses in the blood. FDA-approved assays to detect HIV RNA and hepatitis C RNA are essential for the management of these infections, including the prevention of transmission from mother to infant. Hepatitis B molecular testing is also increasingly used. In addition, molecular testing is now widely used for viruses that cause systemic disease in immunocompromised patients, especially CMV, EBV, HSV, the BK polyomavirus, and adenovirus. BK virus is often tested for in urine samples as well as in blood. For these viruses, as well as for HIV and the hepatitis viruses, quantitative testing is required. An FDA-approved PCR assay for the quantitative measurement of CMV DNA in plasma is now available. In addition, international standards for CMV, EBV, and BK virus have been developed. This is important because their utilization improves the comparability of viral levels measured in different laboratories.

Laboratory-developed PCR and other molecular assays are used by some laboratories for numerous other viruses, including parvovirus B19, human herpesvirus 6, human papillomavirus, mumps, measles, rubella, and the JC polyomavirus.

Host gene expression patterns in whole blood have been used to attempt to differentiate viral from bacterial infections. This approach may rapidly identify a viral or bacterial profile of host gene expression reprise, thus greatly shortening the time to diagnosis and potentially avoiding inappropriate treatment while suggesting indicated therapies. Implementation in the clinic awaits development of rapid tests that incorporate this information.

CHAPTER 196

The Microbiome and Pediatric Health

Patrick C. Seed

From the time of birth, the human infant is exposed to a myriad of microbes found on the mother and in the surrounding environment. Microbes rapidly form assemblages across exposed areas of the body, including the skin and enteral tract. The microbial communities are called the **microbiota** and make a substantial impact on short- and long-term physiology, including immunologic and metabolic development and function. Together the number of body-associated bacterial cells is estimated to be 10 times greater than the number of human cells in the body. In aggregate, the totality of the microbes, including their microbial genes and environmental interactions, constitute the **microbiome** , and the microbial genes in the human microbiome are estimated to exceed the number of human genes by at least 100-fold, together making a macroorganism with an inseparable collective physiology. Current evidence indicates that the microbiome evolves over the life span to influence health and disease.

Measuring the Microbiome

Prior knowledge of microbes on and around the human body was based on specific methods to cultivate organisms. Molecular technologies have revolutionized the identification of poorly cultivatable microbes, rare microbes, and microbes in complex communities such as those associated with the human body (Fig. 196.1). The development of the polymerase chain reaction (PCR) and the availability of modern nucleic acid sequencing have improved the sensitivity of detection of many organisms and resulted in the discovery of new organisms. Modern sequencing technologies, called **next-generation**

sequencing platforms, allow sequencing in high volume and depth, with millions of sequences obtained from a single biologic sample. Three major approaches utilize next-generation sequencing to understand the composition, diversity, and activity of the microbiome: (1) sequencing species-specific regions of genomes such as ribosomal RNA–encoding tracks and intergenic regions termed **metagenomics** , (2) total DNA sequencing from a sample (e.g., feces, saliva) and assembly of the sequence fragments into large genome pieces termed **shotgun metagenomics** , and (3) RNA transcript sequencing to decipher the composition and, as a surrogate for functional activity, the transcriptional activity of a microbiome termed **metatranscriptomics** . Massive computational power and new bioinformatics tools have allowed the analysis and comparison of the large datasets arising from these methods.

FIG. 196.1 Common molecular methodologies for identifying the components and the functions of complex microbial communities.

Two additional approaches to measure the microbiome phenotype have rapidly developed as well. First, large-scale measurements of the peptide composition of the microbiota, called **proteomics** , have been increasingly used to describe the activity of a microbiome sample, as peptides provide information about the composition and function of a microbiome. Second, in a complementary approach called **metabolomics** , microbiome-derived metabolites are measured using advanced gas chromatography and mass spectrometry techniques. Together, proteomics and metabolomics better describe the activity of a microbiome than the nucleotide-sequencing approaches; however, at this point, they provide less depth of resolution and specificity relative to the composition and phenotype of a microbiome.

Despite the power of these methodologies to interrogate the microbiome, they do not yet replace cultivation of microbes in many clinical circumstances. *Cultivation of organisms still represents the most practical means to differentiate potential pathogenic species from more benign species* and to provide clinically actionable information such as susceptibility to a range of antimicrobials.

Early Childhood Development of the Microbiome

Emerging studies suggest that the placenta and fetus are exposed to microbes in utero, but the effect of such an exposure remains to be fully appreciated. **Prematurity** as a complication of an infection of the fetal membranes and either subclinical or clinical **chorioamnionitis** may alter the in utero exposure to microbes. The rupture of the fetal membranes and subsequent delivery provide substantial exposure to new maternal and environmental microbes that will assume common places in the developing microbiota. Mode of delivery has a major influence on the early life microbiome, with vaginally delivered infants becoming acutely colonized with intestinal organisms that reflect the mother's vaginal tract and infants delivered by cesarean section becoming colonized with organisms reflective of maternal skin and oral cavity, including staphylococci and streptococci, as well as the surrounding environment.

In the term infant delivered vaginally, the first intestinal microbes, so-called pioneering organisms, include *Escherichia* and other Enterobacteriaceae, *Bacteroides*, and *Parabacteroides* . Exclusive breastfeeding has been reported to result in high levels of bifidobacteria and *Lactobacillus* in the week following the start of feeding. These probiotic organisms have unique capacities to exclude would-be pathogens from colonization by sequestering nutrients and producing antimicrobial factors while stimulating the intestinal epithelium to tighten cellular junctions and express antimicrobial peptides. However, these genera have been notably deficient from some breastfed infant cohorts, particularly in the United States.

The premature infant is more likely to be delivered by cesarean section and thus is more abundantly colonized with skin-related organisms such as coagulase-negative staphylococci, similar to the term infant delivered by cesarean section. However, the premature infant may fail to progress through the same stages of expansion and diversification of the microbiome over the 1st week to month of life as the term infant. The factors related to the delayed maturation are not fully clear but are predictably related to delayed or limited enteral feeding, normal environmental exposure to the household environment, and exposure to medical interventions such as antimicrobial therapy.

The most significant shift in the intestinal microbiota appears to occur after weaning and the introduction of solid foods. As the infant transitions from breast milk to a solid-food diet containing complex plant-derived polysaccharides, the microbiota begins to reshape progressively into a more mature composition beginning to resemble the adult microbiota. At the same time, the metabolic potential of the microbiome shifts to accommodate the changing diet, with the newborn microbiome enriched with phosphotransferase system (PTS) genes and then shifting to increasing abundance of lactose transporter genes by 4 mo of age, reflecting milk intake, and further shifting to a high abundance of genes such as β-glucoside transporters and enzymes necessary to break down complex carbohydrates by age 12 mo. The maturation of the childhood microbiome after the early years to adulthood is less well understood, and more studies are required in large numbers of children to understand fully the developmental stages of maturation and similarity to the mature, healthy adult state.

The oral microbiota of the newborn is of maternal origin, with vaginally born infants having predominantly *Lactobacillus, Prevotella,* and *Sneathia,* whereas cesarean-born infants have more maternal skin organisms, including *Staphylococcus, Corynebacterium,* and *Propionobacterium* .Within the 1st day of life, Firmucutes dominate the oral cavity, including *Streptococcus* and *Staphylococcus.* Formula-fed babies acquire more Bacteroidetes, whereas breast-fed babies have more bacteria of the phyla Proteobacteria and Actinobacteria. With the eruption of first teeth, new environmental niches are formed to foster microbial communities. Although cariogenic bacteria such as *Streptococcus mutans* were thought to be acquired after dentition, recent data demonstrate the presence of these organisms prior to tooth eruption in a soft tissue reservoir, highlighting the importance of good infant oral care even before primary dentition.

By age 3 yr, the childhood oral and salivary microbiome is complex but less diverse than the adult microbiome. The composition of the microbiota within the oral cavity in the presence of full adult dentition has an estimated 1,000 bacterial species. Even with oral health, the diversity in the gingiva of different types of teeth (**geodiversity**) is substantial, and the diversity changes dramatically with the development of oral disease such as periodontitis. How the microbiota evolves between preschool and adulthood remains a topic for future study. Furthermore, the placement and removal of oral hardware for orthodontics is common in childhood and may produce significant alterations in the microbiome of the oral cavity.

During the 1st yr of life, the infant skin microbiome increases in diversity, including species richness and evenness. The skin of the younger infant is relatively undifferentiated between body sites, with more shared species among different body sites such as arms, forehead, and buttocks than the older infant when the microbial communities at each site undergo differentiation. As with the early infancy oral microbiota, skin of the young infant skin is predominantly colonized by Firmicutes, including Streptococcaceae and Staphylococcaceae, with the inclusion of bacteria from other phyla such as Actinobacteria, Proteobacteria, and Bacteroidetes as the skin matures. The adult skin microbiome displays a high degree of geodiversity—differences in composition depending on site and local physiology, with major differences in dry and wet skin sites. However, the linkage between skin development in childhood and maturation of the skin microbiome remains a subject of ongoing studies.

Social structure and family interactions likely play a significant role in the development of the early life microbiome. Breast milk feeding provides a microbiologic link between mothers and infants, including transmission of probiotic-like organisms such as lactobacilli and bifidobacteria, each of which may have some protective effects, including protection against diarrheal diseases and atopy. Pediatricians have long been aware of the infectious disease risks and benefits of daycare attendance, with examples of shared pneumococcal strains producing otitis media and outbreaks of respiratory syncytial virus infection and associations with reduced atopy, allergy, and possibly asthma. Family contacts are risks for acquisition of methicillin-resistant *Staphylococcus aureus* and subsequent disease. Studies also demonstrate transmission of parts of the human microbiome between household individuals and domesticated pets such as dogs and cats. For example, family members share the same strains of *Escherichia coli* known to produce urinary tract infections in one of the household members. There may be differences in the oral microbiota among infants for whom the parents did and did not use the practice of pacifier sucking for cleaning. In rural settings, microbiome sharing extends to livestock, household surfaces, and household members. Thus, development of the microbiome during childhood with environmental interactions is a complicated process that continues to be explored.

The Microbiome and Physiologic Development

Increasingly complex roles are being identified for the microbiome in the development of mammalian physiology (Fig. 196.2). These roles include the development of the enteral tract, respiratory tract, immune system, hematologic system, metabolic-endocrine system, and neurologic system. The details of how the microbiome contributes to these developmental processes in humans are still under intense investigation; however, modeling in other mammalian systems predicts that the microbiome will have a critical role across species.

Microbiome and Metabolism

Soon after entry into the physical world, the mammalian *enteral tract* is colonized, and the interaction of early pioneering microbes in the enteral tract stimulates the development of the intestinal mucosa. In neonatal and juvenile animal models, delayed or absent intestinal colonization results in incomplete development of the epithelium, flattening of the intestinal crypts, loss of vasculature, and severely reduced enzymatic function, including alkaline phosphatase and glucosidases.

The enteric microbiota has a large number of roles in the physiology of the *intestinal tract* . It stimulates mucosal and systemic immune development, development and regeneration of the epithelium and endothelium, and the maturation and maintenance of metabolism. The latter includes the digestion of otherwise indigestible plant polysaccharides; (2) production of vitamins and cofactors; (3) metabolism of xenobiotics, including clinically relevant drugs; and (4) stimulation of local and systemic metabolism, including lipid storage. Germ-free animals lacking the enteric microbiota have limited nutrient extraction and have a failure-to-thrive phenotype.

Germ-free mice born into a sterile environment serve as a model to understand the role of the microbiome in health. Germ-free mice are humanized through selective colonization with human fecal microbial communities. Similar to weaning to solid-food transition, feeding the humanized mice diets with and without polysaccharides results in dramatic alterations in central metabolites. Humanized mice transitioned from a polysaccharide-rich, low-fat diet to a more Westernized diet high in fat and monosaccharides undergo a blossoming of the phyla Actinobacteria and Firmicutes in the enteric microbiota, with a commensurate reduction in Bacteroidetes, similar to observations of increased Firmicutes and reduced Bacteroidetes in human obesity.

Common patterns of mature enteric microbiota community composition and its predicted function may exist among humans. Sequencing of the fecal microbes from adults across multiple nations revealed 3 common patterns of microbial community compositions, called **biotypes** . High proportions of *Bacteroides, Prevotella*, and *Ruminococcus* in unique biotypes serve as sentinels for each different biotype, and biotypes vary in individuals from different continents, including North America, Europe, and Asia, largely reflecting cultural and dietary variances. The infant microbiome varies considerably; mature, stable biotypes form in the early postweaning period and after infancy.

Breast milk and formula feeding biotypes have been described, with notable enrichment of enteric gram-negative bacteria such as *E. coli* and anaerobic *Clostridia* spp. among the formula-fed infants. The vaginal biotypes of young and aging women are well described and vary by age, race, and ethnicity.

Microbiome, Inflammation, and Immunity

The organisms that compose the microbiome are critical for early immune programming, the development of immune tolerance, and overall maintenance of immune set points. Cells produce a variety of receptors to recognize microbial ligands in a process called **pattern recognition** . In turn, microbes produce intentional and unintentional stimulation of those cellular receptors to activate and repress inflammatory pathways. Classic examples of such regulatory interactions include peptidoglycan on bacteria binding to Toll-like receptor 2 (TLR-2, in complex with TLR-3 and TLR-6), lipopolysaccharide of gram-negative bacteria binding to TLR-4, and glucans of fungi binding to the dectin receptor. The results of these receptor interactions include the production of chemokines and cytokines, cell differentiation and development, alteration in metabolism, and stimulation of cell death and survival programs, all contingent on the type of cell, state of the cell, and magnitude of stimulation.

Microbial stimulation of these microbial recognition systems is so critical in development that animals raised in the absence of microbes have diminished innate immune responses such as antimicrobial peptides at mucosal surfaces, dysregulated proinflammatory and immunologic tolerance responses, and reduced T- and B-cell populations. Following the restoration of normal enteric tract colonization weeks after being sterile, animals retain long-term aberrant cytokine responses with hyperactive proinflammatory responses to stimuli, demonstrating the persistent consequences of altering early microbial acquisition. Different early life colonization patterns also correlate with long-term immune development. In a Scandinavian study, children with persistent early life *E. coli* colonization had higher sustained memory B-cell ($CD3^+$ $CD20^+$ $CD27^+$) levels by 1.5 yr old than children with lower levels of *E. coli* colonization, even despite abundant colonization with the prototypical probiotic bacteria *Lactobacillus* .

Microbiome-Neurobiologic Connections

Emerging studies are demonstrating a gut-brain axis that may be altered by the composition and activity of the enteric microbiome. Investigations in animal models have shown that the microbiome alters the hypothalamic-pituitary-adrenal system. Germ-free mice have exaggerated stress-anxiety behavior accompanied by elevated corticosterone and adrenocorticotropin levels compared with conventionally colonized, pathogen-free mice. *Neuroplasticity* including neurogenesis and microglia activation are regulated by the microbiota. Functional MRI has shown that the ingestion of 5 strains of probiotic-like bacteria alters brain activity in humans, resulting in decreased brain responses to emotional attention tasks in sensory and emotional input regions of the brain. Although the mechanism underlying these changes can only be inferred, the tractus solitarius and thus the vagus nerve appear to mediate the enteral tract–brain connection.

Another mechanism through which the enteric microbiome may alter brain activity is by the metabolites it produces. Administration of fermented milk with probiotic-like organisms, most notably *Bifidobacterium animalis* subsp. *lactis* , to monozygotic human twins and mice did not dramatically change the intestinal microbiome composition but did alter its transcriptional profiles, with a shift to increased carbohydrate fermentation to fatty acids, thought to attenuate sad emotional behavior in humans.

Contributions of Microbiome to Disease

Studies demonstrate that some microbial communities may act in concert to exert negative health effects, whereas other communities may be restorative or resistant to disease. Some examples of this concept of altered microbial communities, also termed **dysbiosis** , are provided in the following sections.

Microbiome of Premature Birth

Although the etiology of premature birth is multifactorial, inflammatory conditions such as subclinical and clinically overt infections of the mother and fetus instigate premature birth. Inflammatory biomarker profiling highlights this point, because women who proceed to preterm birth have increased angiotensin, interleukin-8, and tumor necrosis factor receptor 1, along with race-specific alterations in additional cytokines and chemokines. Prior work reported that women experiencing preterm birth have increased vaginal colonization with

Gardnerella spp. and *Lactobacillus crispatus.* Diversity of the microbiota of the posterior vaginal fornix of women experiencing preterm birth is lower compared to women delivering at term. A meta-analysis of early treatment of vaginosis with clindamycin before 22 wk of pregnancy demonstrated a reduction in spontaneous preterm birth at <37 wk, consistent with an association between dysbiosis of the pregnancy-associated microbiota and preterm birth.

Traditionally, the amniotic cavity and the fetus have been presumed to be sterile before the rupture of the fetal membranes and birth. However, several reports identify evidence for bacterial DNA in meconium with 2 predominant meconium types regardless of the mode of delivery: (1) dominated by Enterobacteriaceae and (2) dominated by Leuconostocaceae, Enterococcaceae, and Streptococcaceae. Furthermore, data indicate that the amniotic fluid in subclinical and clinically apparent chorioamnionitis has evidence of vaginal-derived microbes present, including poorly or noncultivatable organisms such as *Mycoplasma* spp., *Ureaplasma* spp., *Bacteroides* spp., *Fusobacterium, Sneathia sanguinegens,* and *Leptotrichia amnionii* . A correlation exists between the burden of intraamniotic organisms and the degree of prematurity. Microbial invasion of the amniotic space may lead to induction of inflammatory pathways through innate immune microbial pattern recognition receptors such as the TLRs. The result may be the induction of labor and physiologic stress on the fetus and mother. Exposure to microbial factors may have consequences on lung and intestinal development, setting the stage for postnatal pathology, including necrotizing enterocolitis. Beyond the acute threat to the maternal-fetal dyad, chorioamnionitis may not produce the long-term neurodevelopmental consequences it once was thought to cause, with formerly premature infants born to women with chorioamnionitis having similar cognitive and neuropsychiatric outcomes, even to age 18 yr, as infants not exposed to chorioamnionitis.

Changes in the Microbiome With Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a devastating disease of the neonatal intestine that disproportionately affects severely premature infants who weigh <1,500 g at birth. The pathologic steps in NEC include intestinal inflammation with loss of barrier function, microbial invasion of the bowel, and eventual death of the affected bowel. Years of research implicated specific organisms as the cause of NEC in case series; however, none of the proposed specific etiologies proved to be common to all cases of NEC and, instead, appeared to be the emergent organisms after serious intestinal pathology had ensued.

Currently, a model of dysbiosis of the early life intestinal microbiome has been favored in the pathogenesis of NEC. Epidemiologic studies in very-low-birthweight infants have demonstrated an association of cephalosporins and duration of antibiotic exposure with the development of NEC, consistent with the idea that shifts in the microbiota predispose to or incite NEC. Studies demonstrate decreased diversity of the microbiota preceding and during NEC. The NEC microbiota at the time of clinical symptoms resembles the microbiota 72 hr before onset, but not the microbiota 1 wk before onset of symptoms, suggesting that a shift in the intestinal microbiota begins well in advance of the appearance of NEC. Some differences in early colonization after birth may portend an increased risk for NEC.

Microbiome and Allergic Disorders

Given the role of the microbiome in the development and modulation of innate and adaptive immune responses, considerable interest surrounds its role in the development and exacerbation of allergic conditions such as **atopic dermatitis** . The microbiome of the skin has been studied before, during, and after treatment of flares of atopic dermatitis. Flares result in the loss of diversity of bacteria on the affected area, and treatment introduces new diversity. *Staphylococus aureus* and *S. epidermidis* increase before and during atopic flares, whereas *Streptococcus* and *Corynebacterium* spp. increase immediately preceding and during clinical improvement. In mice, oral treatment of infant animals with nonabsorbable antibiotics increases serum immunoglobulin (Ig) E, increases clinical symptoms such as itching, and produces atopic-like features. These data suggest that atopic dermatitis is influenced by the local skin microbiome and more distant microbiomes such as in the intestinal tract, also suggesting why the administration of oral probiotics such as *Lactobacillus* spp. may decrease atopic dermatitis with an accompanying shift in the T-helper cell (Th1/Th2) balance and increased interferon-γ, which are part of immune tolerance.

The respiratory tract is a common site of allergic disease, and infections have long been associated with allergic exacerbations of the respiratory tract. Traditional teaching is that the lower respiratory tree is sterile; however, studies of the airway microbiome in healthy and asthmatic children and adults indicate that this teaching is incorrect. Measured through careful bronchoscopic sampling and cytology brushings, the airways have a diverse microbiota during good health.

Measurement of the microbiota in the lower respiratory tract of healthy and asthmatic children indicates significant differences. Past culture-based studies indicate that early life colonization of the neonatal respiratory tree by *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae* is associated with an increased risk for childhood asthma. These same organisms also are closely associated with exacerbations of asthma. In a mouse model, early life colonization of the neonatal nasopharynx with *H. influenzae* results in reduced airway-associated regulatory T cells, and colonized animals have enhanced airway hyperresponsiveness following allergen sensitization and inhalation challenge. *Mycoplasma pneumoniae* has been proposed as a major bacterial inducer of childhood asthma exacerbations when infection is identified. The employment of culture-independent measurements of lower airway microbiota composition (see Fig. 196.1) indicates that children with asthma are more likely to have higher levels of Proteobacteria, including *H. influenzae*, as well as Firmicutes such as *Staphylococcus* and *Streptococcus* spp. Remarkably, healthy children are more likely than age-matched asthmatic children to have lower airway Bacteroidetes, particularly *Prevotella* spp., a group of anaerobic bacteria. The association of healthy airways with an anaerobic lower respiratory tree bacterial population is unexpected because the high–oxygen tension environment was previously assumed to be toxic to anaerobes. This study indicates that the airway environment is significantly different than previously understood, and the potentially protective attributes of a native health-associated microbiota need to be studied to determine if these associations are also causal.

Airway Microbiome of Cystic Fibrosis

Cystic fibrosis (CF) is characterized by progressive airway disease and inflammation with acute exacerbations accompanied by loss of pulmonary function. An age-dependent change in lower airway colonization occurs among CF patients, which starts in early childhood with *S. aureus* and *H. influenzae* and progressively shifts toward more intrinsically multidrug-resistant organisms, including the notoriously persistent and treatment-refractory bacteria *Pseudomonas aeruginosa* and *Burkholderia cepacia* complex. Culture-independent molecular analysis of the lung-associated microbiota in CF has revealed much more complex microbial communities than previously expected and has demonstrated an association between patient age and disease severity. In addition to the presence of a variety of previously unexpected airway organisms such as anaerobes and mycobacteria, disease severity is inversely related to the lower airway microbial community diversity, with less advanced disease associated with greater species richness and evenness. In contrast, the loss of diversity, including the shift from less complex microbial communities to those dominated by *P. aeruginosa,* is strongly correlated with disease severity, and levels of *H. influenzae*, the early childhood colonizer, have a negative correlation with disease severity. Although antibiotics decrease the rate of progressive lung function deterioration, they also decrease the community diversity, thus suggesting a balance between a diverse microbiota and reducing the dominance of certain organisms such as *P. aeruginosa* .

Microbiome During Antibiotic-Associated Diarrhea and *Clostridium difficile* Colitis

Treatment with oral and parenteral antibiotics results in a rapid and significant alteration of the intestinal microbiota. Healthy study participants taking **ciprofloxacin** experience dramatic but individualized microbiome changes in response to the antibiotic, with significant reductions in bacteria outside its expected spectrum, emphasizing the interdependence of microbial community members on one another for their stability in the community as a whole. Furthermore, the response to ciprofloxacin among participants varied by individual, suggesting different degrees of stability of the microbiota and resilience under stress such as antibiotics. In general, except for some rare members, the community was largely restored within 4 wk after completion of the antibiotic course.

Some antibiotics, such as amoxicillin-clavulanate, for which antibiotic-associated diarrhea is a well-known adverse event, produce a loss of *Clostridium* and *Bacteroides* , known to be important in the production of short-chain fatty acids (SCFAs) and the metabolism of otherwise undigestible carbohydrates. Together, their loss may decrease the metabolic integrity of the intestinal epithelium that uses SCFAs for energy, while resulting in a high-osmotic environment in which fluid is drawn into the intestinal lumen. Antibiotic-associated diarrhea may result from these combined effects.

One of the most severe complications from antibiotic exposure is the development of ***Clostridium difficile*– associated diarrhea (CDAD)** , which has high associated morbidity and even mortality. Microbiologic surveys suggest that *C. difficile* is a common constituent of the developing microbiota early in life, with less prevalence over the life span. More than 30% of infants are colonized with *C. difficile* in the 1st month of life, continuing until approximately 6 mo. By 1 yr of age, colonization ranges between approximately 15% and 70% and then declines through to adulthood, when carriage is estimated to be <3%. Although *C. difficile* has been found within the vaginal microbiota of pregnant women, vaginal delivery has not been associated with increased rates of neonatal *C. difficile* colonization, with vaginal and cesarean delivery having rates of colonization at 30% and 37%, respectively. CDAD has been reported to result in 35-45 hospitalizations per 10,000 pediatric admissions among children 1-9 yr old.

Although the studies have not yet determined the natural history of the intestinal microbiome preceding, during, and with the resolution of CDAD in children, molecular studies of the intestinal microbiota in adults provide some details of the consequences of CDAD on the intestinal microbiota. Studies employing deep sequencing of stool from individuals with CDAD and *C. difficile* colonization without disease have revealed depletion of certain bacterial genera accompanying the presence of *C. difficile* colonization. These genera include *Blautia, Pseudobutyrivibrio, Roseburia, Faecalibacterium, Anaerostipes, Subdoligranulum, Ruminococcus, Streptococcus, Dorea* , and *Coprococcus* . The causal relationship of microbiome changes and the events triggering the transition from colonization to symptomatic disease remain unknown, but presumably relate to depletion of competitive species to *C. difficile* . Similar to the studies of antibiotic-associated diarrhea, these studies also demonstrate a reduction in butyrate-producing *Clostridium* spp., which are proposed to be important for producing butyrate as an energy sources for the intestinal epithelium and its robust integrity.

Although antibiotics such as metronidazole and vancomycin have been employed to treat CDAD, traditional treatment does not eliminate recurrent CDAD to the extent that might be expected. To address this problem, **fecal transplantation** , or administration of feces from healthy donors to CDAD recipients, is cost-effective treatment and superior to antibiotics in reducing the likelihood of recurrent disease. Accompanying clinical resolution is repletion of Bacteroidetes and *Clostridium* clusters IV and XIVa with a matched decrease in Proteobacteria. A recent study of children with CDAD demonstrated 94%, 75%, and 54% successful resolution following intragastric-administered fecal transplant from a donor stool bank in previously healthy children, medically complex children, and children with IBD, respectively.

Microbiome and Association With Inflammatory Bowel Disease

Crohn disease and **ulcerative colitis** are chronic inflammatory diseases of the enteric tract and are believed to be the result of the intersection of host susceptibility and a dysbiosis, an alteration in the intestinal microbiota. Twin-twin studies indicate concordance rates in monozygotic twins of 10–15% in ulcerative colitis and 30–35% in Crohn disease, thus demonstrating a genetic component for each disease while highlighting environmental factors that likely induce and drive disease progression. More than 150 single nucleotide polymorphisms (SNPs) are associated with the diseases, revealing potential defects in handling microbes, including those involved in barrier function, innate immunity, autophagy, adaptive immunity, and metabolism and cellular homeostasis.

In inflammatory bowel disease (IBD), the microbiota undergoes a shift in association with the disease throughout the intestinal tract. Although considerable heterogeneity has been described, IBD is often demonstrated to be accompanied by a decrease in bacteroides, clostridia, bifidobacteria, and Firmicutes. Reciprocally, outgrowths of *E. coli* and other Enterobacteriaceae are described. Increased sulfur-metabolizers have been described with IBD as well. Antibiotics along with biologic therapies such as antibodies directed at neutralizing tumor necrosis factor have been employed to manage the IBD dysbiosis and inflammatory reaction. Trials of fecal transplantation are underway to determine if a noninflammatory microbiota from a healthy donor may mitigate IBD symptoms and progression.

Microbiome of Obesity

Obesity and the metabolic syndrome are associated with notable changes in the intestinal microbiome regarding composition and metabolic function, ultimately resulting in greater energy extraction from the diet. Although a highly cited early study on the microbiome in obesity observed an increase in the ratio of the phyla Firmicutes:Bacteroidetes, debate continues about obesity-specific changes in the microbiome. Multiple studies have demonstrated decreased

Firmicutes:Bacteroidetes ratios in the fecal microbiota from obese individuals compared to lean controls. Further studies show that proportions of phyla-level groups may be less important than changes in Firmicutes subgroups that produce **butyrate** , a known fatty acid substrate easily acquired and utilized by the intestinal epithelium, and thus ready calories for the host.

The intestinal microbiome benefits the host in meaningful ways, including enhancing caloric extraction from indigestible substrates such as polysaccharides in the diet. The microbiome produces degradative enzymes to break down these substrates where enzymes with comparable functions, such as some glycosyl hydrolases, are not encoded in the human genome. Molecular studies indicate that the intestinal microbiome may also interact with the intestinal epithelium in such a way as to alter general energy homeostasis and fat storage. For instance, the intestinal microbiome may produce SCFAs, which in turn alter endocrine peptide expression such as glucagon-like peptide 1 and peptide YY, which alter glucose homeostasis and satiety, respectively. Furthermore, through the production of SCFAs and ketones, the microbiota may alter sympathetic tone. Specific microbiomes are known to suppress others to induce fastening-induced **adipose factor** (also called angiopoietin-like protein 4), a lipoprotein lipase inhibitor of intestinal, hepatic, and adipose origins. Colonization with a diverse microbiota suppresses fastening-induced adipose factor expression, and dietary supplementation of a Western diet with *Lactobacillus paracasei* further suppressed otherwise high fastening-induced adipose factor expression. Mice fed a Western diet developed adiposity, which was transferrable to recipient lean mice following transplantation with the obese mice microbiota. Reciprocally, obese mice treated with antibiotics experienced less insulin resistance, lower fasting glycemic indices, and improved glucose tolerance compared to untreated counterparts, further implicating the microbiome in these physiologic changes.

Microbiome During Malnutrition

Malnutrition is a leading cause of morbidity and mortality across the world. In its most severe form, malnutrition may result in **kwashiorkor** , which is characterized by generalized edema, anorexia, enlarged fatty liver, skin ulcerations, and irritability. Ready-to-use foods are distributed to restore nutrition in areas with severe food restrictions. Monozygotic and dizygotic twins in Malawi were studied for the alterations in the microbiome in association with moderate to severe malnutrition, including kwashiorkor. Among the twins with discordant degrees of malnutrition on food supplements, the twins with mild preexisting malnutrition had intestinal microbiota that changed significantly over the course of supplementation. In contrast, the twins with preexisting kwashiorkor had microbiota with poor to no change in response to nutritional supplementation. These findings were recapitulated to some extent following transplantation of the twins’ microbiota into previous sterile mice. Those mice receiving the microbiota of Malawian twins with kwashiorkor experienced more dramatic weight loss on a Malawian-type diet and more rapid loss of their weight gain once off ready-to-use food supplements than did mice transplanted with the feces of more healthy twins. The mice with the transplanted kwashiorkor microbiota had sustained problems with carbohydrate, lipid, and amino acid metabolism despite nutritional supplementation of the Malawian diet. Together these data indicate that severe malnutrition results from the combination of nutritional deficits and a microbiome with altered metabolic capabilities that are not readily restored with contemporary nutritional supplementation treatments.

Therapeutic Manipulation of the Microbiome

Therapeutic manipulation of the microbiome falls into 6 general categories: antimicrobials, prebiotics, probiotics, synbiotics, postbiotics, and fecal transplantation (see CDAD and IBD earlier). **Postbiotics** are nonviable microbial components or metabolites that may alter the microbiota or produce physiologic changes in the host. Insufficient data exist to warrant a discussion of postbiotic therapeutics here.

Prebiotics

Prebiotic is defined as “nondigestible food components that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon and thereby improving host health.” Whereas antimicrobials deplete portions of the microbiota, prebiotics aim to promote the growth of beneficial organisms such as bifidobacteria and lactobacteria. Typically, prebiotics are carbohydrates such as oligosaccharides that may be selectively metabolized by constituents of the microbiota. They may not only stimulate outgrowth of desirable organisms but also may be catabolized to beneficial end products such as SCFAs, which in turn may be utilized as energy substrates by the intestinal epithelium. Prebiotic oligosaccharides are naturally found in breast milk and have been used as supplements to human breast milk and formula.

Administration of prebiotics to term infants has demonstrated the expected outgrowth of bacteria; however, clinically significant benefits from prebiotic supplementation have not been clearly established. Treatment of term infants with fructooligosaccharides increases fecal bifidobacteria but without a change in infant growth, despite some infants having increased SCFAs in the fecal mass. A systematic review of the topic provided a similar conclusion.

Preterm infants have low to absent levels of bifidobacteria and lactobacilli in their intestinal tracts, despite full breast milk nutrition. Prebiotic supplementation has been proposed to increase these bacterial populations in the preterm infant intestinal tract. Among the proposed benefits may be a decrease in NEC. However, appropriately powered, randomized trials have not been performed to demonstrate the validity of this hypothesis.

Probiotics

Probiotics are viable organisms that have health benefits after administration. Almost all probiotics are isolates from the human microbiota, although they may not necessarily reside in the individual taking them for therapeutic purposes. Alternatively, probiotics may be administrated to increase the levels of an organism already present within the microbiota. Generally, probiotics have been administered orally or as vaginal suppositories.

Multiple bacterial and fungal genera and species have been studied for probiotic effects. Common bacterial genera include bifidobacteria, lactobacilli, streptococci, enterococci, and *E. coli* . Fewer nonbacterial organisms have been studied for probiotic effects. *Saccharomyces boulardii* is related to baker's yeast (*Saccharomyces cerevisiae*) but was isolated for specific beneficial effects.

These probiotic organisms should not be confused with more pathogenic strains within their genera and species. Most probiotics have been isolated on the basis of being associated with healthy states. Bifidobacteria and lactobacilli are common to breast milk and stool among infants with low rates of diarrheal diseases and allergy. With the exception of individuals with significant immunodeficiency, severely compromised mucosal barriers, or central line catheters, where many of these organisms may adhere to the plastic with otherwise benign, transient translocation from the intestinal tract, these bacterial probiotics have proved to be relatively safe even with the administration of billions of colony-forming units. The most common adverse events associated with probiotics include abdominal cramping, nausea, fever, soft stools, flatulence, and taste disturbance.

Although bacterial probiotics have been administered widely to humans, evidence for their efficacy is limited to a small number of conditions. Probiotics have consistently shown efficacy for specific conditions, including antibiotic-associated diarrhea, prevention and reduction of atopy in high-risk children, and reductions in duration and recurrence of *C. difficile* infection. Trials indicate a reduction in NEC among preterm infants. Probiotics may reduce the risk for respiratory infections and recurrent urinary tract infection while reducing the symptoms and frequency of flares in IBD.

Antibiotic-associated diarrhea is reduced in frequency and duration. Meta-analysis indicated a relative risk (RR) of antibiotic-associated diarrhea with probiotic administration of 0.58 (95% confidence interval [CI], 0.05-0.68) among combined studies using *Lactobacillus* , *Bifidobacterium* , *Saccharomyces* , *Streptococcus* , *Enterococcus* , and/or *Bacillus* . Administration of combinations of organisms has not generally resulted in greater efficacy.

Meta-analysis specifically for the efficacy of probiotics in decreasing the incidence of CDAD demonstrated moderate evidence for the practice. In an analysis of >1,800 trials, including many in the pediatric population, probiotics reduced CDAD by 64% with RR of 0.36 (95% CI, 0.26-0.51). A pediatric subgroup was analyzed across relevant studies, revealing benefit in pediatric patients and a well-child subgroup (RR, 0.37; 95% CI, 0.23-0.60). A number of probiotics were used, including different *Lactobacillus* strains and *S. boulardii* .

More than 15 trials have been performed to study the effect of probiotic administration during pregnancy and to infants to prevent atopic dermatitis. Meta-analysis suggests a modest benefit from probiotic administration to prevent the development of atopic dermatitis. Trials have primarily involved the administration of *Lactobacillus rhamnosus*. Studies included administration to the pregnant mother, or the infant, or both. The overall RR of 0.79 (95% CI, 0.71-0.88) was generally consistent regardless of the treatment of the mother, child, or both. The duration was generally >6 mo; apparently, however, duration did not significantly alter the effect. The RR was similar for the prevention of IgE- and non–IgE-associated atopic dermatitis.

Synbiotics are combinations of a probiotic and a prebiotic that is specifically used by the probiotic. A large, double-blind placebo-controlled trial of >4,500 infants in India demonstrated that a daily oral symbiotic preparation of *Lactobacillus plantarum* and fructooligosaccharide given through the neonatal period produced significant reductions in sepsis, pneumonia, skin infections, and all-cause mortality.

Immunization Practices

Henry H. Bernstein, Alexandra Kilinsky, Walter A. Orenstein

Immunization is one of the most beneficial and cost-effective disease-prevention measures available. As a result of effective and safe vaccines, smallpox has been eradicated, polio is close to worldwide eradication, and measles and rubella are no longer endemic in the United States. However, cases of vaccine-preventable diseases, including measles, mumps, and pertussis, continue to occur in the United States. Incidence of most vaccine-preventable diseases of childhood has been reduced by ≥99% from representative 20th century annual morbidity, usually before development of the corresponding vaccines (Table 197.1a), with most of the newer vaccines not achieving quite the same percentage decrease (Table 197.1b). An analysis of effective prevention measures recommended for widespread use by the U.S. Preventive Services Task Force (USPSTF) reported that childhood immunization received a perfect score based on clinically preventable disease burden and cost-effectiveness.

Table 197.1a

Comparison of 20th Century Annual Morbidity and Current Morbidity: Vaccine-Preventable Diseases

DISEASE	20TH CENTURY ANNUAL MORBIDITY*	2016 REPORTED CASES †	PERCENT DECREASE
Smallpox	29,005	0	100%
Diphtheria	21,053	0	100%
Measles	530,217	122	>99%
Mumps	162,344	5,629	96%
Pertussis	200,752	15,808	92%
Polio (paralytic)	16,316	0	100%
Rubella	47,745	9	>99%
Congenital rubella syndrome	152	2	99%
Tetanus	580	31	95%

Haemophilus influenzae type b (Hib)	20,000	22 [‡]	>99%

Immunization is the process of inducing immunity against a specific disease. Immunity can be induced either passively or actively**. Passive immunity** is generated through administration of an antibody-containing preparation. **Active immunity** is achieved by administering a vaccine or toxoid to stimulate the immune system to produce a prolonged humoral and/or cellular immune response. As of 2019, infants, children, and adolescents in the United States are recommended to be routinely immunized against **16 pathogens** : *Corynebacterium diphtheriae*, *Clostridium tetani*, *Bordetella pertusis*, polio virus, *Haemophilus influenzae* type b (**Hib**), hepatitis A, hepatitis B, measles virus, mumps virus, rubella virus, rotavirus, varicella zoster virus, pneumococcus, meningococcus, influenza virus, and human papillomavirus (**HPV**).

Passive Immunity

Rather than producing antibodies through the body's own immune system, passive immunity is achieved by administration of preformed antibodies. Protection is immediate, yet transient, lasting weeks to months. Products used include:

- Immunoglobulin administered intramuscularly (**IGIM**), intravenously (**IGIV**), or subcutaneously (**IGSC**)
- Specific or hyperimmune immunoglobulin preparations administered IM or IV
- Antibodies of animal origin
- Monoclonal antibodies

Passive immunity also can be induced naturally through transplacental transfer of maternal antibodies (IgG) during gestation. This transfer can provide protection during an infant's 1st few mo of life; other antibodies (IgA) are transferred to the infant during breastfeeding. Protection for some diseases can persist for as long as 1 yr after birth, depending on the quantity of antibody transferred and the time until levels fall below those considered protective.

The major indications for inducing passive immunity are immunodeficiencies in children with B-lymphocyte defects who have difficulty making antibodies (e.g., hypogammaglobulinemia, secondary immunodeficiencies), who have exposure to infectious diseases or to imminent risk of exposure when there is inadequate time for them to develop an active immune response to a vaccine (e.g., newborn exposed to maternal hepatitis B), and who have infectious diseases that require antibody administration as part of the specific therapy (Table 197.2).

Table 197.2

Immunoglobulin and Animal Antisera Preparations

PRODUCT	MAJOR INDICATIONS
Immune globulin intramuscular (IGIM)	Replacement therapy in antibody-deficiency disorders Hepatitis A prophylaxis Measles prophylaxis Rubella prophylaxis (pregnant women)
Immune globulin intravenous (IGIV)	Replacement therapy in antibody-deficiency disorders Kawasaki disease Pediatric HIV infection Hypogammaglobulinemia in chronic B-lymphocyte lymphocytic leukemia Varicella postexposure prophylaxis Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy and multifocal motor neuropathy Toxic shock syndrome May be useful in a variety of other conditions
Immune globulin subcutaneous (IGSC)	Treatment of patients with primary immunodeficiencies
Hepatitis B immunoglobulin (IM)	Postexposure prophylaxis
	Prevention of perinatal infection in infants born to hepatitis B surface antigen–positive mothers
Rabies immunoglobulin (IM)	Postexposure prophylaxis
Tetanus immunoglobulin (IM)	Wound prophylaxis
	Treatment of tetanus
Varicella-zoster immunoglobulin (VariZIG, IM)	Postexposure prophylaxis of susceptible people at high risk for complications from varicella
Cytomegalovirus (IV)	Prophylaxis of disease in seronegative transplant recipients
Vaccinia immunoglobulin (IV)	Reserved for certain complications of smallpox immunization and has no role in treatment of smallpox
Human botulism (IV), BabyBIG	Treatment of infant botulism
Diphtheria antitoxin, equine	Treatment of diphtheria
Heptavalent botulinum antitoxin against all 7 (A-G) botulinum toxin types (BAT)	Treatment of noninfant food and wound botulism
Palivizumab (monoclonal antibody), humanized mouse (IM)	Prophylaxis for infants against respiratory syncytial virus (see Chapter 287)

Data from American Academy of Pediatrics: Passive immunization. In Kimberlin DW, Brady MT, Jackson MA, Long SS, editors: *Red Book 2018: Report of the Committee on Infectious Diseases,* ed 31, Elk Grove Village, IL, 2018, American Academy of Pediatrics. (Recommendations for use of specific immune globulins are located in the sections for specific diseases in Section 3 of *Red Book* .)

Intramuscular Immunoglobulin

Immunoglobulin is a sterile antibody-containing solution, usually derived through cold ethanol fractionation of large pools of human plasma from adults. Antibody concentrations reflect the infectious disease exposure and immunization experience of plasma donors. Intramuscular immunoglobulin (IGIM) contains 15–18% protein and is predominantly IgG. Intravenous use of human IGIM is contraindicated. Immunoglobulin is not known to transmit infectious agents, including viral hepatitis and HIV. The major indications for immunoglobulin are:

- Replacement therapy for children with antibody deficiency disorders
- Measles prophylaxis
- Hepatitis A prophylaxis

For **replacement therapy** , the usual dose of IGIM is 100 mg/kg (equivalent to 0.66 mL/kg) monthly. The usual interval between doses is 2-4 wk depending on trough IgG serum concentrations and clinical response. In practice, IGIV has replaced IGIM for replacement therapy.

IGIM can be used to prevent or modify **measles** if administered to susceptible children within 6 days of exposure (usual dose: 0.5 mL/kg body weight; maximum dose: 15 mL). The recommended dose of IGIV is 400 mL/kg. Data suggest that measles vaccine, if given within 72 hr of measles exposure, will provide protection in some cases. Measles vaccine and immunoglobulin should not be administered at the same time.

Two methods are available for **postexposure prophylaxis** against **hepatitis A** depending on the patient's age: hepatitis A immunization or immunoglobulin. In those 12 mo-40 yr of age, hepatitis A immunization is preferred over immunoglobulin for postexposure prophylaxis and for protection of people traveling to areas where hepatitis A is endemic. Children 6-11 mo old should receive a dose of hepatitis A vaccine before international travel. However, the dose of hepatitis A vaccine received before 12 mo should not be counted in determining compliance with the recommended 2-dose schedule. In adults >40 yr, immunoglobulin may be administered for prophylaxis and for postexposure prophylaxis to people traveling internationally to hepatitis A–endemic areas (0.06 mL/kg). Immunoglobulin is preferred over hepatitis A immunization if there is an underlying immunodeficiency or chronic liver disease.

The most common adverse reactions to immunoglobulin are pain and discomfort at the injection site and, less commonly, flushing, headache, chills, and nausea. Serious adverse events are rare and include chest pain, dyspnea, anaphylaxis, and systemic collapse. Immunoglobulin should *not* be administered to people with selective IgA deficiency, who can produce antibodies against the trace amounts of IgA in immunoglobulin preparations and can develop reactions after repeat doses. These reactions can include fever, chills, and a shock-like syndrome. Because these reactions are rare, testing for selective IgA deficiencies is not recommended.

Intravenous Immunoglobulin

IGIV is a highly purified preparation of immunoglobulin antibodies prepared from adult plasma donors using alcohol fractionation and is modified to allow intravenous (IV) use. IGIV is more than 95% IgG and is tested to ensure minimum antibody titers to *Corynebacterium diphtheriae* , hepatitis B virus, measles virus, and poliovirus. Antibody concentrations against other pathogens vary widely among products and even among lots from the same manufacturer. Liquid and lyophilized powder preparations are available. IGIV does not contain thimerosal.

Not all IGIV products are approved by the U.S. Food and Drug Administration (FDA) for all indications. The major recommended FDA-approved indications for IGIV are:

- Replacement therapy for primary immunodeficiency disorders
- Kawasaki disease to prevent coronary artery abnormalities and shorten the clinical course

- Replacement therapy for prevention of serious bacterial infections in children infected with HIV
- Prevention of serious bacterial infections in people with hypogammaglobulinemia in chronic B-lymphocyte leukemia
- Immune-mediated thrombocytopenia to increase platelet count

IGIV may be helpful for patients with severe toxic shock syndrome, Guillain-Barré syndrome, and anemia caused by parvovirus B19. IGIV is also used for many other conditions based on clinical experience. IGIV may be used for varicella after exposure when varicella-zoster immune globulin is not available.

Reactions to IGIV may occur in up to 25% of patients. Some of these reactions appear to be related to the rate of infusion and can be mitigated by decreasing the rate. Such reactions include fever, headache, myalgia, chills, nausea, and vomiting. More serious reactions, including anaphylactoid events, thromboembolic disorders, aseptic meningitis, and renal insufficiency, have rarely been reported. Renal failure occurs mainly in patients with preexisting renal dysfunction.

Specific or hyperimmune immunoglobulin preparations are derived from donors with high titers of antibodies to specific agents and are designed to provide protection against those agents (see Table 197.2).

Subcutaneous Immunoglobulin

Subcutaneous administration of immunoglobulin (IGSC) is safe and effective in children and adults with primary immune deficiency disorders. Smaller doses administered weekly result in less fluctuation of serum IgG concentrations over time. Systemic reactions are less frequent than with IGIV, and the most common adverse effects of IGSC are injection-site reactions. There are no data on administration of IGIM by the subcutaneous route.

Hyperimmune Animal Antisera Preparations

Animal antisera preparations are derived from horses. The immunoglobulin fraction is concentrated using ammonium sulfate, and some products are further treated with enzymes to decrease reactions to foreign proteins. The following 2 equine antisera preparations are available for humans (as of 2018):

- **Diphtheria antitoxin** , which can be obtained from the U.S. Centers for Disease Control and Prevention (http://www.cdc.gov/diphtheria/dat.html) and is used to treat diphtheria.
- **Heptavalent botulinum antitoxin** , available from the CDC for use in adults with botulism. To request it, one can call the CDC's 24 hr line at 770-488-7100. This product contains antitoxin against all 7 (A-G) botulinum toxin types.

Great care must be exercised before administering animal-derived antisera because of the potential for severe allergic reactions. Due caution includes testing for sensitivity before administration, desensitization if necessary, and treating potential reactions, including febrile events, serum sickness, and anaphylaxis. *For infant botulism, IVIG (BabyBIG), a human-derived antitoxin, is licensed and should be used.*

Monoclonal Antibodies

Monoclonal antibodies (mAbs) are antibody preparations produced against a single antigen. They are mass-produced from a hybridoma, a hybrid cell used as the basis for production of large amounts of antibodies. A hybridoma is created by fusing an antibody-producing B lymphocyte with a fast-growing immortal cell such as a cancer cell. **Palivizumab** is used for prevention of severe disease from respiratory syncytial virus (RSV) among children ≤24 mo old with bronchopulmonary dysplasia (BPD, a form of chronic lung disease), a history of premature birth, or congenital heart lesions or neuromuscular diseases. The American Academy of Pediatrics (AAP) has developed specific recommendations for use of palivizumab (see Chapter 287). Monoclonal antibodies also are used to prevent transplant rejection and to treat some types of cancer, autoimmune diseases, and asthma. Use of mAbs against interleukin (IL)-2 and tumor necrosis factor (TNF)-α are being used as part of the therapeutic approach to patients with a variety of malignant and autoimmune diseases.

Serious adverse events associated with palivizumab are rare, primarily including cases of anaphylaxis and hypersensitivity reactions. Adverse reactions to mAbs directed at modifying the immune response, such as antibodies against IL-2 or TNF-α, can be more serious and include cytokine release syndrome, fever, chills, tremors, chest pain, immunosuppression, and infection with various organisms, including mycobacteria.

Active Immunization

Vaccines are defined as whole or parts of microorganisms administered to prevent an infectious disease. Vaccines can consist of whole inactivated microorganisms (e.g., polio, hepatitis A), parts of the organism (e.g., acellular pertussis, HPV, hepatitis B), polysaccharide capsules (e.g., pneumococcal and meningococcal polysaccharide vaccines), polysaccharide capsules conjugated to protein carriers (e.g., Hib, pneumococcal, and meningococcal conjugate vaccines), live-attenuated microorganisms (e.g., measles, mumps, rubella, varicella, rotavirus, and live-attenuated influenza vaccines), and toxoids (e.g., tetanus, diphtheria) (Table 197.3). A **toxoid** is a bacterial toxin modified to be nontoxic but still capable of inducing an active immune response against the toxin.

Table 197.3

Currently Available* Vaccines in the United States by Type

PRODUCT	TYPE
Adenovirus	Live, oral vaccine indicated for active immunization for the prevention of febrile acute respiratory disease caused by adenovirus types 4 and 7, for use in military populations 17-50 yr of age
Anthrax vaccine adsorbed	Cell-free filtrate of components including protective antigen
Bacille Calmette-Guérin (BCG) vaccine	Live-attenuated mycobacterial strain used to prevent tuberculosis in very limited circumstances
Cholera vaccine	Oral vaccine containing live-attenuated *Vibrio cholerae* CVD 103-HgR strain for

	protection against serogroup O1 in adults age 18-64 traveling to cholera-affected areas
Diphtheria and tetanus toxoids adsorbed	Toxoids of diphtheria and tetanus
Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine	Toxoids of diphtheria and tetanus and purified and detoxified components from *Bordetella pertussis*
DTaP–hepatitis B–inactivated polio vaccine (DTaP-HepB-IPV)	DTaP with hepatitis B surface antigen (HBsAg) produced through recombinant techniques in yeast with inactivated whole polioviruses
DTaP with IPV and *Haemophilus influenzae* type b (Hib) (DTaP-IPV/Hib)	DTaP with inactivated whole polioviruses and Hib polysaccharide conjugated to tetanus toxoid
DTaP and inactivated polio vaccine (DTaP-IPV)	DTaP with inactivated whole polioviruses
Hib conjugate vaccine (Hib)	Polysaccharide conjugated to either tetanus toxoid or meningococcal group B outer membrane protein
Hepatitis A vaccine (HepA)	Inactivated whole virus
Hepatitis A–hepatitis B vaccine (HepA-HepB)	Combined hepatitis A and B vaccine
Hepatitis B vaccine (HepB)	HBsAg produced through recombinant techniques in yeast
Human papillomavirus vaccine 9-valent (9vHPV)	The L1 capsid proteins of HPV types 6 and 11 to prevent genital warts and types 16 18, 31, 33, 45, 52, and 58 to prevent cervical cancer (9vHPV).
Influenza virus vaccine inactivated (IIV [†])	Available either as trivalent (A/H_3 N_2 , A/H_1 N_1 , and B) split and purified inactivated vaccines containing the hemagglutinin (H) and neuraminidase (N) of each type or as quadrivalent preparations (which include representative strains from 2 B strains in addition to the 2 influenza A strains in trivalent inactivated influenza vaccine)
Influenza virus vaccine live-attenuated, intranasal (LAIV)	Live-attenuated, temperature-sensitive, cold-adapted quadrivalent vaccine containing the H and N genes from the wild strains reassorted to have the 6 other genes from the cold-adapted parent
Japanese encephalitis vaccine	Purified, inactivated whole virus
Measles, mumps, rubella (MMR) vaccine	Live-attenuated viruses
Measles, mumps, rubella, varicella (MMRV) vaccine	Live-attenuated viruses
Meningococcal conjugate vaccine against serogroups A, C, W135, and Y (MCV4)	Polysaccharide from each serogroup conjugated to diphtheria toxoid CRM_{197} protein
Meningococcal polysaccharide vaccine against serogroups A, C,	Polysaccharides from each of the serogroups conjugated to diphtheria toxoid protein

W135, and Y (MPSV4)	
Meningococcal B (MenB)	Recombinant proteins from serogroup B developed in *Escherichia coli*
Pneumococcal conjugate vaccine (13 valent) (PCV13)	Pneumococcal polysaccharides conjugated to diphtheria toxin CRM$_{197}$, contains 13 serotypes that accounted for >80% of invasive disease in young children prior to vaccine licensure
Pneumococcal polysaccharide vaccine (23 valent) (PPSV23)	Pneumococcal polysaccharides of 23 serotypes responsible for 85–90% of bacteremic disease in the United States
Poliomyelitis (inactivated, enhanced potency) (IPV)	Inactivated whole virus highly purified from monkey kidney cells, trivalent types 1, 2, and 3
Rabies vaccines (human diploid and purified chicken fibroblasts)	Inactivated whole virus
Rotavirus vaccines (RV5 and RV1)	Bovine rotavirus pentavalent vaccine (RV5) live reassortment attenuated virus, and human live-attenuated virus (RV1)
Smallpox vaccine	Vaccinia virus, an attenuated poxvirus that provides cross-protection against smallpox (variola)
Tetanus and diphtheria toxoids, adsorbed (Td, adult use)	Tetanus toxoid plus a reduced quantity of diphtheria toxoid compared to diphtheria toxoid used for children <7 yr of age
Tetanus and diphtheria toxoids adsorbed plus acellular pertussis (Tdap) vaccine	Tetanus toxoid plus a reduced quantity of diphtheria toxoid plus acellular pertussis vaccine to be used in adolescents and adults and in children 7 through 10 yr of age who have not been appropriately immunized with DTaP
Typhoid vaccine (polysaccharide)	Vi capsular polysaccharide of *Salmonella typhi* Ty2 strain
Typhoid vaccine (oral)	Live-attenuated Ty21a strain of *S. typhi*
Varicella vaccine	Live-attenuated Oka/Merck strain
Yellow fever vaccine	Live-attenuated 17D-204 strain
Herpes zoster (shingles) vaccine	Live-attenuated Oka/Merck strain for use in adults ≥60 yr old (Zostavax) Recombinant zoster vaccine, adjuvanted (Shingrix) for use in adults ≥50 years

[*] As of November 2018.

[†] There are various types of inactivated flu vaccines—IIV3, IIV4, RIV4, ccIIV4, aIIV3.

Data from US Food and Drug Administration: Vaccines licensed for use in the United States. http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm093833.htm .

Vaccines can contain a variety of other constituents besides the immunizing antigen. *Suspending fluids* may be sterile water or saline but can be a complex fluid containing small amounts of proteins or other constituents used to grow the immunobiologic culture. *Preservatives, stabilizers,* and *antimicrobial agents* are used to inhibit bacterial growth and prevent degradation of the antigen. Such components can include gelatin, 2-phenoxyethanol, and specific antimicrobial agents. Preservatives are added to multidose vials of vaccines, primarily to prevent bacterial contamination on repeated entry of the vial. In the past, many vaccines for children contained **thimerosal** , a preservative containing ethyl mercury. Removal of thimerosal as a preservative from vaccines for children began as a precautionary measure in 1999 in the absence of any data on harm from the preservative. This objective was accomplished by switching to single-dose packaging. Of the vaccines recommended for young children, only some preparations of influenza vaccine contain thimerosal as a preservative.*

Adjuvants are used in some vaccines to enhance the immune response. In the United States, the only adjuvants currently licensed by the FDA to be part of vaccines are **aluminum salts** ; AsO_4 , composed of 3-O-desacyl-4′-monophosphoryl 301 lipid A (MPL) adsorbed on to aluminum (as hydroxide salt); and MF59 and 1018 adjuvant. **AsO_4** is found in 1 type of HPV vaccine, no longer available in the United States, but used in Europe. **MF59** is an oil-in-water emulsion found in 1 type of influenza vaccine approved for people ≥65 yr old. 1018 is an immunostimulatory sequence adjuvant used in HepB-CpG, a hepatitis B vaccine approved for persons > 18 yr. HepB-CpG contains yeast-derived recombinant HBsAg and is prepared by combining purified HBsAg with small synthetic immunostimulatory cytidine-phosphate-guanosine oligodeoxynucleotide motifs. The 1018 adjuvant binds to Toll-like receptor 9 to simulate a directed immune response to HBsAg. Vaccines with adjuvants should be injected deeply into muscle masses to avoid local irritation, granuloma formation, and necrosis associated with SC or intracutaneous administration.

Vaccines can induce immunity by stimulating antibody formation, cellular immunity, or both. Protection induced by most vaccines is thought to be mediated primarily by B lymphocytes, which produce antibodies. Such antibodies can inactivate toxins, neutralize viruses, and prevent their attachment to cellular receptors, facilitate phagocytosis and killing of bacteria, interact with complement to lyse bacteria, and prevent adhesion to mucosal surfaces by interacting with the bacterial cell surface.

Most B-lymphocyte responses require the assistance of CD4 helper T lymphocytes. These T-lymphocyte–dependent responses tend to induce high levels of functional antibody with high avidity. The T-dependent responses mature over time from primarily an IgM response to a persistent, long-term IgG response and induce immunologic memory that leads to enhanced responses on boosting. **T-lymphocyte–dependent vaccines** , which include protein moieties, induce good immune responses even in young infants. In contrast, polysaccharide antigens induce B-lymphocyte responses in the absence of T-lymphocyte help. These **T-lymphocyte–independent vaccines** are associated with poor immune responses in children <2 yr old and with short-term immunity and absence of an enhanced or booster response on repeat exposure to the antigen. With some polysaccharide vaccines, repeat doses actually are associated with reduced responses, as measured by antibody concentrations, compared to 1st doses (i.e., *hyporesponsive*). To overcome problems with plain polysaccharide vaccines, polysaccharides have been **conjugated** , or covalently linked, to protein carriers, converting the vaccine to a T-lymphocyte–dependent vaccine. In contrast to plain polysaccharide vaccines, conjugate vaccines induce higher-avidity antibody, immunologic memory leading to booster responses on repeat exposure to the antigen, long-term immunity, and community protection by decreasing carriage of the organism (Table 197.4). As of 2018 in the United States, licensed conjugate vaccines are available to prevent Hib, pneumococcal, and meningococcal diseases.

Table 197.4

Characteristics of Polysaccharide and Conjugate Vaccines

CHARACTERISTIC	CONJUGATE	POLYSACCHARIDE
T-lymphocyte–dependent immune response	Yes	No
Immune memory	Yes	No
Persistence of protection	Yes	No
Booster effect	Yes	No
Reduction of carriage	Yes	No
Community protection	Yes	No
Lack of hyporesponsiveness	Yes	No

Serum antibodies may be detected as soon as 7-10 days after initial injection of antigen. Early antibodies are usually of the IgM class that can fix complement. IgM antibodies tend to decline as IgG antibodies increase. The IgG antibodies tend to peak approximately 1 mo after vaccination and with most vaccines persist for some time after a primary vaccine course. Secondary or booster responses occur more rapidly and result from rapid proliferation of memory B and T lymphocytes.

Assessment of the immune response to most vaccines is performed by measuring serum antibodies. Although detection of serum antibody at levels considered protective after vaccination can indicate immunity, loss of detectable antibody over time does not necessarily mean susceptibility to disease. Some vaccines induce immunologic memory, leading to a booster or anamnestic response on exposure to the microorganism, with resultant protection from disease. In some cases, cellular immune response is used to evaluate the status of the immune system. Certain vaccines (e.g., acellular pertussis) do not have an accepted serologic correlate of protection.

Live-attenuated vaccines routinely recommended for children and adolescents include measles, mumps, and rubella (**MMR**); MMR and varicella (**MMRV**); rotavirus; and varicella. In addition, a cold-adapted, live-attenuated quadrivalent influenza vaccine (**LAIV**) is available in the past for persons 2-49 yr old who do not have conditions that place them at high risk for complications from influenza. Notably lower vaccine effectiveness during the 2013–2016 influenza seasons has resulted in LAIV not being recommended in the United States for the 2016–2017 and 2017–2018 seasons; LAIV is recommended for the 2018–1019 season. **Live-attenuated vaccines** tend to induce long-term immune responses. They replicate, often similarly to natural infections, until an immune response inhibits reproduction. Most live vaccines are administered in 1-dose or 2-dose schedules. The purpose of repeat doses, such as a 2nd dose of the MMR or MMRV vaccine, is to induce an initial immune response in those who failed to respond to the 1st dose. Because influenza viruses tend to mutate to evade preexisting immunity to prior strains, at least 1 of the strains in influenza vaccines each year is often different than in the previous year. Thus, influenza vaccines are recommended to be administered yearly.

The remaining vaccines in the recommended schedule for children and adolescents are inactivated vaccines. **Inactivated vaccines** tend to require multiple doses to induce an adequate immune response and are more likely than live-attenuated vaccines to need booster doses to maintain that immunity. However, some inactivated vaccines appear to induce long-term or perhaps lifelong immunity, after a primary series, including hepatitis B vaccine and inactivated polio vaccine.

Vaccination System in the United States

Vaccine Production

Vaccine production is primarily a responsibility of private industry. Many of the vaccines recommended routinely for children are produced by only one vaccine manufacturer. Vaccines with multiple manufacturers include Hib, hepatitis B, rotavirus, **MCV4** (meningococcal conjugate vaccine against serogroups A, C, W135, and Y), diphtheria and tetanus toxoids and acellular pertussis (**DTaP**), and tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccines for adolescents and adults. Inactivated polio vaccine (**IPV**) as an IPV-only vaccine has only one manufacturer, but IPV is also available in combination products (DTaP–hepatitis B–IPV, DTaP-IPV/Hib, and DTaP-IPV) from different manufacturers. Influenza vaccine for children 6-35 mo of age is produced by fewer manufacturers (see http://www.cdc.gov/flu/protect/vaccine/vaccines.htm for available influenza vaccines). MMR, MMRV, varicella, pneumococcal conjugate vaccine (13 valent, **PCV13**), and tetanus and diphtheria (**Td**) vaccines also are produced by single manufacturers.

Vaccine Policy

Two major committees make vaccine policy recommendations for children: the Committee on Infectious Diseases (COID) of the AAP (the *Red Book* Committee) and the Advisory Committee on Immunization Practices (ACIP) of the CDC. Annually, the AAP, ACIP, American Academy of Family Physicians (AAFP), and American College of Obstetricians and Gynecologists (ACOG) issue a harmonized childhood and adolescent immunization schedule (http://www.cdc.gov/vaccines/schedules/index.html). The ACIP recommendations (http://www.cdc.gov/vaccines/acip/recs/index.html) are official only after adoption by the CDC director, which leads to publication in the *Morbidity and Mortality Weekly Report (MMWR Morb Mortal Wkly Rep).* The AAP recommendations are published in *Pediatrics* and the *Red Book* , which includes its continuously updated online version (aapredbook.org).

Vaccine Financing

Approximately 50% of vaccines routinely administered to children and adolescents <19 yr of age are purchased through a contract negotiated by the federal government with licensed vaccine manufacturers. Three major sources of funds are available to purchase vaccines through this contract. The greatest portion comes from the **Vaccines for Children (VFC)** program (http://www.cdc.gov/vaccines/programs/vfc/index.html), a federal entitlement program established in 1993. The VFC program covers children receiving Medicaid, children without insurance (uninsured), and Native Americans and Alaska Natives. In addition, underinsured children whose insurance does not cover immunization can be covered through VFC, but only if they go to a federally qualified health center (http://www.cms.gov/center/fqhc.asp). In contrast to other public funding sources that require approval of discretionary funding by legislative bodies, VFC funds are immediately available for new recommendations. These funds are only available if the ACIP votes the vaccine and the recommendation for its use into the VFC program, the federal government negotiates a contract, and the Office of Management and Budget (OMB) apportions funds. The VFC program can provide free vaccines to participating private providers for administration to children eligible for coverage under the program. The 2nd major federal funding source is the Section 317 **Discretionary Federal Grant Program** to states and selected localities. These funds must be appropriated annually by Congress, and in contrast to VFC, they do not have eligibility requirements for use. The 3rd major public source of funds is **state appropriations** .

The VFC program itself does not cover vaccine administration costs. Medicaid covers the administration fees for children enrolled in the program. Parents of other children eligible for VFC must pay administration fees out of pocket, although the law stipulates that no one eligible for the program can be denied vaccines because of inability to pay the administration fee. The Affordable Care Act (ACA) states that all vaccines recommended by ACIP and those included in the harmonized annual immunization schedules must be provided by qualified insurance programs with no copay and no deductible.

Vaccine Safety Monitoring

Monitoring vaccine safety is the responsibility of the FDA, CDC, and vaccine manufacturers. A critical part of that monitoring depends on reports provided to the **Vaccine Adverse Event Reporting System (VAERS)** . Adverse events following immunization can be reported by completing a VAERS form, which can be obtained from http://www.vaers.hhs.gov or by calling 1-800-822-7967. Individual VAERS case reports may be helpful in generating hypotheses about whether vaccines are causing certain clinical syndromes. In general, however, the reports are not helpful in evaluating the causal role of vaccines in the adverse event, because most clinical syndromes that follow vaccination are similar to syndromes that occur in the absence of vaccination, which constitute background rates. For causality assessment, epidemiologic studies are often necessary, comparing the incidence rate of the adverse event after vaccination with the rate in unvaccinated individuals. A statistically significant higher rate in vaccinated individuals would be consistent with causation.

The **Vaccine Safety Datalink** consists of inpatient and outpatient records of some of the largest managed-care organizations in the United States and facilitates causality evaluation. In addition, the **Clinical Immunization Safety Assessment (CISA)** network has been established to advise primary care physicians on evaluation and management of adverse events (http://www.cdc.gov/vaccinesafety/Activities/CISA.html). CISA facilitates CDC's collaboration with vaccine safety experts at leading academic medical centers and strengthens national capacity for vaccine safety monitoring. (For more information, refer to: https://www.cdc.gov/vaccinesafety/ensuringsafety/monitoring/cisa/index.html .)

The Health and Medicine Division (HMD) of the National Academies of Sciences, Engineering and Medicine, previously the Institute of Medicine (IOM), has independently reviewed a variety of vaccine safety concerns and published reports summarizing its findings.* From 2001 through 2004, the IOM released 8 reports, concluding that the body of epidemiologic evidence did not show an association between vaccines and **autism** . In 2012 the IOM (HMD) report *Adverse Effects of Vaccines: Evidence and Causality* ** reviewed a list of reported adverse effects associated with 8 vaccines to evaluate the scientific evidence, if any, of an event-vaccine relationship. The IOM committee had developed 158 causality conclusions and assigned each relationship between a vaccine and an adverse health problem to 1 of 4 causation categories. The committee concluded that available evidence convincingly supported a causal relationship between **anaphylaxis** and MMR, varicella-zoster, influenza, hepatitis B, meningococcal, and tetanus-containing vaccines. Additionally, the evidence favored rejection of 5 vaccine–adverse event relationships, including MMR vaccine and autism, inactivated influenza vaccines and asthma episodes and Bell palsy, and MMR and DTaP and type 1 diabetes mellitus. For the majority of cases (135 vaccine–adverse event pairs), the evidence was inadequate to accept or reject a causal relationship because of the rarity of the events. Overall, the committee concluded that few health problems are caused by or clearly associated with vaccines.

In 2013, the HMD released the report *Childhood Immunization Schedule and Safety: Stakeholder Concerns, Scientific Evidence, and Future Studies* . [†] The HMD uncovered no evidence of major safety concerns associated with adherence to the recommended childhood immunization schedule. The HMD specifically found no links between the immunization schedule and autoimmune diseases, asthma, hypersensitivity, seizures, child developmental disorders, learning or developmental disorders, or attention-deficit or disruptive disorders. Additionally, use of nonstandard schedules is harmful, because it increases the period of risk of acquiring vaccine-preventable diseases and increases the risk of incomplete immunization. [‡] In addition, the Agency for Healthcare Research and Quality (AHRQ) contracted with the Rand Corporation for an independent systematic review of the immunization schedule. That review concluded that while some vaccines are associated with serious adverse events, these events are extremely rare and must be weighed against the protective benefits that vaccines provide. AAP has summarized the information on a variety of safety issues and different vaccines. [§]
